An investigation of the first incident found that the children had consumed soup diluted with a mixture of hot and cold tapwater. The soup contained 459 mg/L of nitrite, while the hot water contained 4–10 mg/L of nitrite. The hot-water boiler had been returned to service that morning after earlier servicing using a commercial conditioning fluid containing nitrite and sodium metaborate. Investigations found that a backflow-prevention valve preventing flow of water from the boiler to the drinking-water system was stuck in the open position. In addition, taps for the boiler treatment solution and the hot-water coil were in the same area but unlabelled. The water system was flushed, and the school discontinued heating water through boiler coils.

An investigation of the second incident also found that a faulty backflow-prevention valve had allowed boiler conditioning fluid to contaminate hot water used to prepare coffee.

Although the potential for this type of contamination from boilers was recognized with a regulatory requirement for backflow-prevention valves, there were no requirements for routine inspection, maintenance and replacement of valves. Maintenance of backflow-prevention devices used to prevent contamination of drinking-water is essential.

A48235836

5 Hot-water piping systems

Hot-water systems should be mapped and catalogued in a similar fashion to cold drinking-water systems. One of the problems associated with hot-water systems is balancing the need to maintain water temperatures above 50 °C to minimize risks from *Legionella*, while minimizing the risk from scalding. This applies particularly in aged-care and child-care facilities and health-care facilities. Hot-water piping systems can be installed as one unit at the scale of the entire building, or to serve sections of buildings.

When mapping hot-water systems, the following components and features should be identified:

- hot-water devices and storage vessels;
- thermal insulation of piping systems and physical separation from cold systems;
- the presence of looped distribution systems (circulating systems);
- temperatures throughout the system, including at most distal points and, in the case of looped systems, on point of return to heating devices;
- installation of temperature-control devices to reduce the risk of scalding (e.g. thermostatic mixing valves) and distance from these devices to PoU;
- length and numbers of branch pipes and dead legs;
- areas with potential for intermittent or seasonal use;
- materials in pipes and other components;
- access for maintenance or disinfection.

6 Equipment installed at PoU

Description of systems should identify all equipment using water.

Equipment at PoU varies in type, size and flow rates. Equipment includes sinks, taps, baths and showers, dishwashers, washing machines, medical devices, sprinkler systems, drinking-water fountains, decorative fountains and ice machines. All devices should be identified, together with frequency of use. Installation of backflow prevention should be recorded.

7 Water treatment systems at PoU

Treatment may be applied at PoU using devices such as carbon filters, membrane filters, water softeners, deionizers or ultraviolet disinfection systems. In large buildings, staff may install PoU devices such as carbon filters without approval. All PoU devices should be identified. Unauthorized equipment should be removed. Installation of backflow prevention should be recorded.

Issues to be considered include correct installation and maintenance. For example, filters need to be replaced regularly. Old carbon filters that have passed their “use-by” dates can support growth of large concentrations of microorganisms.

Existence of standards and regulations that apply to PoU equipment connected to water supplies should be determined. Where standards and regulations have been established, all equipment should be checked for compliance.

Box 4.3 provides a case study of a *Pseudomonas* outbreak in a haematology unit.

Box 4.3 Resolution of a *Pseudomonas aeruginosa* outbreak in a haematology unit with the use of disposable sterile water filters

In 2002, a high incidence of *Pseudomonas aeruginosa* bacteraemia was detected in a haematology unit in which severely neutropenic patients were admitted. A total of 61 of 1478 blood cultures were positive for *P. aeruginosa*, compared with 19 of 824 blood cultures performed in 2001.

In an initial investigation in June 2002, eight water samples were collected from bathrooms used by patients, but only one contained *P. aeruginosa*. However, when the outbreak persisted, a further 85 samples were collected. These included 46 samples of water from outlets such as taps, showers and water traps, as well as samples of detergent, air, and bathroom and toilet surfaces. Twenty-nine of the water samples contained *P. aeruginosa*, while none of the other samples were positive.

The installation of 0.2 µ membrane filters on taps and water heads significantly reduced the incidence of bacteraemia. In 2003 and 2004, *P. aeruginosa* was detected in 7 of 1445, and 11 of 1479 blood cultures, respectively.

Tapwater has been documented as a potential source of *P. aeruginosa* infections in hospital settings. Additional measures such as point-of-use treatment can reduce the risk of infection in high-risk patients.

4.5 Identifying hazards and hazardous events

In hazard identification, the WSP team is required to assess what could go wrong and where hazards and hazardous events could occur. The following sections discuss a range of possible generic hazards and hazardous events that may occur in buildings. However, it is important that hazards and related events are specifically identified for individual buildings under investigation.

Box 4.4 provides definitions of hazards, hazardous events and risk, in the context of risk management.

A48235836

Box 4.4 Definitions of hazards, hazardous events and risk

Effective risk management requires the identification of potential hazards and their sources, and potential hazardous events, and an assessment of the level of risk presented by each. In this context:

- a hazard is a biological, chemical, physical or radiological agent that has the potential to cause harm;
- a hazardous event is an incident or situation that can lead to the presence of a hazard (what can happen and how);
- risk is the likelihood of identified hazards causing harm in exposed populations in a specified time frame, including the magnitude of that harm and/or the consequences.

4.5.1 Microbial hazards

Faecal contaminants

In common with most drinking-water supplies, ingress of enteric pathogens (bacteria, viruses and protozoa) associated with faecal contamination can be a significant source of hazards. Faecal contamination can enter through public water supplies provided to buildings, building-specific water supplies, faults in internal plumbing systems (e.g. unroofed water-storage tanks, cross-connections with sewage systems or with recycled-water systems) and poor hygiene at PoU.

Growth of environmental organisms

Water systems in buildings can be prone to environmental microorganism growth, including potentially pathogenic species and nuisance species, which can cause off-tastes and odours. Environmental pathogens include *Legionella*, *Mycobacterium* spp. and *Pseudomonas aeruginosa*. Water-borne *Legionella* is strongly associated with buildings, while *Pseudomonas* has been identified as a particular concern in health-care settings (Anaissie et al., 2002; Exner et al., 2005) and water-using devices such as swimming pools and hot-tub pools (Yoder et al., 2004, 2008a; Djiuban et al., 2006; WHO, 2006a). In hospitals, a broader range of environmental microorganisms have been identified as causes of nosocomial infections, including *Acinetobacter* spp., *Aeromonas* spp., *Burkholderia cepacia, Serratia, Klebsiella, Stentrophomonas maltophilia* and fungi such as *Aspergillus, Fusarium* and *Exophilia* (Annaisie et al., 2002; Sehulster et al., 2004).

Small invertebrate animals can survive and grow in distribution systems under conditions that support microbial growth and biofilms (Ainsworth, 2004). These small animals are not of health concern but can reduce the acceptability of water supplies.

4.5.2 Chemical hazards

Chemicals from environmental and industrial sources, agriculture, water treatment and materials in contact with water can contaminate building systems. Contamination could be introduced from external community supplies, building-specific water supplies or distribution systems within buildings. Chemical quality of all water supplies used in buildings should be determined. For external supplies, this information should be available from water providers, while building-specific supplies will require monitoring (WHO, 2008).

Chemicals used in water-using devices can also represent hazards, either from back-siphonage from the devices or from storages kept within buildings. These chemicals can include disinfectants, antiscalants, coolants, heating fuels, oils and other chemicals used in boilers.

Materials

Chemicals that can be leached from materials used in pipework, solders and associated fittings include aluminium, antimony, arsenic, benzo(a)pyrene, bismuth, cadmium, copper, iron, lead, nickel, organolead, organotin, selenium, styrene, tin, vinyl chloride and zinc (WHO, 2008; Health Canada, 2009). Organic substances can be released from plastic pipes and fittings, flexible hoses, glues, adhesives and tank-lining materials (plastic and bitumen based). These substances may be direct hazards or may cause indirect problems by supporting microbial growth (e.g. from polymeric or elastomeric compounds).

In addition to potential health impacts, materials can contain chemicals that cause aesthetic problems. For example, iron and zinc do not produce health impacts, but rust will discolour water, while elevated levels of many metals such as zinc will add a metallic taste to water. Users will often assume that discoloured or poorly tasting water is unsafe.

If the materials are suitable for use in drinking-water systems and corrosion is controlled (see section 4.6), the concentrations of hazardous chemicals released into water supplies should not represent a health risk. However, hazardous concentrations could be released by unsuitable materials. Some countries have established programmes to certify products and materials used in drinking-water distribution systems.

Water-treatment chemicals

Water treatment is used in some buildings to either improve untreated water supplies or to supplement treatment applied by the drinking-water provider. It may also be used to produce water of higher quality required for specialist purposes (e.g. renal dialysis or manufacturing processes). Common forms of treatment include filtration, disinfection and softeners. Water-treatment chemicals, such as disinfectants and coagulants, and chemicals used to maintain treatment processes, such as membrane-cleaning agents, can represent hazards.

Annex 2 provides a summary of microbial and chemical hazards that can present a risk to building water supplies, including potential outcomes of infection or exposure as well as sources of exposure and methods for identification.

4.6 Hazardous events

4.6.1 Contaminated or intermittent water supply

The quality or quantity of external sources of piped water supplied to a building may be compromised due to intermittent supply, contaminated water or poor condition of the distribution system.

Those responsible for water supplies in buildings should liaise with operators of external piped water supplies to review the performance and previous history of the supply. This review should consider the quality (including contamination events) and quantity (volume,

reliability, frequency and length of interruptions) of the supply. The presence of buffering storages and alternative sources of water will influence the impact of interruptions to external supplies.

In cases where information on water quality of external supplies is inadequate, building managers may need to consider monitoring.

4.6.2 Ingress of contamination

Water sources

Contamination of building water systems can be caused by ingress of hazards into sources of external or building-specific supplies. Further information is provided in the supporting texts on protecting groundwater (Schmoll et al., 2006) and the GDWQ (WHO, 2008). Ingress of microbial and chemical contaminants can be caused by a range of hazardous events, including contamination of water sources by human and animal waste, industrial spills and discharges, inadequate treatment, inappropriate storage, pipe breakages and accidental cross-connections. Water utilities should provide warnings to building owners and managers when incidents threaten the safety of water delivered to buildings. Building owners should ensure that mechanisms have been established for notifications to be received and for appropriate responses to be initiated.

Building systems

Possible events leading to ingress of contamination can be determined by a systematic review of the system components, taking a “what-can-happen” brainstorming approach. The input of plumbing specialists, together with water microbiologists, is important in hazard identification. Any break or disruption to the integrity of drinking-water distribution systems can lead to ingress of microbial contamination. The likelihood of contamination events is increased where drinking-water and wastewater networks are installed in close proximity.

Box 4.5 provides a case study of water quality in rural health-care facilities.

Box 4.5 Water quality at rural South African health-care facilities

Water quality problems at health-care facilities in developing areas are often not only the result of on-site microbial deterioration but start with the quality of the water supplied to the facility. In South Africa, rural facilities have to rely on boreholes or surface water for their source of potable water. The water is often supplied without treatment, or after only limited treatment. The quality of the potable water used in health-care facilities in rural areas in South Africa is not monitored routinely. During 2006, a small study was conducted at 21 clinics in the Limpopo province in the north of South Africa to determine the microbial water quality of the drinking-water. Water was tested for *Escherichia coli*. General information on water supply and sanitation issues at the clinics was also collected.

Water availability was one of the most pressing problems experienced by many of the clinics. In many cases, this was blamed on inadequate technical support and maintenance. A significant percentage of the clinics studied used water that did not comply with South African drinking-water standards. This may have been partly due to the variety of sources upon which they need to rely, particularly when their primary source fails. A significant health risk to users was indicated by positive *E. coli* counts found in 14 of the 49 samples (29%), representing 38% of the clinics. This study highlighted the fact that health-care facilities in rural areas often receive water of inadequate microbial water quality, which could jeopardize the health of both patients and staff at the clinics.

Source: M du Preez, Council for Scientific and Industrial Research, South Africa.

Events that can lead to ingress of contamination include the following:

- Cross-connection of different water qualities (e.g. drinking-water and water of other quality) (USEPA, 2002) may not be readily apparent, because differences in physical appearance may not be recognized by users. Inadvertent connections may be introduced during maintenance and repair.
- Inadequate backflow prevention on PoU equipment can allow contaminated water or chemicals used in the equipment to flow back into and contaminate drinking-water systems.
- Leakage of chemicals or fluids, and cross-connections with chemical storages (e.g. heat transporters or corrosion-preventing additives associated with hot-water devices) can contaminate drinking-water (USEPA, 2002).
- Inadequate protection of building storage tanks can lead to contamination from the water supply. Similarly, unprotected tanks are at risk of faecal contamination from birds and vermin.
- Water supplies can be deliberately contaminated (Ramsay & Marsh, 1990).
- Hydrophobic compounds can migrate through plastic piping. Storing or using hydrocarbons or solvents close to plastic piping that is porous to hydrophobic compounds can contaminate drinking-water. Storing such products in boiler rooms can lead to increased migration of organic substances due to elevated temperatures.

A48235836

Box 4.6 provides a case study of poor water-supply management in a health-care facility.

Box 4.6 Poor management of a hospital water supply

A hospital in Eastern Europe with 400 beds has two separate water sources of water: an intermittent community supply that provides sufficient water, and a shallow on-site bore that provides salty water. The community supply is sourced from a well about 5 km from the hospital. This community supply is treated using a rudimentary, manually controlled chlorination device. The community supply is poorly protected from contamination at both the source and during distribution. Supply from the community system is limited by the availability of power to the whole system, coupled with inadequate pumping and storage capacity at the hospital.

As a result, the hospital has two internal systems. The first system distributes a mixture of water from the community supply and the on-site bore. This water is too salty to drink (it is classified as being non-drinkable), and is used for toilet flushing and to supply firefighting equipment. The second system delivers drinking-water from the community supply to about half the building. There is no labelling to distinguish between the two systems, even in rooms that have outlets from both systems. There is no evidence of backflow prevention in any parts of the plumbing systems.

When water is available from the community supply (about twice a day), it is collected and stored for later use in bathtubs, buckets and any other available containers. There is no hot-water system, no bathing facilities in the hospital, and no hand-washing facilities near toilets. Drainage pipes from some sinks are not sealed at the point of entry into floors. The plumbing system is prone to freezing, because the central heating system has not operated for more than 15 years.

A number of measures could lead to large improvements. The quality, management and constancy of the community supply could be greatly improved, but this is beyond the control of the hospital. The most pressing need at the hospital is to ensure that there is sufficient pump capacity and storage at the hospital to provide greater security of supply of water from the community system. This would allow disconnection of the on-site bore and reduce the need to collect water in open containers. Constant pressure in the hospital system would also reduce the likelihood of backflows and ingress of contaminated water. Sanitation at the hospital could be improved by providing more hand-washing facilities, ensuring that toilet facilities are functional and ensuring that drainage systems are maintained. The system should be examined for cross-connections, and, where necessary, backflow-prevention devices should be installed.

Alternative sources of water such as deep bores could be investigated.

Source: Prospal (2010).

4.6.3 Poorly controlled treatment

Installing water-treatment systems should improve water quality, if they are managed properly. However, potential hazards may arise from:

- lack of validation that treatment systems will be effective;
- incorrect installation (e.g. softening systems should be calibrated so that they do not produce water that could be corrosive);
- operation by staff with insufficient training and knowledge;

- inadequate monitoring and poor control;
- insufficient maintenance;
- inadequate response to equipment failures or poor monitoring results (e.g. inadequate disinfectant residuals);
- excessive doses of treatment chemicals (e.g. disinfectants) and poor control of chemicals used in maintenance of treatment processes (e.g. cleaning agents for membrane filters).

Disinfection by-products are likely to increase if disinfection is applied. While excessive doses of chlorine should be avoided, it is important that microbial control is maintained.

4.6.4 Microbial growth and biofilms

Water supplies in buildings connected to public or external supplies represent end-of-pipe systems. As such, they can often provide environments and conditions (e.g. low flows, stagnation) that are favourable for microbial growth and biofilm formation.

Environmental pathogens are often adapted to grow in biofilms, and growth can be greater in conditions that support biofilm development. In well-managed systems, biofilms will be thin and relatively well contained. Concern arises when these biofilms become too thick and start to disseminate throughout the system. Organisms in established biofilms can be difficult to remove. Poorly managed building water systems are prone to colonization, and biofilms can develop within pipes and on components such as washers, thermostatic mixing valves and outlets. Biofilms are extremely difficult to remove from all parts of the system once they are established, and they can be resistant to disinfectants, such as chlorine. Well-managed disinfection regimes that maintain disinfectant residuals through water systems can inactivate potential pathogens released into the aqueous phase, but this protection is lost if disinfectant residuals fall below effective levels.

Factors associated with microbial growth and biofilm formation in cold-water systems include:

- stagnation and low water flows;
- poor temperature control, which creates conditions supporting microbial growth; several environmental pathogens (e.g. *Legionella*) grow more quickly at body temperature (37 °C), and hot and cold water should therefore be kept above 50 °C and below 25 °C, respectively (inadequate separation and insulation of cold- and hot-water systems can lead to warming of cold water);
- scaling (because of its impact on hydraulics);
- scaling and corrosion, which provide rough surfaces that promote development of biofilms;
- suspended matter, which can provide nutrients favouring microbial growth, and create deposited sludges that support biofilms;
- source water that contains a high organic load (i.e. high total organic carbon);

A48235836

- inappropriate materials containing microbial nutrients in contact with water;
- poor maintenance and intermittent use of PoU equipment and devices (e.g. ice machines, cooling towers, old carbon filters past their "use-by" date), which can support microbial growth (e.g. *Listeria*, *Pseudomonas*, *Legionella* and fungi); for example, filters need to be replaced regularly.

The case study in Box 4.7 describes what can happen when a cold-water system fails.

Box 4.7 Outbreak of legionellosis due to failure in cold-water system

A hospital in Brandenburg, Germany, with more than 900 beds opened a new building and began to move patients from some older wards to the new one. The management of the hospital changed with the opening of the new building. Soon after starting operation of the new wards, seven patients were diagnosed with legionellosis. Samples had been collected from the hot-water distribution system before moving patients and had not contained *Legionella*. As soon as the outbreak was detected, the water distribution system was inspected. Use of water from showers and other utilities was restricted, filters were installed, and patients were subjected to stricter surveillance.

At the same time, alterations were made to the water-system operations, particularly the disinfection regimes. Details of theses alterations remain unclear due to the simultaneous change of management and limited availability of documentation. Afterwards, the system was checked again and was considered safe.

Six months later, another new building was opened, and again patients were moved from old wards to the new building. Again, the hot-water distribution was examined before the move, with no detection of *Legionella*. And again, five patients fell ill with legionellosis shortly afterwards.

A more in-depth inspection of the whole water system was conducted, along with immediate measures such as installing filters and carrying out disinfection procedures. Both new buildings had separate hot-water distribution systems. Both were only sparsely contaminated with *Legionella*. However, both buildings shared the same cold-water distribution system, and the temperature in these pipes was shown to be higher than allowed by technical standards (25 °C maximum allowed for cold water). Apart from insufficient insulation of the cold-water pipes, the hydraulics of the whole system had not been optimized, leading to stagnation. There were cross-connections with fire hydrants and pipe sizes that were inadequate.

Corrective measures introduced following the initial response (disinfection and installation of filters) comprised installation of regulation valves and recirculation pipes to avoid stagnation and heating of cold water. Changes in management had been associated with poor documentation associated with planning, construction and modifications. Documentation of the water distribution system and disinfection procedures was improved. A more detailed risk assessment was performed.

The two outbreaks following the opening of the biggest new hospital buildings in the region drew major public attention, and the new management faced severe criticism. Costs for corrective action to avoid closing the hospital (or at least the buildings affected) were remarkably high. Two of the twelve patients who were confirmed cases of legionellosis died. Legal action was pursued.

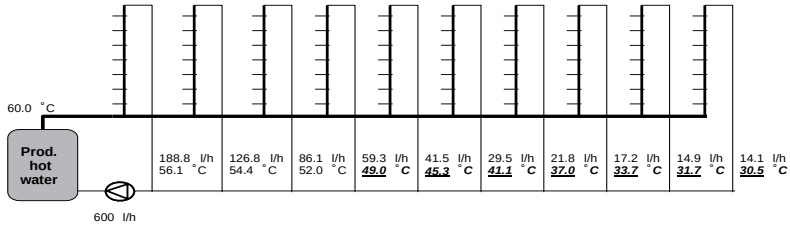
Adapted from Robert Koch Institute (2004).

Factors associated with biofilm formation and growth of environmental pathogens in hot-water systems include:

- insufficient heating capacity to cope with demand;
- poor temperature control, leading to reduction of hot-water temperatures below 50 °C; factors can include
  - poor insulation of hot-water systems
  - poor design, leading to low flow or stagnant areas (long branch pipes and dead ends)
  - installation of high-volume storage tanks that support stagnation and stratification (stratification can lead to lower water temperatures at the bottom of storage vessels)
  - failure to maintain water at sufficiently high temperatures in storage vessels (in some cases, temperatures in storage vessels may be reduced in a bid to save heating costs or to reduce risks of scalding by cooling the whole hot-water system)
  - insufficient equilibrium of permanent flow in looped systems or insufficient total flow rates to feed all parts of the piping system (see Box 4.8)
  - incorrect positioning or operation of temperature-reduction measures (e.g. thermostatic mixing valves); the main fault is locating these devices too far away from taps and outlets, creating long lengths of pipework containing warm water;
- corrosion and scaling, resulting in the accumulation of sediments and microorganisms at the bottom of storage tanks;
- inadequate cleaning and maintenance.

Box 4.8 *Legionella* hazard due to unbalanced looped hot-water systems

Looped hot-water networks are designed in such a way that the temperature in the loops is maintained because the loops are insulated and a minimum flow rate is maintained in each loop. For a given loop, the difference in temperature between the two points where it is connected to the main distribution circuit ("departure" and "arrival") is inversely proportional to the flow rate in the loop. For example, in a typical building with six levels, a 5 °C temperature difference may be maintained only under the condition that the flow rate in the loop is equal to or above 40 litres per hour. Very often, this condition can be attained only by specific valves that equilibrate flows among the loops. However, if the design or construction of such networks is poor, flows may not be balanced—that is, the first loops take the largest part of the flow rate, so that there is not enough flow for the last loops. As the figure below shows, this frequent type of fault can directly affect the temperature of the last loops, which can then become incubators of *Legionella* and other environmental pathogens at temperatures below 50 °C.



Example of unbalanced flow rates in a looped hot water system and its consequences on the temperature of circulated water

4.6.5 Release of hazards from materials and equipment

Unsuitable materials and equipment used in water systems may release hazardous substances into drinking-water (Health Canada, 2009). The chemicals could be contaminants in the materials (see section 4.5.2), be leached during initial use, or be leached due to elevated corrosion.

Stagnation of water within the building system can increase concentrations of hazardous chemicals released from materials. Intermittent use of end-of-plumbing fixtures (e.g. drinking-water coolers in schools) can result in the presence of elevated concentrations of heavy metals such as copper from copper piping or lead from brass fixtures.

Corrosion and scaling

A wide range of materials can be potential sources of chemicals through corrosion, including pipes, solders and fittings (Health Canada, 2009). Corrosion of materials in contact with water is natural and will eventually cause leakages or failures, allowing ingress of contamination. In addition, the formation of corrosion product layers can promote microbial growth. The aim is to keep corrosion to a minimum; however, it can be accelerated by a number of factors, including water quality (particularly pH, chloride and sulfate, disinfectant concentrations, organic materials), poor material quality, use of materials that are incompatible with the given water quality, poor installation (poor

welding, interconnection of different types of metal piping), water stagnation and temperature (Health Canada, 2009). Some waters, particularly those with low levels of dissolved minerals, can be corrosive for metal pipes and fittings, including copper, lead and brass (which often contains lead). Water utilities should be able to supply information on the characteristics of water supplied to buildings, including the likelihood of corrosion.

Water with high levels of hardness can cause increased scaling. Again, water utilities should be a source of information on hardness of incoming water supplies. Hot-water devices are particularly susceptible to scaling.

Scaling can cause energy losses (due to increased pumping and heating costs), resistance to disinfection, and premature failure of appliances (e.g. boilers and hot-water systems).

4.6.6 Specific uses

Sources of specific hazards can arise from specific uses (e.g. medical, dental), or from water-using devices, such as cooling towers, swimming pools, water coolers, water fountains or misting systems (e.g. in garden centres and conservatories).

Hazardous events associated with specific uses include:

- inadequate backflow prevention, allowing contaminated water or chemicals used in water-using devices to flow into drinking-water systems;
- aerosol formation (from showers, decorative fountains, etc.), providing potential exposure to respiratory diseases (e.g. legionellosis, mycobacterial hypersensitivity pneumonitis);
- poor maintenance and intermittent use, providing conditions that support microbial growth (e.g. *Listeria*, *Pseudomonas*, *Legionella* and fungi), corrosion (e.g. copper leaching from piping in drinking-water coolers) or leaching of chemicals from materials (e.g. plasticizer from plastic piping and tubing);
- inadequate treatment in swimming pools and hot-tub pools, allowing survival of enteric pathogens (e.g. *Giardia*, *E. coli* 0157, *Norovirus*) or growth of environmental pathogens (e.g. *Legionella* and *Pseudomonas*) (Craun et al., 2005; Pond, 2005; Sinclair et al., 2009).

4.6.7 Poor management (intermittent use)

Water distribution systems require proper management. Where parts of buildings and associated plumbing are not used for extended periods (e.g. months), the water system should be physically disconnected to avoid stagnation. Stagnant water can support growth of biofilms and environmental pathogens, such as *Legionella* and mycobacteria, and can contain elevated concentrations of chemicals released from pipework, such as copper and lead.

4.6.8 Construction work, renovations and repairs

If not properly planned and managed, renovation, repairs and modifications to buildings and associated water supplies can lead to introduction of microbial and chemical hazards. Where water distribution systems are extended, modified or repaired, there will be periods when flow is stopped and when pipework is intentionally cut and left open for periods, allowing potential ingress of contamination.

Hazardous events that could occur during construction, extension or repairs of systems include:

- the use of inappropriate materials—this can include using metallic products that are incompatible with existing materials in the system, causing corrosion;
- microbial or chemical contamination during repair or maintenance;
- accidental cross-connection between systems delivering different water qualities—renovation work may highlight deficiencies in labelling of existing pipework, which should be rectified;
- temporary switching to alternative supplies during construction, as well as introduction of temporary stagnation, dead legs and blind ends;
- failure to upgrade heating capacity when hot-water systems are extended;
- changes to the established equilibrium of operation in terms of hydraulic conditions, thermal capacity and corrosion risks; for example, renovating or altering the type of system described in Box 4.8 (above) could change performance, and extending the system may increase the total pressure too much for regulation valves to counterbalance, making equilibrium among loops impossible.

Extensions and renovations should not be assessed as separate entities from the existing system. Modifications can have wide-ranging ramifications on performance of the existing system through changing flow patterns, increasing capacity requirements and complexity. Renovations leading to change of use (e.g. from a commercial building to an apartment block) can be particularly complex and involve substantial changes to water systems and water usage. After construction, the existing system and extension should be considered as a single "new" system to be reassessed for potential hazardous events. WSPs will need to be reviewed and amended following any significant modifications.

Changes need to be recorded in system descriptions and distribution system maps.

4.6.9 Emergencies leading to contamination of external supplies

Major events such as flooding and other faults leading to contamination of external supplies (e.g. leading to a boil-water advisory) can contaminate building water supplies, including end-of-plumbing and PoU devices such as ice machines, beverage dispensers, drinking-water coolers and other water-using devices.

Alternative water supplies used in the event of an emergency may be a source of hazards and should be used with care.

4.7 Risk assessment

Risk assessment is a process by which identified hazards and hazardous events are evaluated to decide whether they represent a significant risk that needs to be controlled. The type of information that should be considered in a risk assessment is shown in Figure 4.3.

Risk assessments should take into account the number and vulnerability of exposed people and the type of exposure.

In the risk-assessment process, the important issue is to identify and prioritize unacceptable risks that need to be controlled. It is important not to get caught by identifying all risks and providing them with equal weighting.

Risk assessments can be applied at the time of planning or constructing a system; they can also be applied to an existing system. The preventive approach to include risk assessment with planning and construction is always preferable. Modifying existing systems, including retrofitting additional monitoring and control measures, is typically more expensive. Reactive risk assessments and modifications taken after harm has been caused can be complicated by political and legal influence, and time constraints.

Assessments for new buildings will identify risks that need to be controlled and the measures that need to be incorporated in the new water systems. Therefore, risk assessments should be conducted as early as possible within planning and design phases.

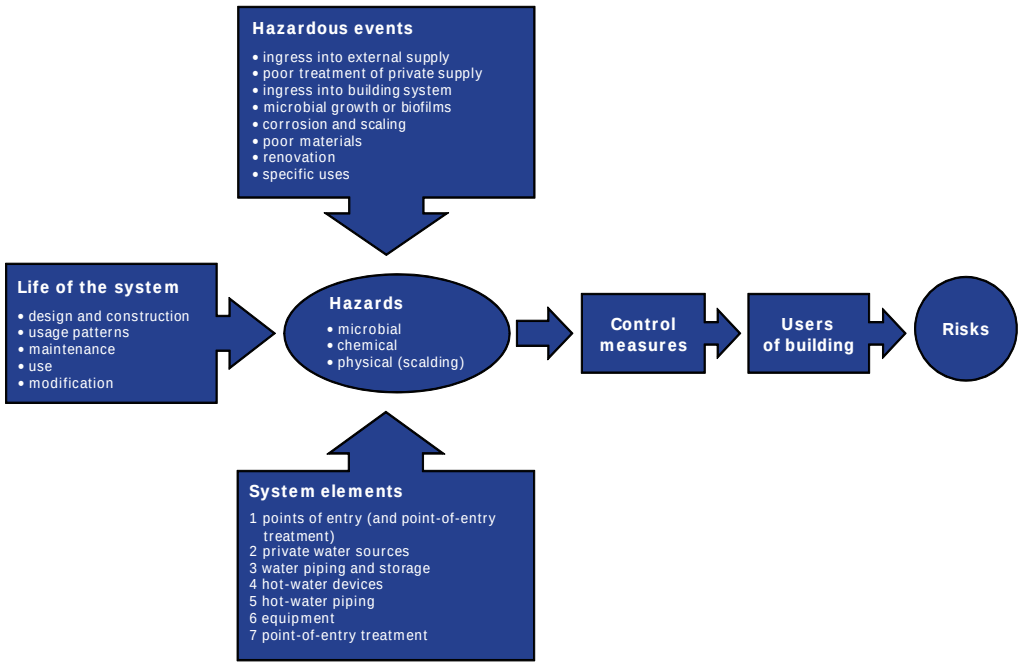


Figure 4.3 Types of information to consider in risk assessment

Risk assessments for existing buildings should identify and consider the effectiveness of established control measures. If the control measures are either insufficient or not effective, the risk-assessment process will identify significant risks and point to system modifications required to achieve water-quality targets. Therefore, the outcome of risk assessment is a plan of action that documents necessary additional or improved control measures, including time lines and responsibilities for their implementation. This should include establishing priorities for action.

Risk assessment and prioritization methods range from relatively simple team decision approaches, through semiquantitative, matrix-based approaches, to fully quantitative risk assessments (WHO, 2009). Which method is best in a given situation will depend on the complexity of the building water system assessed. The method of choice for a small or simple structured building may be qualitative team decisions based on the judgement and experience of the WSP team. For example, risks could be classified as significant,

A48235836

uncertain or insignificant. Those classified as significant should be considered as clear priorities for further action that could include application of additional control measures, while risks classified as uncertain may require further investigation.

Similarly, this type of approach could be applied to assess the risks from contamination or failure of external supplies. Where data are available on performance in the preceding years (e.g. over the past 5–10 years), a risk assessment could be based on:

- one or no major contamination or water-shortage events in the past 5–10 years, safe supply resumed after less than two days (= reliable public distribution);
- one to two major contamination or water-shortage events per year, resumed after less than two days (= generally satisfactory public distribution; PoE treatment may be considered for high-risk buildings or populations); or
- frequent major contamination or water-shortage events (= public distribution is not sufficiently reliable; PoE treatment or alternative sources should be considered).

Risk assessments for more complex buildings with a range of different water usages and technologies may benefit from a more formal and structured approach. In all cases, the WSP team needs to decide on a consistent risk-assessment methodology.

Tables 4.2 and 4.3 illustrate one approach for assessing and ranking risks. In this approach, the likelihood of a hazard occurring is combined with the severity of consequences to provide a risk matrix and is particularly applicable to hazardous events. The tables can be varied to meet the needs of the organization undertaking the risk assessment. For example, the numbers of categories for likelihood and consequence could be reduced.

Table 4.2 Example of a simple risk-scoring matrix for ranking risks

	Severity of consequences				
Likelihood	**Insignificant**	**Minor**	**Moderate**	**Major**	**Catastrophic**
Almost certain					
Likely					
Moderately likely					
Unlikely					
Rare					

Table 4.3 gives an example of descriptors that can be used to rate the likelihood of occurrence and severity of consequences. A “cut-off” point must be determined above which all hazards will require immediate attention. There is little value in expending large amounts of effort to consider small risks. For example, in the first instance, a cut-off point could be those risks above the bold line. Once these risks are managed, the cut-off point could be lowered.

For some hazards, it may be possible to incorporate a quantitative risk assessment. This assessment can provide a numerical estimate of whether the risk is tolerable or unacceptable. For chemicals, this estimate can include guideline values. For microbiological quality, quantitative risk assessment can be applied using a four-step process involving hazard identification, dose–response determination, exposure assessment and risk characterization. Hazardous events that lead to chemical guideline values being exceeded, or to high levels of microbial risk, should be considered unacceptable and hence require management.

The risk assessment should consider the effectiveness of existing control measures. Where risk remains unacceptably high, alternative or additional controls will be required (after existing measures have been considered). These additional measures must be evaluated in a supplementary risk assessment after additional control measures have been put in place.

Table 4.3 Examples of definitions of likelihood and severity categories that can be used in risk scoring

Item	Definition
Likelihood categories	
Almost certain	Once per day
Likely	Once per week
Moderately likely	Once per month
Unlikely	Once per year
Rare	Once every five years
Severity categories	
Catastrophic	Potentially lethal to all people using the building, including vulnerable groups (e.g. immunocompromised patients, infants and the elderly), following acute exposure
Major	Potentially harmful to all people using the building following acute exposure
Moderate	Potentially harmful to vulnerable groups (e.g. immunocompromised patients, infants and the elderly) following chronic exposure
Minor	Potentially harmful to all people using the building following chronic exposure
Insignificant	No impact or not detectable

Regardless of which method is preferred, any decision taken in the risk assessment needs to be documented to ensure that decisions are sufficiently transparent for external examination (e.g. in audits) and to allow reassessment in periodic reviews.

Further information on hazards, risks and responses is provided in Box 4.9.

A48235836

Box 4.9 Example of a risk assessment

A water safety plan (WSP) team investigated the water system in a school building for 600 pupils. The building included a gymnasium with two shower rooms (40 showers in total). The WSP team found the following problems:

- One distribution pipe within the building was made of lead. This pipe delivers water to three bathrooms and one small kitchen.
- One small leakage in a pipe in the basement was identified.

Hot water was prepared from a centralized system in the main building at a temperature of 60 °C. There was no circulation loop. The hot-water pipes supplying water to the showers in the gymnasium were not insulated properly. Cold-water pipes were close to the hot-water pipes.

The WSP team prepared the following table for the risk assessment and for the decision about additional control measures.

Risk assessment and additional control measures for an example water system

	Hazard 1	Hazard 2	Hazard 3
Hazard or hazardous event	Lead pipe	Leaking pipe	Temperature loss from heater to shower; maximum water temperature at shower at 48 °C
Hazard type	Chemical contamination by lead	Chemical and microbial contamination	Microbial growth (Legionella)
Current control measure	None	None	Thermostatically controlled water heating
Basis for risk assessment	Daily consumption of lead-contaminated water at the taps in the bathrooms and in the small kitchen by children is likely	A breakdown of the water supply is not considered likely in the near future	It is very likely that there are long stagnation periods of the warm water supplying the showers. Temperatures below 60 °C will occur, and the potential for the growth of Legionella is high. Also, elevated temperatures in cold-water pipes are likely. These could support growth of Legionella.
Risk	**Major**	**Low–minor**	**Major**
Further investigations	Water analysis for lead	Check integrity of distribution system Check material compatibility Check corrosion	Temperature profiling of the system Check water heaters Check water system usage Water analysis for Legionella

Box 4.9 Example of a risk assessment *continued*

Risk	Major	Low–minor	Major
New or modified control measures	Short term: • Provide information to the teachers and pupils that water can only be drunk at certain taps • Label the taps that deliver lead-contaminated water Long term: • Replace all lead pipes	Replace with appropriate material	Short term: • Close showers Long term: • Install a warm-water circulation system, proper thermal insulation of warm-water and cold-water pipes

4.8 Control measures

Control measures are barriers to risks. They need to be identified and implemented for hazards identified as a significant priority. In the context of a WSP, control measures are defined as those steps in drinking-water supply that directly affect drinking-water quality, either by preventing the occurrence of significant hazards or by inactivating, removing or reducing them to acceptable levels.

Control measures can include a wide range of activities and processes. They can be:

- preventive (and be incorporated in design, planning, construction and commissioning)
- treatment (e.g filtration, disinfection, softeners)
- technical (e.g. temperature control, maintenance procedures)
- behavioural (e.g. measures that influence how water is used).

Control measures must be defined specifically and precisely for all significant risks, and adapted to the local conditions. They should never be imprecise or vague.

While the type and number of control measures will vary for each supply system, their collective implementation and maintenance is essential to ensure that water quality is controlled effectively.

Adequate control measures may already be established in many buildings. However, after reviewing their effectiveness in the course of system assessment, additional measures may need to be identified or existing measures may need to be modified. Improvement plans should be designed to deal with significant risks. Optimum solutions may not be economically, technically or socially feasible in the short term, and improvement plans may need to set short-, medium- and long-term goals.

Table 4.4 (at the end of this section) provides examples of control measures. Some of the control measures are applied during design and installation, while others involve a range of practical measures, including flushing, cleaning, disinfection and other routine maintenance procedures. Simple systems will require fewer control measures than more complex systems in large buildings.

A48235836

While control measures are directed at ensuring water quality, there may also be preventive actions and responses applied to maintain constancy of supply. These could include installation of sufficient buffering storage tanks or identification of alternative sources of water. Examples are included in Table 4.4.

4.8.1 Validation

All control measures should be validated to ensure effectiveness. Validation is the process of obtaining evidence that control measures are effective and achieve the required results. Validation can take the form of intensive monitoring during commissioning or initial implementation of a new or modified control. Alternatively, validation can take the form of assessing technical data from published studies or data provided by manufacturers (preferably confirmed by independent certification). This is a common approach used in assessing treatment processes. Validation can also be informed by successful implementation in other buildings.

Validation will typically only apply under certain conditions and these will typically be defined by operational limits. For example, chlorination could be validated (confirmed) as being effective if a minimum chlorine residual of 0.5 mg/l is achieved. In this case, 0.5 mg/l is used as a lower limit in operational monitoring (see section 4.9).

4.8.2 Ingress of contamination

Microbial contamination

Control measures to reduce ingress of microbial contamination from water sources can include water treatment at the PoE. This is particularly important where the quality of the source water cannot be guaranteed or where improved quality water is required—for example, in health-care facilities that accommodate patients with increased risk of infection.

Water treatment can be used:

- at PoE to
  - supplement treatment applied by the drinking-water provider
  - improve untreated building-specific water supplies or supplementary sources of water (e.g. rainwater);
- before devices such as hot-water systems or specialized equipment to improve water quality;
- at PoU (e.g. carbon filters, membrane filters).

Common forms of treatment include filtration, disinfection, softeners and carbon filters. Selection of PoE devices will be based on the nature of the source water (surface water, groundwater, rainwater, etc.), susceptibility to contamination (e.g. by human and livestock waste), the intended use of the water and the vulnerability of users.

Within buildings, control measures include ensuring the physical separation of systems transporting different qualities of water (e.g. drinking-water from sewage). These systems should be clearly marked to ensure that the possibility of inadvertent cross-connections is minimized during maintenance, repairs and renovations. Where systems and devices

are connected to drinking-water systems (e.g. firefighting supplies, cooling towers), backflow devices need to be installed to prevent ingress of contaminated water. Many countries have technical guides on how this should be achieved.

Where possible, positive pressure should be maintained to reduce the likelihood of ingress of external contamination. Pressure fluctuations should be minimized for the same reason.

Chemical and physical contamination

Control measures to ensure the physical and chemical quality of water entering buildings can include treatment at PoE. This could apply to either public or building-specific water supplies. The selection of appropriate solutions will depend on the nature of the chemical contamination. Selection of PoE devices should be based on expert advice.

Common forms of treatment include water softeners, deionizers, activated carbon and filtration.

Microbial growth and biofilms

Pathogen-control strategies inside buildings should prevent the development of conditions that can foster growth of hazardous environmental pathogens, such as *Legionella* and *Pseudomonas aeruginosa*.

Control measures should focus on good design principles and temperature management, and limit the development of biofilms. Systems should be designed and operated to maximize circulation and flows (avoiding stagnation, low flows, long branch pipes and dead ends, poor distribution of flow among branch pipes, etc.). Water temperatures should be kept below 20 °C in cold-water systems and above 50 °C in hot-water systems. Pipes carrying hot water should be insulated, while cold-water systems should be protected from heat sources. Ideally, hot water should be stored at above 60 °C and circulated at 50 °C or higher. In tropical and hot climates, keeping cold-water systems below 20 ºC during summer months is difficult. In these cases, using alternative controls (e.g. reducing stagnation, low flows and other risk factors) will have a higher priority.

Temperature reduction to reduce the risk of scalding in hot-water systems (e.g. by using thermostatic mixing valves) should be applied as close as possible to PoU. Distribution systems that incorporate multiple loops should be designed to ensure that flow rates can be equilibrated among the various loops. The capacity to disinfect hot-water systems using elevated temperatures or chemical processes should be considered. If PoE disinfection is installed to reduce the risk of microbial growth, it should be maintained and monitored to ensure effectiveness.

Additional safety measures may be applied in buildings or parts of buildings used by higher risk populations. This could include PoU devices (e.g. filters or ultraviolet disinfection units) installed on showers and taps. Effectiveness of these devices has been demonstrated in high-risk areas of health-care facilities, such as intensive-care units, for control of *Legionella* and *Pseudomonas* (Exner et al., 2005; Trautmann et al., 2008). Use of these devices should also be considered as a general measure where there are concerns about the quality of water entering buildings. Installation should be accompanied by ongoing maintenance and replacement programmes. Poorly maintained devices will not perform effectively and may support growth of biofilms.

4.8.3 Materials and equipment

Degradation, corrosion and scaling

The aim is to minimize corrosion and hence control the release of chemical hazards and extend the life of pipework and associated equipment. In many countries, water suppliers are required to provide water that is not aggressive (likely to cause corrosion in internal plumbing systems). However, this is not always the case, and building owners may need to implement control measures.

Corrosion can be controlled by:

- selection of suitable materials (i.e. not only more "resistant" material but also a better quality of the same material);
- minimizing water stagnation;
- preventing galvanic corrosion by avoiding contact between different metals;
- preventing bacterial regrowth (biofilm formation);
- treating water (e.g. removing corrosive ions such as chloride);
- adding corrosion inhibitors (e.g. polyphosphates, sodium silicates);
- encouraging corrosion "competition" with cathodic protection (e.g. using sacrificial galvanic anodes that dissolve instead of the piping material, or using inert electrodes powered by an external source of direct current in water-storage tanks).

Water with high levels of hardness can cause increased scaling. Increased temperature can exacerbate scaling, and hot-water devices and heating elements are particularly susceptible. A common control measure to reduce scaling is installation of water softener to reduce hardness.

4.8.4 Specific uses and water-using devices

Risks associated with specific uses (e.g. medical, dental) and water-using devices can be controlled by measures directed towards reducing contamination and preventing direct exposure to contaminated water or aerosols. Where devices are connected to drinking-water systems, the ingress of contamination to the main supply should be prevented by installing appropriate backflow-prevention devices.

All devices need to be maintained to minimize microbial growth and biofilm formation. Control measures for these types of devices should be based on regular cleaning, flushing of piping and tubing, and disinfection. Where devices produce sprays, possible exposure to fine aerosols should be minimized. This can be achieved by reducing release from devices such as cooling towers (e.g. by installing drift eliminators) or, where possible, reducing public exposure by operating systems outside opening hours (e.g. irrigation systems in garden centres).

Many countries have regulations and standards that apply to water-using devices. These regulations and standards can include general requirements such as requiring installation of backflow prevention on equipment connected to drinking-water supplies. Regulations may also specify application of control measures, including water treatment, disinfection and regular cleaning for specific devices such as cooling towers, swimming pools, hot-tub pools and hot-tub baths. Further information on control measures for these devices

can be found in *Guidelines for safe recreational water environments volume 2: swimming pools and similar environments* (WHO, 2006a) and *Legionella and the prevention of legionellosis* (Bartram et al., 2007).

4.8.5 Management, maintenance and repair

Water treatment devices at PoE and PoU and water-using devices should be cleaned regularly to minimize microbial growth and corrosion (softeners and carbon filters may be colonized if not adequately maintained). Water-using devices should be decommissioned when not in use, and drained where possible. Water-using devices such as cooling towers and evaporative condensers will often require cleaning and decontamination before being returned to service. Devices such as drinking-water fountains should be flushed following periods of non-use (e.g. school holidays).

4.8.6 Construction and renovation

In new buildings and upgraded parts of buildings, appropriate planning, construction and commissioning provides the first opportunity to apply control measures for preventing hazards and minimizing risks.

Planning

Initial planning of new buildings and upgrades for existing buildings often give little attention to water quality and hygiene issues. Functional and aesthetic features of a new building are generally given higher priority. Planning and designing safe water systems normally has to adapt to a physical framework that is already set. Planning of water systems is commonly left to subcontractors or subordinates in teams of designers. If not integrated in early stages of planning, there can be major consequences for the functionality and safety of water distribution within the building. Malfunction of water installations and subsequent retrofitting and remedial action can be very expensive and can interrupt construction or commissioning. Therefore, it is important to include specialists for water utility planning as soon as possible.

Definitions of water usage in new buildings are often imprecise, particularly in multipurpose buildings. This can be exacerbated where the intended uses of a new building are not known or are subject to substantial changes during the planning phase. Owners may not have decided where to put certain devices and end-of-use equipment, and can often be unaware of consequences and associated risks. Calculations of water usage and appropriate dimensions of the water distribution system are essential to ensure that systems are designed with appropriate capacities. This involves consideration of how the system and any associated equipment are to be used (e.g. numbers of users, frequency). Both over- and under-estimation of water capacity can compromise safety. As much detail as possible about projected water use and equipment requirements must be obtained from owners or intended users of buildings. Dual plumbing systems incorporating recycled water for toilet flushing and other non-drinking uses are becoming more popular. Installation of these systems will reduce water usage through drinking-water systems, and unless this taken into account it will lead to over-capacity and increased risks of stagnation.

In some cases, building owners are not the users or managers of buildings. For example, hotel buildings are quite often built and owned by companies other than those responsible for operating and managing the hotel. Early consultation between the various parties,

A48235836

including documentation of water-installation issues, is recommended to prevent the need for modifications during commissioning.

It may help to learn from existing buildings and transfer this experience to new, comparable projects. In most cases, pre-existing examples of safe water distribution systems are available. Dealing directly with manufacturers and providers of equipment (e.g. dimensions for water boilers or tanks) is useful, but design engineers may be a better source of information, because water hygiene depends on the whole system, rather than on individual components.

Construction phase

The initial plan for water distribution facilities should be followed wherever practical. If changes are made, they need to be incorporated into an amended plan; this includes changes to materials or dimensions of pipework and equipment. It is not appropriate to use working sketches from the planning office that do not reflect the actual installation.

Risks of biofilm formation or corrosion can be reduced by using only materials that are certified for use with drinking-water. Using incorrect or inferior—and possibly cheaper—alternatives will generally incur high costs for subsequent corrective measures.

Special care must be taken with procedures that are known to be crucial for system performance. It is essential that only water of drinking quality comes in contact with fittings and materials, even during construction. Alternatively, measures should be taken to ensure that the dead water is completely removed and the new fittings are flushed before being commissioned.

Pressure tests for distribution systems can be critical. Sometimes, water of lower quality is used for this purpose. While draining, flushing and high-dose chlorination can reduce risks from contamination, they may not always be completely successful. The pressure test should be used (with air, oil-free gas or drinking-water) to avoid this risk of residual contamination. If lower quality water is used, the system must be thoroughly drained and disinfected afterwards.

Timing also needs to be considered. Construction of a large building is often done in several phases. It is important to keep all finished parts of the water installation dry until the whole system is commissioned for routine operation. Introducing water into the system too early (e.g. weeks or months before a system becomes fully operational) can cause long-term problems. Retained water will become stagnant and support growth of biofilms, which are difficult to remove. Wherever possible, water should only be added to the system as a final step before it becomes operational. If this is not possible, sections that remain stagnant for extended periods should be thoroughly drained and disinfected before the system is commissioned.

4.9 Operational monitoring of control measures

A key requirement in identifying control measures is that performance can be monitored. Thus, operational monitoring procedures need to be established for each newly identified or existing control measure. Operational monitoring is used to assess the performance of individual control measures to ensure that they are working effectively, as designed. Monitoring frequencies should be selected to ensure that corrective actions can be introduced in a timely fashion to prevent loss of control and development of hazardous situations.

WSPs should incorporate a monitoring plan to answer the following questions:

- What will be monitored?
- How will it be monitored?
- Where will it be monitored?
- When and how often will it be monitored?
- Who will do the monitoring?
- Who will receive the results for analysis and, where necessary, ensure appropriate remedial responses are implemented?

Operational monitoring does not necessarily involve complex and time-consuming microbial or chemical tests. It rather takes the form of a planned sequence of inspections of observable features. As summarized in Table 4.4, many of the operational monitoring requirements involve regular inspection (e.g. checking structural integrity of storage tanks) or auditing of maintenance procedures (e.g. checking that PoU devices have been maintained according to manufacturers' instructions). Operational monitoring can include relatively simple field measurements, such as monitoring for turbidity, the appearance of the water, temperature and chlorine residuals. The general principle is that frequent performance of quick field tests is preferable to infrequent and expensive laboratory-based testing. Poor performance of hot-water systems can be detected more quickly and on an ongoing basis through monitoring of water temperatures, rather than by testing for pathogens such as *Legionella*, *Pseudomonas* or mycobacteria.

For each control measure, operational limits defining acceptable performance need to be identified and applied to operational monitoring parameters. These limits are typically identified during validation of control measures and can take the form of upper or lower limits or tolerance ranges. For example, this could include identifying a minimum temperature of 50 °C for hot-water systems and a maximum temperature of 20 °C for cold-water systems to prevent the growth of environmental pathogens, such as *Legionella*. Control measures are considered to be effective if monitoring results comply with the limits. If these limits are not met, corrective actions need to be taken immediately to bring the measure back under control. Corrective actions must be specific and predetermined, where possible, to enable rapid implementation. For hot-water systems, this includes identified actions to ensure that temperatures above 50 °C are restored and maintained. In some cases, it can be useful to set preliminary targets that provide an early warning if control measures are not be performing as well as possible. If these targets are not met, corrective actions can be implemented before control is lost. For example, if the low temperature limit in a hot-water loop is 50 °C, a preliminary target at which action is initiated could be 53 °C.

4.10 Management procedures and corrective responses

All aspects of WSPs need to be documented in a management plan. This includes system mapping, hazard identification, risk assessment, identification of control measures, monitoring programmes, corrective actions, improvement plans and communication strategies. Much of the management plan will describe monitoring and maintenance

A48235836

procedures that will be routinely followed on a day-to-day basis during normal performance. Many of these procedures will relate to sensible and practical measures to maintain cleanliness, hygiene, integrity and performance of systems. The key is to ensure that procedures are precisely described, with clear directions on what needs to be done and who will do it. However, documentation should also include corrective actions and response to incidents and failures. Many potential incidents are predictable (e.g. ingress of contamination, microbial growth and biofilms), and specific responses can be identified. A procedure also needs to be developed to deal with unpredictable events. This should take the form of an incident-response plan dealing with general principles, including responsibilities and communication requirements.

4.10.1 Ingress of contamination from external water sources

Chemical and microbial contamination may enter the distribution system of the buildings from external water supplies. If contamination is detected in a public water supply, advice should be provided to building owners or managers by the water supplier. This should include advice on recommendations for users of the water, alternative sources, responses implemented by the water utility, and estimated time frames for return to normal operation.

Depending on the contamination and potential impacts, the following measures could be considered for building water supplies:

- **Prevent the consumption of contaminated water.**
  - Provide advice to all users of the building that water from the building system should not be consumed. Label taps and outlets with appropriate advice.
  - Consider the need to provide bottled, packaged or tankered water to the building users. The building owner should ensure that the alternative source of water is safe and, if tankers are used, that they are suitable for delivering safe drinking-water.
  - Switch to an uncontaminated source of water to the building, if possible.
  - Use mobile treatment units (e.g. temporary chlorinators) to produce safe drinking-water, if contamination is likely to persist for an extended time. Monitor the operation of treatment devices to ensure that they produce safe drinking-water.
- **Disinfect the system.**
  - If microbially unsafe water is or was supplied to the building, it will be necessary to disinfect and flush the whole water system. This process should be monitored by on-line and field measurement of disinfectant concentrations at outlets throughout the building. The effect of the disinfection should be verified by microbiological analysis.
- **Flush the system.**
  - If chemically contaminated water is or was supplied to the building, it will be necessary to flush the whole water system. The effect of flushing should be verified by chemical analysis.

4.10.2 Ingress of contamination from building systems

If ingress of contamination in the building is identified, the source must be eliminated. Other corrective actions and responses could include the following:

- **Prevent the consumption of contaminated water.**
  - Issue advice to all users of the building or users of mains water in the affected section of the building that the water supply should not be consumed. Label taps and outlets with appropriate advice.
  - Consider the need to provide bottled, packaged or tankered water to building users while remedial action is taken. The building owner should ensure that the alternative source of water is safe and, if tankers are used, that they are suitable for delivering drinking-water.
- **Disinfect the system.**
  - In the event of microbial contamination, it will be necessary to disinfect and flush the whole water system or the affected sections of the system, depending on the type and extent of the contamination. This process should be monitored by on-line and field measurement of disinfectant concentrations at outlets throughout the building. The effect of disinfection should be verified by microbiological analysis.
- **Flush the system.**
  - In the event of chemical contamination, it will be necessary to flush the whole water system or the affected sections of the system. The effect of flushing should be verified by chemical analysis.

Failure of point of entry

PoE treatment devices need to be monitored to ensure that they function effectively. Non-compliance with critical limits should lead to an immediate assessment of impacts and remedial action. Further actions will depend on the nature and significance of the treatment (e.g. disinfection of a building-specific water supply compared with secondary disinfection of a treated external water supply).

Where PoE treatment is required to produce safe drinking-water from unsafe private or public supplies, responses and actions could be similar to those applied to contaminated external supplies. If the PoE treatment (e.g. water softeners) improves water quality but is not critical for safety or the performance of other control measures, the responses will not be as substantial and warnings about consuming the water will not be required.

4.10.3 Microbial growth and biofilms

If impacts from microbial growth are detected (e.g. discoloured water, odours, off-tastes, and slimes and sludges in water-using devices), it is likely that water systems will require disinfection and flushing. Hot-water systems can be "pasteurized" by flushing with water at temperatures greater than 60 °C (preferably greater than 70 °C). Users should be notified when disinfection or "pasteurization" is implemented. Water hotter than 60 °C can cause severe scalding, while water containing high levels of disinfectants can have objectionable tastes and odours for some users. Water-using devices will also require cleaning and disinfection.

The source of microbial growth should be examined. For example, the performance of treatment used in water-using devices should be checked. Where water temperatures

A48235836

are too high in cold-water systems or too low in hot-water systems, the cause should be investigated and corrected. This could include examining separation of systems, insulation, temperatures produced by water heaters, location and performance of thermostatic mixing valves, and flow rates in all branches—particularly in return mains.

The operation of the system should be checked to determine whether usage patterns have changed and whether areas of water stagnation have been introduced.

4.10.4 Release of hazards from materials and equipment

Improvement programmes should be established to reduce or stop the release of hazards by replacing the responsible components within the distribution system. Where this involves large amounts of pipework and fittings, this may need to be a staged process. For example, if there are large numbers of lead-based pipes (in some cases, most pipes in a building could contain lead), it is often impractical to replace it all at once. Depending on the extent and significance of contamination and potential impacts, the following measures should be considered:

- **Prevent the consumption of contaminated water where the water is considered unsafe.**
  - Issue advice to all users of the building or users of mains water in the affected section of the building that the water supply should not be consumed. Label taps and outlets with appropriate advice.
  - Consider the need to provide bottled, packaged or tankered water to the users of the building while remedial action is taken. The building owner should ensure that the alternative source of water is safe.
- **Flush the system.**
  - It may be necessary to flush the whole water system or the affected sections of the system. It may be appropriate to implement regular flushing programmes (e.g. for lead contamination; USEPA, 2002; Ontario Ministry of the Environment, 2010). The effect of flushing should be verified by chemical analysis.
- **Prevent corrosion.**
  - Corrosion can lead to chemical contamination. If the contamination includes hazardous chemicals, then similar management procedures applied to ingress of chemical contamination (see above) should be considered. Corrosion can affect the taste and appearance of water. If this occurs, building water supplies should be flushed to reduce concentrations of corrosion products.
  - Corrosion can also lead to faults that allow microbial contamination. Faults should be immediately repaired following standard maintenance procedures. This should include flushing and disinfection of affected parts of distribution systems.

4.10.5 Specific uses and water-using devices

Corrective actions and responses associated with incidents and failures detected in water for specific uses normally focus on taking remedial action and preventing exposure.

Where faults and contamination are detected, a standard response is to stop use or operation of the device until remedial action has been taken. Procedures describing when and how to shut down devices, and how to clean and decontaminate them, should be documented

and made available. These procedures should include monitoring requirements that must be met before devices are returned to service.

Advice should be issued to users of the building or users of specialized equipment when the devices are not available. Devices should be labelled with appropriate advice.

Where water is used for specific medical or dental procedures, alternative sources may be required. Procedures should be established to ensure that alternatives are available.

Box 4.10 provides a case study of *Legionella* infection from a private hot tub.

Box 4.10 *Legionella* infections from a private whirlpool (hot tub) in Sweden

In mid-February, a middle-aged Swedish man fell severely ill with legionellosis. The cultivation of his sputum sample showed growth of *Legionella bozemanii*, an unusual species in Sweden.

Since the patient had not recently travelled abroad, an investigation to find the source of infection was initiated by the department of communicable disease control and prevention in Stockholm County. The man was staying at his summer cottage during the incubation time. The water supply to his cottage was delivered through a long pipe via his neighbour's property. Water in the pipe was suspected to be the source of infection, and so the water was sampled and analysed for the presence of *Legionella*, but none was detected. On further questioning, the patient recalled that he had visited a friend and they had bathed in the friend's whirlpool bath.

The owner of the whirlpool was contacted and was found to be suffering from protracted symptoms of a respiratory tract infection. He had taken a course of penicillin for about two months, with no effect on his symptoms. Serological results later showed raised titres of antibodies to *Legionella bozemanii*.

At the end of April, samples were taken from the whirlpool, and very high concentrations of *Legionella bozemanii/anisa* were detected in the whirlpool water (3 600 000 cfu/l). The bacteriological analysis also showed high numbers of *Pseudomonas aeruginosa* and very high numbers of heterotrophic bacteria (>30 000 cfu/ml). These results indicated that the whirlpool had not been maintained correctly.

The owner of the whirlpool stated that he had maintained the whirlpool according to the manufacturer's maintenance instructions, although he had changed the filter more often than was recommended. The whirlpool has a volume of about 3 m^3; the owner changed the water every second week, and added chlorine (manually) as a disinfectant. The owner of the whirlpool contacted people who had visited him previously and had bathed in the whirlpool. He reported that about 40 people had developed mild respiratory symptoms after their visit.

The growth of the unusual *Legionella bozemanii/anisa* may have been due to the fact that the water used in the household was a mixture of well water and water from a nearby lake. Outbreaks caused by whirlpools distributing *Legionella* are becoming more frequent. Outbreaks of Pontiac fever with high attack rate are more common, but legionellosis outbreaks also occur.

Whirlpools are commonly installed in public places such as hotels, gyms or hot tubs, and poor maintenance of whirlpools is common. This was the first time that a private whirlpool had been found to be the vehicle of legionellosis in Sweden, but it is likely that the number of people contracting an infection with milder symptoms from their private whirlpools is underestimated.

Guidelines have been produced for hotels and public places to help reduce the risk of whirlpools becoming sources of *Legionella*.

Source: de Jong et al. (2004).

A48235836

4.10.6 Emergencies affecting external supplies

The quality of alternative water supplies provided in emergencies should be verified. Where treatment of these supplies is implemented, operational procedures and monitoring will be required to ensure that acceptable performance is achieved.

As part of remediation following a contamination event, the entire distribution system, including water-using devices, PoU and end-of-pipe devices will need to be flushed and possibly disinfected or decontaminated. Treatment systems such as water softeners, deionizers and filtration systems will need to be regenerated, backwashed or recommissioned before being returned to service. Small PoU filters could harbour contamination and may need replacing.

4.11 Management procedures for new buildings or major upgrades

Water systems, particularly in major buildings, tend to be complex in terms of both their geometry and the technical elements being installed. It is challenging to operate such systems correctly. In addition, personnel who will take responsibility for the new building may not have extensive expertise or training.

Thus, commissioning of water systems in buildings can have a critical influence on the quality of water. The design, construction and function of water systems, as well as management procedures, need to be documented by the constructer of the building and by manufacturers of specific devices and specialized equipment installed in buildings. Operating instructions and maintenance plans should be included. The instructions must cover details about the proper operation of the drinking-water supply system and about adequate functional checks. The nature, scope and frequency of inspections should be specified.

For buildings with specific requirements and potentially vulnerable users (e.g. hospitals, residential homes for the elderly, nursery schools), a specific hygiene plan should be established in cooperation with a hospital hygienist, the responsible public health authority and, if necessary, the water supplier.

A complete documentation folder of management plans and procedures should contain detailed plans of the system and technical fact sheets for all installed components (e.g. water filters, disinfection systems, drinking-water heaters), water-using devices (e.g. cooling towers) and specialized equipment (e.g. medical equipment, dental chairs).

Commissioning should incorporate a management and instruction protocol, which must be signed by both parties (manufacturer and operator of the system). There must also be an appropriate handover process to ensure that the building manager or operator is aware of all features and technical specifications of water systems, devices and associated equipment in the building. The responsible operator has to be informed about reporting requirements, legal obligations, codes of practice, national standards, technical rules and training requirements. Hygiene training may be required.

At the time of commissioning, water quality should be documented by hygienic testing of microbial and chemical quality in an adequate set of drinking-water samples. Initial higher intensity monitoring (additional samples and parameters) might be necessary, depending on intended use of the facility, outcomes of inspection, any irregularities during construction or commissioning, and delays in beginning of regular use (see section 4.8.5). In these cases, a water-quality expert should be consulted.

4.12 Verification

Verification is required to provide reassurance that WSPs are effective and water systems as a whole operate safely. Verification typically includes two components:

- testing water quality
- auditing WSPs.

4.12.1 Water-quality testing

The extent of water-quality testing will be influenced by the size and characteristics of the building, and the reliability and quality of the external water supply. In most buildings that have reliable, high-quality water supplies, there will be limited requirements for independent verification. Part of the responsibilities of the water utility is to ensure that the chemical and microbiological quality of water delivered to buildings is safe. The water utility should provide results on request.

Testing of water-quality safety in buildings is generally only required where:

- additional building-specific sources of water are used to augment the external supply;
- the building has specific purposes that increase potential risks (e.g. hospitals and other health-care facilities);
- water-using devices such as cooling towers, swimming pools and hot tubs are installed;
- management actions are established to minimize ongoing sources of contamination (e.g. flushing to deal with lead contamination).

Where additional building-specific sources of water are used, verification should include traditional indicators of faecal contamination, such as *E. coli*, and chemical parameters. The range of chemical parameters and frequency of testing will depend on the source of the water supply. Guidance on verification of microbial and chemical quality is provided in the GDWQ (WHO, 2008). In health-care buildings, particularly those incorporating intensive-care units, verification may include testing for specific microorganisms such as *Legionella* in hot-water systems. Further guidance is provided in *Legionella and the control of legionellosis* (Bartram et al., 2007). Verification of water quality in water-using devices such as cooling towers and swimming pools may also include testing for specific organisms. Further guidance is provided in *Guidelines for safe recreational water environments volume 2: swimming pools and similar environment* (WHO, 2006b). In some countries, verification of water-using devices may be a regulatory requirement.

The quality of water allocated to specific uses may also need to be verified. The parameters included in monitoring will depend on the specific requirements of the end use.

4.12.2 Water safety plan audits

Verification should include audits of WSPs to demonstrate that the plans have been properly designed, are being implemented correctly and are effective. As described in the GDWQ (WHO, 2008), factors to consider include:

- all significant hazards and hazardous events have been identified
- appropriate control measures have been included

A48235836

- appropriate operational monitoring procedures have been established
- appropriate operational limits have been defined
- corrective actions have been identified
- appropriate verification monitoring procedures have been established.

Audits should be included in internal reviews by building managers. Audits by independent experts should also be considered. Independent audits may be required by regulatory authorities or accreditation agencies for certain types of buildings (e.g. health-care facilities) or where buildings use independent sources of water.

4.13 Supporting programmes

Supporting programmes are activities that support implementation of WSPs and assurance of water quality. Operators, maintenance staff, employees and users of buildings may have limited knowledge of WSP principles, technical aspects and good practice associated with water supplies in buildings. Therefore, an important component is developing training and education programmes for personnel who are involved in activities that influence the delivery of safe water, and personnel for whom it is critical to use water safely (e.g. health-care professionals).

Section 5 provides further information on training.

Codes of good operating practices and hygiene are also important components of supporting programmes. These can be captured in standard operating procedures that include but are not limited to:

- hygienic use of water supplies
- hygienic practices in maintaining water supplies, water-using devices and equipment
- hygienic practices in performing repairs
- calibration of monitoring equipment
- instructions on access to equipment and modification of systems
- training requirements for maintenance staff.

The case study in Box 4.11 describes the response to a hospital water supply after contamination with *Pseudomonas aeruginosa*.

Box 4.11 Contamination of a hospital water supply with *Pseudomonas aeruginosa* in Germany

Pseudomonas aeruginosa in concentrations up to and above 100 organisms per 100 ml were detected in the water supply to a new hospital building in a number of locations and on repeated occasions during 2005–06. The colonization could not be eliminated, despite repeated thermal disinfection and implementation of continuous chlorine dioxide disinfection. As a result, the building was vacated, and an expert consultant was engaged to provide advice.

An ultraviolet plant was installed at the point of entry to the water system. The water system was intensively flushed and decontaminated with higher doses of chlorine dioxide disinfection for three days. This was augmented by intermittent dosing with hydrogen peroxide, as recommended in guidelines of the German Association for Gas and Water. After decontamination, there were only isolated detections of *Pseudomonas* (downstream of the pressure-increasing system).

Further measures included replacing and disinfecting the pressure-increasing system, and placing the ultraviolet plant before the pressure-increasing system.

Following these actions, it was decided to:

- move patients and employees into the building to avoid further stagnation (regular water throughput);
- establish an incident plan;
- continue microbiological testing.

Ongoing testing has shown that the strategy has been successful, with no further contamination. The alternative was to completely replace the water distribution system at a projected cost of approximately €2 million.

Source: Exner, Pleischl & Koch (personal communication, 2007).

4.14 Periodic review

Periodic review is a key requirement of effective WSPs; for example, after every three to five years or after significant changes of the supply system. Periodic review ensures regular updates of system assessment and management procedures, and also allows for the inclusion of incremental improvement strategies in system upgrades.

WSPs can become out of date due to modifications to water systems, changes in water uses, and changes in building ownership or tenancies. Therefore, WSPs should be reviewed whenever substantial changes occur.

A48235836

A48235836

Table 4.4 Examples of hazards, hazardous events and responses

Hazards and hazardous events	Control measures	Operational monitoring	Management procedures, protective actions	Supporting programmes
Intermittent supply				
Loss of water supply (isolated event)	• Back up water systems (e.g. alternative supply, standby disinfection facilities) • Ensure carted water is available	• Measure disinfectant residuals (e.g. chlorine concentration), pH • Monitor levels of water in storage tanks • Monitor integrity of storage	• Develop contingency plans to deal with emergencies • Establish procedures for activating back-up systems • Establish procedures before resuming the water supply or use	• Inform building occupants or users on what to do during interruption • Communication protocol with water utility • Train operational and maintenance staff in use of back-up systems
Intermittent supply (regular event)	• Back up water systems (e.g. alternative supply, standby disinfection facilities) • Ensure carted water is available • Provide large storages for supply during interruptions	• Monitor water pressure or water availability • Record times of water availability and water usage • Measure disinfectant residuals (e.g. chlorine concentration), pH • Monitor levels of water in storage tanks • Monitor integrity of storage	• Establish procedures for activating back-up systems • Establish procedure before resuming the water supply or use	• Inform building occupants or users on what to do during interruptions • Discuss the communication protocol with water utility • Train operational and maintenance staff in use of back-up systems

Page 3448

Table 4.4 Examples of hazards, hazardous events and responses *continued*

Hazards and hazardous events	Control measures	Operational monitoring	Management procedures, protective actions	Supporting programmes
Contamination of external supply entering the building				
Poor microbial quality (long term)	• Install PoE treatment systems (e.g. filtration and disinfection) • Install PoU devices (e.g. filtration) • Back up systems (alternative supply, standby disinfection facilities) • Ensure carted water, packaged water or bottled water supplies are available • Issue advice to boil water • Isolate building from external supply	• Measure disinfectant residuals (e.g. chlorine concentration), pH • Monitor turbidity if PoE treatment includes filtration • Monitor performance of PoU devices and equipment • Monitor use of carted or bottled water • Ensure water is boiled before use • Monitor cross-connection control preventing ingress of external supply	• Develop procedures for operating PoE systems and treating back-up supplies • Develop procedures for maintaining PoU devices (these should be consistent with manufacturers' instructions) • Identify sources of bottled, packaged or tankered water supplies • Restore disinfection • Restore filtration if provided • Monitor water quality (verification)	• Develop communication procedures for informing building occupants or users • Discuss communication protocol with water utility • Establish contracts with bottled, packaged or tankered water suppliers • Train operational and maintenance staff in use of back-up systems
Poor chemical quality (long term)	• Install PoE treatment systems (e.g. deionizers, softeners, activated carbon) • Install PoU devices (e.g. filtration) • Provide an alternative supply • Ensure carted water, packaged water or bottled water supplies are available • Isolate building from external supply	• Monitor operation of PoE treatment • Monitor performance of PoU devices and equipment • Monitor treatment of back-up supply • Monitor use of carted or bottled water • Monitor cross-connection control preventing ingress of external supply	• Develop procedures for operating PoE systems and treating back-up supplies • Develop procedures for maintaining PoU devices (these should be consistent with manufacturers' instructions) • Monitor water quality (verification)	• Train operational and maintenance staff in use of back-up systems

A4823836

Table 4.4 Examples of hazards, hazardous events and responses *continued*

Hazards and hazardous events	Control measures	Operational monitoring	Management procedures, protective actions	Supporting programmes
Contamination of external supply entering the building *continued*				
Poor microbial quality (short term) (e.g. treatment failure, pipe breakage, natural disasters)	• Back up systems (alternative supply, standby disinfection facilities) • Ensure carted water, packaged water or bottled water supplies are available • Issue advice to boil water	• Measure disinfectant residuals (e.g. chlorine concentration), pH • Monitor appearance (turbidity, colour) and odour of water • Monitor use of carted or bottled water • Ensure water is boiled before use	• Develop contingency plans to deal with emergencies • Provide alternative sources of water (bottled, packaged water or tankered supplies) • Issue advice to boil water • Liaise with water utility on repair of external system • Develop a procedure for flushing and disinfecting internal supply when the water quality of external supply is restored • Verify water quality after normal supply is restored	• Communicate with water utility, including about incident protocol • Establish communication procedures for informing building occupants or users during incident and recovery • Develop a communication protocol with water utility • Train operational and maintenance staff in use of back-up systems
Poor chemical quality (short term) (e.g. treatment failure, pipe breakage, natural disasters)	• Back up water systems (e.g. alternative supply, with standby disinfection facilities) • Ensure that carted water, packaged water or bottled water supplies are available	• Monitor appearance (turbidity, colour) and odour of water	• Develop contingency plans to deal with emergencies • Provide alternative sources of water (bottled, packaged water or tankered supplies) • Activate back-up systems • Develop a procedure for flushing the system when the water quality of external supply is restored • Verify water quality after normal supply is restored	• Establish communication with water utility, including incident protocol • Develop communication procedures for informing building occupants or users during incident and recovery • Develop a communication protocol with water utility • Train operational and maintenance staff in use of back-up systems

Table 4.4 Examples of hazards, hazardous events and responses *continued*

Hazards and hazardous events	Control measures	Operational monitoring	Management procedures, protective actions	Supporting programmes
Contamination of internal supply				
Pipe breaks or entry of contamination into storage tanks	• Regularly inspect systems, including water-storage tanks • Minimize pressure fluctuations • Ensure that the water distribution system is designed properly • Install pressure-reducing valves	• Monitor water pressure • Check turbidity, signs of corrosion or unusual taste	• Develop procedures for repairing or replacing broken pipes • Develop a procedure for disinfecting and flushing affected areas • Develop a procedure for inspecting, repairing and disinfecting storage • Identify sources of bottled or packaged water, or tankered supplies	• Develop procedures for building occupants or users to report loss of supply or changes in appearance, taste and odours • Use materials and pipes that are certified as being suitable • Train operational and maintenance staff on selection of materials and procedures for repairing faults
Cross-connection of different water qualities (chemical or microbial contamination)	• Physically separate and label water systems delivering different water types or removing sewage/greywater • Minimize accidental or unintended cross-connections and provide backflow prevention where required • Maintain positive pressure in the distribution system	• Monitor integrity of system separation and inspect system labelling • Monitor operation of backflow-prevention devices	• Develop procedures for installing or replacing pipework and fittings • Remove unintended cross-connections. • Develop a procedure for disinfecting and flushing affected areas	• Develop communication procedures for informing building occupants or users • Provide instructions for maintenance staff and plumbers or fitters installing new or replacement pipework and equipment
Connection with PoU devices and equipment	• Install appropriate backflow-protection systems • Prevent huge pressure variation in pipe network • Maintain continuous pressure	• Monitor performance of PoU devices and equipment • Monitor operation of backflow-prevention devices	• Develop procedures for installing and connecting devices and equipment to distribution systems	• Provide instructions for people who install equipment • Follow plumbers' codes of practice

A4823836

A48235836

Table 4.4 Examples of hazards, hazardous events and responses *continued*

Hazards and hazardous events	Control measures	Operational monitoring	Management procedures, protective actions	Supporting programmes
Contamination of internal supply *continued*				
Poor maintenance of equipment and PoU devices, leading to microbial growth or corrosion	• Monitor performance of equipment and PoU devices • Ensure that the system is maintained in accordance with manufacturers' instructions • Install appropriate backflow-protection systems	• Monitor performance of PoU devices and equipment • Monitor appearance of water for signs of growth (discolouration, turbidity, odours) or corrosion	• Develop procedures for maintaining devices (consistent with manufacturers' instructions)	• Train maintenance staff
Backflow from chemical storages Inadequate backflow prevention on equipment	• Minimize connections and provide backflow prevention where required	• Monitor operation of backflow-prevention devices • Monitor use of chemicals	• Develop procedures for installing and connecting storages to distribution systems	• Provide instructions for people who install chemical storages • Follow plumbers' codes of practice

Page 3452

Table 4.4 Examples of hazards, hazardous events and responses *continued*

Hazards and hazardous events	Control measures	Operational monitoring	Management procedures, protective actions	Supporting programmes
Sewerage or septic systems				
Aerosol contamination	• Install water traps in sewage lines • Filter double traps in high-risk environments • Prevent contamination from septic tanks	• Monitor integrity of system separation	• Develop procedures for installation during construction and upgrades	• Follow plumbers' codes of practice
Cross-connection with drinking-water system	• Ensure separation from water systems and appropriate labelling and marking of pipework and fittings	• Monitor separation of system	• Develop procedures for installation during construction and upgrades • Remove unintended cross-connections. • Develop a procedure for disinfecting and flushing affected areas • Identify sources of bottled or packaged water, or tankered supplies	• Follow plumbers' codes of practice
PoE treatment				
Incorrect operation and interruption to treatment	• Assign staff to perform maintenance • Monitor operation of processes (e.g. that ultraviolet lights and chlorinators are functioning) • Install alarms on key processes • Have a standby generator	• Measure disinfectant residuals (e.g. chlorine concentration), pH • Monitor turbidity if PoE treatment includes filtration	• Develop procedures for operating PoE systems • Restore disinfection • Restore filtration if provided	• Train operational and maintenance staff

Table 4.4 Examples of hazards, hazardous events and responses *continued*

Hazards and hazardous events	Control measures	Operational monitoring	Management procedures, protective actions	Supporting programmes
PoE treatment *continued*				
Inadequate maintenance	• Assign staff to perform maintenance • Ensure processes are maintained according to manufacturers' instructions	• Monitor the effectiveness of maintenance procedures	• Develop maintenance procedures	• Train operational and maintenance staff
Overdosing with treatment chemicals or release of treatment chemicals into distribution systems	• Ensure dosing equipment and storages are maintained • Avoid overdesigning chemical storage capacities • Minimize cross-connections and provide backflow prevention where required	• Monitor use of chemicals	• Develop procedures for operating PoE systems, including calibration of dosing systems • Restore correct doses	• Train operational and maintenance staff
Microbial growth and biosystems				
Complex systems	• Apply additional disinfection at PoE • Sanitize or disinfect hot-water systems regularly • Install PoU devices (e.g. filtration)	• Measure disinfectant residuals (e.g. chlorine concentration), pH, after PoE device, and monitor disinfectant residuals in system • Monitor disinfectant residuals and temperature during sanitization • Monitor performance of PoU devices and equipment	• Restore disinfection • Develop procedures for sanitization and flushing • Develop procedures for maintaining PoU devices (consistent with manufacturers' instructions)	• Develop communication procedures for informing building occupants and users during sanitization • Train operational and maintenance staff in use of PoE treatment and sanitization procedures

Table 4.4 Examples of hazards, hazardous events and responses *continued*

Hazards and hazardous events	Control measures	Operational monitoring	Management procedures, protective actions	Supporting programmes
Microbial growth and biosystems *continued*				
Stagnation and low water flows (cold systems)	• Avoid overdesigning capacities • Remove the causes of fluctuation (e.g. high peak water demand, fire drills) • Prevent negative pressure • Flush systems that are not used frequently • Isolate areas that are not used for extended periods • Remove dead legs and minimize length of branch pipes	• Monitor appearance, taste and odour of water • Monitor use of water throughout the building	• Develop procedures for isolating sections of water systems that are not in use • Develop procedures for sanitization and flushing	• Develop procedures for building occupants or users to report loss of supply or changes in appearance, taste and odours • Train operational and maintenance staff
Stagnation and low water flows (hot systems)	• Avoid overdesigning capacities • Flush systems that are not used frequently • Isolate areas that are not used for extended periods • Remove dead legs and minimize length of branch pipes	• Monitor appearance, taste and odour of water • Monitor temperature • Monitor use of water throughout the building	• Develop procedures for isolating sections of water systems that are not in use • Flush all taps on weekly basis if not being used regularly • Develop procedures for sanitization and flushing	• Develop procedures for building occupants or users to report loss of supply or changes in temperature, appearance, taste and odours • Train operational and maintenance staff
Intermittent/ seasonal use/closed hospital wards	• Isolate areas not in use • Drain system and disinfect on return to service	• Monitor occupancy and use of water throughout the building	• Develop procedures for isolating sections of water systems that are not in use • Develop procedures for returning supply before reopening closed sections • Develop procedures for sanitization and flushing	• Train operational and maintenance staff

A48235836

A48235836

Table 4.4 Examples of hazards, hazardous events and responses *continued*

Hazards and hazardous events	Control measures	Operational monitoring	Management procedures, protective actions	Supporting programmes
Microbial growth and biosystems *continued*				
Poor temperature control (cold systems)	• Insulate cold- and hot-water pipes. • Keep systems physically separate	• Monitor temperature	• Investigate and remove sources of elevated temperatures	• Follow plumbers' codes of practice
Low water temperatures in hot-water storage vessels	• Adjust heater temperature • Ensure sufficient energy delivery (e.g. with distant hot-water supply) • Check heater thermostat • Maintain temperatures above 50 °C in distribution system • Maintain temperatures above 60 °C in storage vessels • Install temperature-reduction devices as close as possible to PoU • Insulate system • Avoid stagnation and low flow areas (minimize branch pipes, dead ends, etc.) • Ensure sufficient capacity for maximum flows	• Monitor temperatures in storage vessels, distribution systems and at PoU • Monitor maintenance of temperature-reducing devices	• Develop procedures for operating hot-water systems, including remedial action if temperatures are too low	• Develop procedures for building occupants or users to report low temperatures • Train operational and maintenance staff • Follow plumbers' codes of practice
Inappropriate materials	• Select appropriate materials (where certification schemes have been established, use only authorized materials)	• Check that only authorized materials are used	• Develop procedures for selecting materials • Replace unsuitable materials	• Train operational and maintenance staff on selection of materials • Follow plumbers' codes of practice

Page 3456

Table 4.4 Examples of hazards, hazardous events and responses *continued*

Hazards and hazardous events	Control measures	Operational monitoring	Management procedures, protective actions	Supporting programmes
Microbial growth and biosystems *continued*				
Poorly maintained PoU devices	• Assign staff to perform maintenance • Ensure devices are maintained according to manufacturers' instructions • Check and/or install appropriate backflow-protection systems	• Monitor performance of PoU devices and equipment • Monitor appearance of water for signs of growth (discolouration, turbidity, odours) or corrosion • Monitor production and release of aerosols	• Develop procedures for maintaining devices (consistent with manufacturers' instructions)	• Train maintenance staff
Poor control of looped water supplies	• Check design and operation of pipe loops • Check flow rates in circulated loops, and recalculate equilibrium conditions among loops	• Monitor water pressures and temperatures	• Repair systems so that flows are balanced	• Train operational and maintenance staff
Materials				
Release of organic substances	• Select appropriate materials • Where certification schemes have been established, use only authorized materials	• Check that only authorized materials are used • Where solvents are used during installation, monitor application and curing	• Develop procedures for selecting materials and using solvents • Replace unsuitable materials	• Develop procedures for building occupants or users to report odours • Train operational and maintenance staff on selection and use of materials • Follow plumbers' codes of practice

A48235836

Table 4.4 Examples of hazards, hazardous events and responses *continued*

Hazards and hazardous events	Control measures	Operational monitoring	Management procedures, protective actions	Supporting programmes
Materials *continued*				
Entry of organic substances through plastic piping	• Select appropriate pipe material, particularly in areas where solvents or hydrocarbons are stored • Avoid inappropriate materials in areas where solvents or hydrocarbons are stored or manipulated	• Check that only authorized materials are used • Monitor chemical storages	• Develop procedures for selecting materials • Replace unsuitable materials • Develop procedures for storing chemicals	• Follow procedures for building occupants or users to report odours and tastes • Train operational and maintenance staff on selection of materials • Follow plumbers' codes of practice
Corrosion and scaling				
Poor installation	• Choose quality materials • Follow national or international choice and construction rules • Use active protection of pipes (e.g. sacrificial anodes, anticorrosion products)	• Check appearance of water (red-brown for rust, blue-green at outlets for copper)	• Develop procedures for installing piping and fittings	• Develop procedures for building occupants or users to report changes in appearance, taste and odours • Follow plumbers' codes of practice
Dissolution or corrosion of metals (from pipework, fittings, drinking-water fountains, etc.)	• Follow correct installation • Select appropriate materials • Avoid interconnection of incompatible metal materials • Use PoE chemical treatments to reduce corrosion • Flush pipework regularly • Flush drinking-water fountains regularly after interruptions to use (weekends, holidays, etc.) • Install PoU devices	• Check appearance of water (red-brown for rust, blue-green at outlets for copper) • Monitor performance of PoE and PoU devices and use of chemicals • Monitor performance of flushing programmes	• Develop procedures for installing piping and fittings • Develop procedures for operating PoE and PoU devices • Develop procedures for implementing flushing programmes	• Train operational and maintenance staff in the operation of PoE and PoU equipment • Follow plumbers' codes of practice

Page 3458

Table 4.4 Examples of hazards, hazardous events and responses *continued*

Hazards and hazardous events	Control measures	Operational monitoring	Management procedures, protective actions	Supporting programmes
Corrosion and scaling *continued*				
Incompatibility with incoming water quality	• Check incoming water quality and recommendations relating to materials used in distribution systems • Install water softeners to reduce water hardness	• Monitor development of scale (particularly on hot-water elements) • Check appearance of water	• Develop a procedure for consulting with water supplier about materials compatible with water quality • Develop procedures for operating PoE devices	• Train operational and maintenance staff in the operation of PoE equipment • Follow plumbers' codes of practice • Follow advice from water utilities on characteristics of external water supply
Specific uses				
Contamination of dental hygienic equipment, dental assembly (water for mouth washing, wash basin, cooling dynamic tools, auxiliary uses)	• Ensure effective disinfection • Allow easy cleaning and disinfection of the assembly and the material in contact with water • Install adequate backflow prevention • Use suitable material in contact with water (no natural rubber, no nickel plating)	• Monitor implementation of disinfection and cleaning • Check operation of backflow prevention	• Document procedures • Repeat cleaning and disinfection if there are doubts about cleanliness	• Train staff to ensure that procedures are understood and applied

A48235836

Table 4.4 Examples of hazards, hazardous events and responses *continued*

Hazards and hazardous events	Control measures	Operational monitoring	Management procedures, protective actions	Supporting programmes
Specific uses *continued*				
Exposure to aerosols from contaminated cooling towers and evaporative condensers	• Maintain devices (check to see if regulations or standards have been developed) • Maintain cleanliness • Decontaminate regularly (e.g. twice per year) • Decontaminate on return to service • Drain system when not in use • Install biocide dosing • Install drift eliminators • Install outlets away from fresh air inlets to air-conditioning systems	• Monitor cleanliness of devices • Monitor operation of treatment systems (antiscalant, disinfection) • Monitor implementation of maintenance procedures • Inspect and maintain drift eliminators	• Make sure the system is designed according to established standards • Develop procedures for operating and maintaining devices • Develop procedures for cleaning and decontamination • Develop procedures for shut-down and reactivation	• Follow codes of practice for installation, operation and maintenance • Train operational and maintenance staff
Contamination of hot tubs, whirlpools, water display	• Drain and clean regularly • Ensure continuous filtration and disinfection	• Measure disinfectant, pH, turbidity	• Develop procedures for operating and maintaining devices • Develop procedures for cleaning and decontamination	• Follow codes of practice for operation and maintenance • Train operational and maintenance staff
Contamination of respiratory system equipment	• Drain and clean regularly • Disinfect at PoU (ultraviolet radiation) • Ensure backflow prevention is adequate • Wash nebulizers with sterile water and dry thoroughly	• Inspect the system and equipment regularly • Monitor disinfection procedures • Monitor implementation of maintenance procedures	• Develop procedures for operating and maintaining devices • Develop procedures for cleaning and decontamination	• Train operational and maintenance staff

Table 4.4 Examples of hazards, hazardous events and responses *continued*

Hazards and hazardous events	Control measures	Operational monitoring	Management procedures, protective actions	Supporting programmes
Specific uses *continued*				
Contamination of humidifiers	• Maintain droplets separator • Maintain and clean the generator, and disinfect the PoU (e.g. using ultraviolet radiation) • Ensure air catchments are far from polluted area (e.g. cooling towers) • Avoid condensed water recovery • Ensure that the system design separates droplets of critical size, and does not allow stagnation	• Inspect humidifiers regularly • Monitor disinfection procedures • Monitor implementation of maintenance procedures	• Develop procedures for operating and maintaining devices • Develop procedures for cleaning and decontamination	• Train operational and maintenance staff
Drinking-water coolers	• Ensure that coolers are used or flushed regularly to prevent excessive corrosion or leaching of metals, particularly in buildings with seasonal use or extended closures (e.g. schools)	• Inspect drinking-water coolers regularly • Monitor implementation of maintenance procedures	• Develop procedures for maintaining devices, including flushing after periods of low or no use	• Develop procedures for building occupants or users to report changes in taste and odours • Train operational and maintenance staff
Contamination of decorative fountains	• Clean and maintain regularly • Completely drain system for cleaning • Use appropriate water disinfectant	• Inspect fountains regularly • Monitor implementation of maintenance procedures	• Develop procedures for operating and maintaining devices • Develop procedures for cleaning and decontamination	• Train operational and maintenance staff
Contamination of eye wash stations and safety showers	• Flush stagnant water frequently • Disinfect the system regularly • Replace with bottles for eye wash	• Inspect regularly • Monitor implementation of maintenance procedures, including flushing and disinfection	• Develop procedures for operating and maintaining devices • Develop procedures for cleaning and disinfection	• Train operational and maintenance staff

A48235836

Table 4.4 Examples of hazards, hazardous events and responses *continued*

Hazards and hazardous events	Control measures	Operational monitoring	Management procedures, protective actions	Supporting programmes
Construction work				
Use of inappropriate materials	• Select appropriate materials (where certification schemes have been established, use only authorized materials)	• Check that only authorized materials are used	• Develop procedures for selecting materials	• Train designers and builders on selection of materials • Follow plumbers' codes of practice
Microbial or chemical contamination events during repair or maintenance works Temporary switching to alternative supply Temporary stagnation, dead legs and blind ends Extensions of existing installations (which may change the established equilibrium of operation in terms of hydraulic conditions, thermal capacity and corrosion risks)	• Pre-plan extensions to ensure that they are appropriately designed and installed (design should take into account the characteristics and requirements of the existing system) • Isolate new sections from existing systems until integrity can be ensured • Flush and disinfect new construction before it is connected • Ensure that new work is inspected and certified by a qualified plumber or engineer before use • Thoroughly test the operation of the new system in combination with existing infrastructure	• Ensure that design requirements are followed, and that installation procedures are monitored • Monitor isolation of the sections under construction.	• Develop rocedures for constructing and installing new systems, equipment and devices	• Train designers and builders • Follow plumbers' codes of practice • Follow auditing and certification procedures for completed work before commissioning

Page 3462

Table 4.4 Examples of hazards, hazardous events and responses *continued*

Hazards and hazardous events	Control measures	Operational monitoring	Management procedures, protective actions	Supporting programmes
Construction work *continued*				
Accidental or unintended cross-connection between systems delivering different water qualities	• Ensure that new work is inspected and certified by a qualified plumber or engineer before use • Check connections with existing systems • Ensure that all new work is labelled appropriately • Install backflow-prevention devices where required to protect drinking-water systems	• Ensure that design requirements and installation procedures are followed • Monitor isolation of the sections under construction	• Develop procedures for constructing and installing new systems, equipment and devices	• Train designers and builders • Follow plumbers' codes of practice • Follow auditing and certification procedures for completed work before commissioning

PoE = point of entry; PoU = point of use.

A48235836

5 Supporting environment

This section describes the roles of supporting personnel to ensure the smooth running of water safety plans (WSPs). This includes surveillance, inspection, outbreak detection, regulatory and policy frameworks, and capacity building and training.

5.1 Independent inspection and surveillance

5.1.1 Inspection

Independent inspection and surveillance of drinking-water systems is essential for ensuring that systems are well designed and are managed and operated in a manner that protects public health. Independent inspections and surveillance can be undertaken during construction and major renovations of buildings, or can be applied to existing buildings.

Independent technical inspections are often required as part of construction and renovation of buildings. For example, engineering inspections and certification of plumbing systems can be required under building and plumbing codes. These inspections should include assessments of public health impacts of drinking-water systems and associated devices. Public health agencies should also be consulted as early as possible during design and construction to assess the suitability of water systems, including the selection, installation and monitoring of control measures. Where possible, public health agencies should assess and approve WSPs developed for new buildings and new or renovated water systems, particularly in buildings where potential health risks can be high (e.g. health facilities).

Independent technical inspections of existing buildings can be undertaken by auditors or specialists with expertise in areas such as WSPs, plumbing, water treatment, operation of water devices (e.g. water-cooled air-conditioning, swimming pools, hot tubs), water microbiology, infection control, and occupational health and safety. Technical inspections can be commissioned by building managers to provide assurance that systems are being operated so that they protect public health and are consistent with regulatory requirements. Remedial action or improvements identified by such independent inspections should be documented and implemented. In some circumstances, independent inspections may be included as part of accreditation activities. For example, accreditation of facilities such as hospitals or hotels can include independent inspection of drinking-water systems and WSPs. Independent inspections can also be a regulatory requirement. Outcomes of these inspections should be documented within WSPs.

5.1.2 Surveillance

Surveillance is one of the five key components of the *Framework for safe drinking-water* (WHO, 2008) and is necessary to verify that WSPs are well designed and correctly implemented. Surveillance is a specific and ongoing activity that should be undertaken by public health agencies to assess and review the safety of drinking-water systems. As well as being a measure of compliance with regulatory requirements, surveillance helps to protect public health by promoting ongoing improvement, and by contributing to the early detection of water quality risk factors and the subsequent selection of appropriate

remedial actions. Ensuring timely implementation of corrective action and targeted improvement can prevent waterborne disease.

Surveillance of drinking-water systems in buildings can involve audits, direct assessment or, ideally, a combination of these two approaches. Audits will generally include reviewing and approving new WSPs, as well as routine auditing of implementation of individual WSPs. Direct assessment involves testing of water quality. The advantage of audits is that they assess the capability to consistently produce safe drinking-water, while direct assessment assesses whether safe drinking-water was produced at the time of testing. Direct audits are more useful when they are included as part of broad surveys.

Both approaches require the surveillance agency to understand drinking-water systems and the way in which WSPs are applied, as well as the capability to undertake audits and respond to significant water incidents. In addition, direct assessments require the surveillance agency to have expertise in identifying appropriate monitoring locations and parameters, and collecting samples. They must also have access to testing facilities, be able to interpret results, and provide reports to building managers.

There are large numbers of buildings in urban centres, and routine surveillance of all building water systems will generally be impossible. Effective planning and development of surveillance programmes should identify priorities based on levels of risk. This requires an analysis of the types of buildings to be included in surveillance programmes, together with information on building characteristics and risk factors associated with building occupiers and users. Characteristics to be considered include:

- building types (hotels, apartments, hospitals, aged-care facilities, hospices, clinics, schools, child care, recreation centres, etc.);
- size and location of buildings and numbers of people potentially exposed;
- vulnerability of occupiers or users of buildings (residents, workers, patients, elderly or very young people, etc.);
- type and size of water systems (drinking-water supplies, hot-water systems, water-cooled air-conditioning systems, swimming pools, hot tubs, etc.);
- expertise of building operators and employees;
- availability of specialist service providers;
- geographical and climatic conditions (e.g. temperature, humidity, climate variability).

In many cases, surveillance may be based on occasional surveys. However, buildings such as hospitals and aged-care facilities should be audited at least once per year. Specific surveillance may be conducted for buildings that are closed for extended periods and reopened (e.g. schools and seasonal hotels). Targeted surveillance may be performed for specific devices and equipment, such as cooling towers, evaporative condensers, swimming pools and hot tubs. In some countries, this type of targeted surveillance may be required by specific legislation.

Surveillance can be undertaken or coordinated by central public health authorities in conjunction with regional and local offices, or with environmental health departments within local government. Programmes should be based on practical considerations, taking into account the capability of surveillance agencies. Greater attention should be focused on buildings that have potentially higher risks.

When designing surveillance programmes, consideration should be given to whether surveillance will be the responsibility of public health agencies or third parties (e.g. specialist auditors), certified or approved by these agencies, or a combination of both. Where third parties are used, the public health agency needs to retain responsibility for implementing the surveillance programmes. The public health agency should also provide directions on the frequency of inspections and audits, as well as the procedures to be applied. Public health agencies should receive and assess third-party reports and communicate assessments with building owners and managers.

Audits

Audits are on-site assessments, from intake to tap, of the whole water system—including sources, transmission infrastructure, treatment processes, storage, distribution systems, maintenance and monitoring programmes, and water uses within the building. Audits should embrace all water systems existing within the building, such as cold-, hot- and warm-water treatment and distribution systems; water-cooled air-conditioning systems; swimming pools; hydrotherapy pools; and hot-tub pools. The objective is to evaluate the ability of building management to produce and deliver safe drinking-water, as well as water of quality suitable for other specific uses within a building (e.g. in clinics, dental surgeries).

Audit-based approaches rely on data and information being provided by building owners and managers. This will include descriptions of water systems and end uses, results of operational monitoring to check that control measures are working effectively, results of monitoring at point of delivery to assess compliance with water-quality requirements, and evaluation of consumer satisfaction and complaints. Information should also be provided on independent inspections, internal audits, previous surveillance audits, and implementation of remedial action and improvement programmes.

Audits will normally focus on the design and implementation of WSPs. This could include:

- reviewing the building's water systems to examine whether all systems and uses are included and described accurately in WSPs;
- ensuring that WSPs consider all appropriate regulations, codes, guidelines and accreditation requirements;
- examining records to ensure that the system is being managed according to the WSP;
- assessing whether operational monitoring parameters have been kept within operational limits, that compliance was maintained, and that appropriate action was taken to respond to non-compliance, where necessary;
- ensuring that verification programmes are in place, that results demonstrate effectiveness of WSPs, and that appropriate action was taken to respond to non-compliance;
- examining maintenance records;
- assessing whether systems have been operated by appropriate personnel or appropriate service providers;
- ensuring that regulatory requirements have been met;

- examining reports of independent inspections and internal audits;
- ensuring that all actions and results have been documented and reported according to the WSP;
- assessing incident plans, contingency measures, and communication and reporting protocols;
- assessing supporting programmes and strategies for improving and updating the WSP.

Audits may involve interviewing building managers, operators and technical staff involved in water-system management. A final report should be completed at the end of the audit to formally notify the building owner or manager of the findings. The report may be used for future compliance actions and inspections and should summarize the findings of the survey, remedial action and recommended improvements, together with timelines for implementing actions and improvements.

Targeted audits should be conducted after substantial changes to the source, distribution system or treatment process, and in response to significant incidents.

Audits conducted in response to significant incidents detected by building operators should focus on verifying that:

- the incident was investigated promptly and appropriately
- the incident was reported to appropriate authorities in a timely fashion
- the cause was determined and corrected
- the incident and corrective actions were documented
- the WSP was reassessed and amended, where necessary, to avoid a similar situation.

Direct assessment

Direct assessment involves the collection and analysis of water quality by the surveillance agency. It does not replace requirements for audits, and should not be used to reduce the frequency of audits. Results should always be reported to building managers and should complement verification testing.

5.1.3 Incidents, emergencies and outbreaks

Additional inspections will be required in the event of incidents, emergencies (including natural disasters) and waterborne outbreaks. This will involve inspection of WSPs and of associated water systems. Investigations will normally require immediate collection of water samples. Wherever possible, samples should be collected before remedial actions are taken—as long as this does not cause unnecessary delays. This is important in trying to establish the cause of outbreaks.

The types of systems inspected will depend on the nature of the incident or outbreak. For example, investigations of waterborne gastroenteritis will be different from investigations of waterborne legionellosis. The former will focus on systems delivering water for ingestion, either directly or through food production; the latter will focus on systems containing water between 20 °C and 50 °C, and producing aerosols.

A48235836

Following an outbreak, a further inspection will be required to ensure that any required remedial action has been taken, and that WSPs have been amended to minimize the likelihood of recurrence. The effectiveness of remedial action and amended WSPs should be verified by water-quality testing.

5.1.4 Supporting programmes

Surveillance should incorporate complementary health promotion and educational components. It should be seen as an activity to maintain or improve public health standards in a collaborative approach. Regulations should allow for penalties and sanctions, but these should only be imposed as a last resort.

Building owners and managers should be aware of the standards required by surveillance agencies, the purpose of audits and inspections, how audits will be performed, what features will be examined, and what information is required from building managers during an audit.

5.1.5 Reporting and communication

Reporting and feedback are essential elements of a successful surveillance programme and should support the development of effective remedial strategies. Outcomes of surveillance should always be reported to building managers. Annual reports should be prepared by coordinating authorities and distributed to all agencies involved in surveillance activities (e.g. national, regional and local agencies).

Agencies responsible for surveillance should also develop strategies for disseminating and explaining outcomes of surveillance to building occupiers and users.

5.1.6 Use of information

Information gained from surveillance programmes should be collated and assessed. This information is an invaluable source of data on effective management of water systems, and can help to identify recurrent causes of problems. Analysing collated data may identify common factors associated with potential water contamination, such as inadequate or ineffective treatment processes, structural conditions (e.g. impacts of water-main breaks, faulty valves or hydrants), hydraulic capacity (e.g. low-pressure complaints, rusty or coloured water occurrence), leakage (e.g. pro capita water demand), or water quality deficiencies due to cross-contaminations or to unintended uses.

Collated information can also be used to review relative health risks presented by different types of buildings and circumstances; it can also be used to refine surveillance programmes.

5.2 Disease surveillance and detection of outbreaks

5.2.1 Purpose of disease surveillance programmes

Establishing and verifying effective disease-control programmes, including WSPs, requires effective surveillance programmes. These surveillance programmes should provide:

- accurate and timely information on disease occurrence
- early detection and notification of outbreaks
- assessment of responses to outbreaks
- efficient monitoring of intervention programmes.

The World Health Organization (WHO) *Guidelines for drinking-water quality* (WHO, 2008) define the reduction of disease and outbreaks as health outcome targets. Reducing disease provides the most direct evidence of the success of WSPs, while continued disease provides evidence that WSPs are inadequate and require modification. While the immediate response to detection of disease is necessarily reactive, the subsequent responses can be proactive in identifying and eliminating building-specific and systemic risks.

Many countries have mechanisms for surveillance and reporting of communicable diseases. The importance of these mechanisms is reinforced by the International Health Regulations (IHR) (WHO, 2005), which call for Member States to apply and—where necessary—strengthen capabilities for surveillance, reporting, notification and communication of infectious disease. While surveillance programmes often include waterborne organisms, specific surveillance of water as a source of disease is generally not well developed or coordinated. This includes waterborne disease associated with buildings.

5.2.2 Structure of disease-surveillance systems

The structure of disease-surveillance systems is governed by a number of factors, including legislation, the strategy for implementing surveillance, responsible agencies, and stakeholders and communication (WHO, 2006c).

Legislation

Public health legislation, including the IHR, provides the regulatory framework governing the identification, reporting and communication of notifiable diseases.

Public health legislation can also include requirements for health-care facilities to implement infection-control capabilities, while legislation dealing with occupational health and safety can include requirements relating to control of specific diseases, such as legionellosis.

Strategy

Disease-surveillance strategies depend on the nature of the diseases under investigation, the objectives of surveillance, the methods for conducting surveillance, and the application of data in informing public health practice. Countries may have multiple

A48235836

disease-surveillance systems operating simultaneously. Some will be aimed at early detection and response to outbreaks; others will focus on monitoring longer term disease trends, or the impact of interventions and control programmes. Each type of surveillance has specific characteristics. Disease surveillance used in health-care facilities is typically more active and immediate than surveillance of the outcomes of interventions, such as disease-control regulations or longer term public health programmes.

Disease-surveillance strategies can include:

- ongoing monitoring of reporting of communicable diseases by medical practitioners and laboratories;
- short-term and long-term analysis of results;
- investigation of clusters of illness or increased incidence of disease.

Monitoring of waterborne disease generally lags behind general disease surveillance (Bartram et al., 2002; Hunter et al., 2003). One of the principal factors is that most of the diseases transmitted by ingestion of contaminated water are transmitted in higher frequencies from other sources, such as food and person-to-person contact. This makes assessing the contribution of water difficult. In Europe, only 2% of gastrointestinal disease between 1986 and 1996 was linked to water (Bartram et al., 2002). Based on epidemiological investigations and intervention studies, estimates for the United States of America have placed the contribution at 8–12% (Colford et al., 2006; Messner et al., 2006).

Hence, while national and regional surveillance systems typically incorporate enteric organisms that can be waterborne, confirming association with water supplies is generally limited to outbreaks.

Some countries have established systems for detecting and reporting waterborne outbreaks. These data indicate that waterborne disease outbreaks associated with large water supplies have been substantially reduced, and that the proportion of outbreaks associated with buildings has increased (Blackburn et al., 2004; Yoder et al., 2004, 2008ab; Djiuban et al., 2006; Liang et al., 2006). In 2003–2004, the classification of waterborne disease by the United States Centres for Disease Control and Prevention was modified to include specific categories dealing with plumbing deficiencies (Liang et al., 2006).

Some diseases are exclusively waterborne; for example, legionellosis (caused primarily by *Legionella pneumophila*) and dracunculiasis (caused by *Dracunculus medinensis*). For these organisms, disease surveillance has been an important tool in supporting implementation of control measures. Waterborne legionellosis is strongly associated with building water supplies.

Initially, improved surveillance can detect an increased prevalence of disease. This has been reported for legionellosis in Europe (Bartram et al., 2007). Furthermore, improved surveillance provides a more accurate basis for establishing the need for, effect of and benefit of interventions. For example, in Australia, disease surveillance has demonstrated the effectiveness of *Legionella* regulations in reducing both the occurrence of the organism in cooling towers and the frequency of disease (Vic DHS, 2007).

Disease surveillance strategies can be tailored to deal with specific issues. For example, surveillance in health-care facilities is likely to involve a different spectrum of diseases

from those included in general surveillance schemes, due to the increased and varied vulnerabilities of patients and residents. As described in section 2, organisms such as *Acinetobacter*, *Aspergillus*, *Burkholderia*, *Klebsiella* and *Pseudomonas* have been associated with disease in health-care facilities.

Priority diseases and case definitions

It is not economically possible or practical to monitor all diseases. General surveillance systems should include diseases of national public health importance. WHO has produced guidance for selection of priority diseases, including waterborne diseases (WHO, 2006d, 2006e).

Specific disease-surveillance systems, such as those in health-care facilities, should target diseases of public health concern within the setting in question. The range of agents can vary within buildings; for example, within health-care facilities, renal dialysis patients are more susceptible than other patients to endotoxins, toxins and chemical contaminants in water used for dialysis.

Disease surveillance of water supplies in buildings will generally involve microbial pathogens, but should also consider chemical agents such as corrosion products (e.g. copper, lead, nickel and cadmium). Surveillance for chemicals is uncommon; prevention is by far the preferable approach. However, surveillance has been performed for lead (in blood) in certain circumstances (CDC, 2010).

Case definitions should be identified and documented for all priority diseases. A national register of case definitions should be developed and applied in all disease-surveillance schemes.

Responsible agencies and stakeholders

Public health surveillance is typically coordinated at a national level by ministries of health, and operates at national, regional and local levels. Coordination and oversight of operations by a central agency is essential.

Infection-control teams in health-care facilities play a key role in public health surveillance. Similarly, in commercial and industrial buildings, occupational health services play a role in disease surveillance. In some countries, control of legionellosis is regulated at least in part by occupational health legislation (Bartram et al., 2007).

Coordination of all disease surveillance activities is important to support efficiency and to avoid duplication.

Reporting and communication

Reporting and communication support the collection of disease information, dissemination of outcomes, implementation of immediate responses, and longer term interventions.

Reporting systems should be established to ensure that information moves from the point of generation (i.e. disease detection) to collection and coordination agencies. Standard operating procedures should be established for reporting. The procedures should deal with transmission of routine data, as well as data on suspected and confirmed outbreaks. Procedures should be communicated to everyone involved in disease surveillance.

A48235836

Communication between all stakeholders involved in disease surveillance is essential. Coordination of all disease-surveillance activities undertaken by national, regional and local authorities, infection-control teams and occupational health services is required to ensure effective reporting of disease, timely detection of outbreaks, implementation of responses and longer term control measures.

Disease-surveillance strategies typically involve reporting by medical practitioners and laboratories. Timeliness and accuracy of reporting are crucial. In addition, systems should be established to ensure that results of disease surveillance undertaken by infection-control teams are routinely reported to coordinating agencies. Outbreaks detected in health-care facilities should be reported immediately.

Communication of outcomes is required. This can include routine reports, as well as issuing of warnings and advice to health practitioners, the public and managers of buildings. It is important to have communication procedures in place to deal with suspected or confirmed outbreaks of potentially waterborne disease. For example:

- the detection of outbreaks of legionellosis could result in communication with building owners during the outbreak about immediate action (e.g. precautionary decontamination of cooling towers);
- outbreaks of waterborne cryptosporidiosis could lead to issuing of advice to operators of leisure centres and swimming pools regarding practices to avoid primary and secondary transmission;
- increased incidence of nosocomial disease will require communication with staff and managers of health-care facilities.

Mechanisms should be established to facilitate this communication before outbreaks occur.

After a disease outbreak, communication should be widened to include information on the lessons learnt, and how practices will be used or applied to minimize the likelihood of recurrence.

Communication should also include sharing of information between agencies and stakeholders. For example, this should include establishing communication networks for infection-control teams, to help identify common problems, causes and interventions. Disease surveillance at a regional level should be supported by a national communication system. Higher levels of travel have increased the spread of diseases across boundaries; therefore, communication should be extended across borders to meet obligations of the IHR (2005) and also to share experiences and lessons learnt.

Disease-surveillance guidelines and standards

Effective disease-surveillance systems are underpinned by comprehensive standards and guidelines. These standards and guidelines should define priority diseases, and include case definitions, notification and reporting requirements, responsibilities, data management, evaluation, immediate and long-term responses, outbreak preparedness and training.

Guidelines should deal with related aspects, such as infection control in health-care facilities (WHO, 2002; Sehulster et al., 2004) and laboratory procedures such as standard methods and quality control.

5.2.3 Disease surveillance for water supplies in buildings

Disease surveillance for disease associated with buildings is a subset of general surveillance. However, building water supplies have some specific characteristics:

- The water systems and hence the sources of disease are typically discrete and defined.
- Buildings such as hospitals, medical clinics, aged-care facilities and child-care centres can cater for subgroups with increased vulnerabilities.
- In health and aged-care facilities, infection-control teams play a central role in surveillance.

Microbial pathogens represent the greatest risk associated with building water supplies, but toxic chemicals such as heavy metals, industrial compounds, coolants and boiler fluids can also cause illness.

Microbial disease and outbreaks associated with buildings can be detected by active surveillance by national or regional agencies and infection-control teams, by passive processes such as reporting by medical practitioners and other health-care professionals, or through anecdotal reporting by building users.

Acute disease caused by building-specific chemicals (e.g. boiler fluid) is generally detected by passive processes, while chronic and acute disease caused by heavy metals (e.g. copper and lead) can be detected by either passive processes or broader investigations. The latter could be implemented where there is evidence of systematic issues such as corrosion of plumbing systems caused by public water supplies.

5.2.4 Disease-surveillance strategies for waterborne disease

Surveillance of waterborne disease can be included in a range of programmes with different functions and characteristics. These can include surveillance of:

- national and regional incidence of infectious disease
- waterborne disease outbreaks
- specific diseases, to measure incidence and the need for intervention
- disease in specific settings, such as health-care facilities.

National and regional incidence of infectious disease

National and regional surveillance programmes can include specific waterborne diseases such as cholera, legionellosis and dracunculiasis. For these diseases, the outcomes of disease surveillance can be used to assess longer term trends as well as the outcome of intervention programmes.

National and regional programmes typically include diseases that may be waterborne. General surveillance does not identify endemic waterborne disease without the addition of ancillary epidemiological studies (Calderon & Craun, 2006), but can detect waterborne outbreaks—although the sensitivity is poor (Padiglione & Fairley, 1998; Craun et al., 2004).

A48235836

Waterborne disease outbreaks

The likelihood of detection of waterborne disease outbreaks can be increased by augmenting infectious-disease programmes with specific mechanisms to promote reporting of such outbreaks. The data from outbreaks can be used to identify important pathogens, water-system deficiencies and interventions to reduce waterborne disease (Craun et al., 2006). The best example of outbreak detection is in the United States of America, where statistical data on waterborne disease outbreaks have been collected and reported since the 1920s (Djiuban et al., 2006; Yoder et al., 2008ab). Recent surveillance data indicate that a substantial proportion of outbreaks in recreational water and drinking-water was associated with buildings such as sports centres, hotels, schools, child-care centres, nursing homes, hospitals and restaurants. Diseases were caused by a range of agents, including *Cryptosporidium*, *Giardia*, *Shigella*, *Legionella*, *Pseudomonas*, *Norovirus*, copper and ethylene glycol (Blackburn et al., 2004; Yoder et al., 2004, 2008ab; Djiuban et al., 2006; Liang et al., 2006).

The reports have highlighted water-system deficiencies, such as cross-connections in buildings and the need for improved control of opportunistic pathogens such as *Legionella* and *Pseudomonas*.

Specific diseases

Surveillance for legionellosis is a good example of a targeted monitoring programme and has been well documented elsewhere (Bartram et al., 2007). Surveillance has been used to identify the prevalence of disease, the need for improved control, and the success of intervention programmes (WHO, 2006c; Vic DHS, 2007).

Infection control

Infection rates in health-care facilities are an indicator of the quality of care, including the safety of the environment. Surveillance is used to monitor incidence of disease, identify risk factors and evaluate the impact of interventions. Waterborne disease involving organisms such as *Acinetobacter*, *Aspergillus*, *Burkholderia*, *Klebsiella*, *Legionella*, mycobacteria, *Pseudomonas* and *Stenotrophomonas* has been identified as cause for increased concern in health-care facilities (Annaisie et al., 2002; Sehulster et al., 2004).

Results of disease-surveillance programmes have been used to identify control measures to minimize the risk of infection associated with building water supplies (Sehulster et al., 2004; Bartram et al., 2007).

Review

The results of disease-surveillance programmes should be subject to regular review to identify trends, including increases and decreases in disease rates, changes in patterns of disease, the occurrence of emerging disease and the impacts of control measures. Outcomes and any recommendations arising from reviews should be reported.

5.2.5 Detection of outbreaks

Outbreaks are generally defined as two or more cases linked in location and time. Waterborne outbreaks associated with water supplies in buildings represent preventable failures in WSPs. All outbreaks should be investigated to confirm occurrence, identify the source, implement immediate control measures, and identify the need for longer term and general changes in management programmes.

Agencies and teams involved in disease surveillance should establish investigation protocols to respond to outbreaks. Early detection of outbreaks and appropriate, timely responses will reduce the size and impact of outbreaks. Pre-planning promotes rapid responses and avoids planning on the run, which is very likely to lead to poor coordination, mistakes and delays.

Outbreak investigations follow a sequence of activities that includes:

- pre-planning
- outbreak confirmation
- case definition
- outbreak description
- hypothesis generation and confirmation
- control and prevention
- communication.

Pre-planning

Pre-planning should identify who should be involved in the investigation of outbreaks. This should include responsibilities, leadership and coordination. Methods for investigating outbreaks and basic requirements (e.g. case definitions, data transfer and communication procedures) should be identified.

Outbreak confirmation

An increase in reported cases or detection of specific pathogens in clinical samples is generally the first sign of an outbreak. However, it is important to confirm that the apparent outbreak is real. Factors that have been shown to contribute to "pseudo-outbreaks" have included increased detection due to increased testing, contamination of clinical samples, false positive tests and coincidence of unrelated cases (CDC, 1995, 1997b, 2009; Regan et al., 2000; Kressel & Kidd 2001; Blossom et al., 2008).

Case definition

Once an outbreak is confirmed, a case definition should be developed to establish criteria for inclusion. The definition should include descriptions of place and time of onset, and specific biological and clinical criteria (symptoms and test results). Cases could be categorized as definite, probable or possible, based on the level of data available. Case definitions may also change during investigations as new information becomes available.

A48235836

Outbreak description

A detailed description of the outbreak should be generated as investigations progress. The description could include information on numbers of cases, place, time, sex, age and movement. Epidemic curves and mapping of geographical distribution can provide evidence of sources of contamination and whether they are from single, intermittent or ongoing events (WHO, 2002; Hunter et al., 2003).

Hypothesis generation and confirmation

As the outbreak description develops, it should be possible to formulate hypotheses on sources of infection and routes of transmission, and identify possible control measures. Confirmation is necessary, even in cases that appear to have an obvious source. Hypotheses will be strengthened, refined, modified or discarded as the investigation continues. For waterborne outbreaks, confirmation will generally involve collecting and analysing water samples, and assessing the design and implementation of WSPs for failures. Genetic typing of isolates is an important tool for identifying sources of cases, and can support or reject hypotheses (Heath et al., 1998; Hunter et al., 2003; Gilmour et al., 2007). Epidemiological methods such as case–control studies are also used to test hypotheses by comparing risk factors between groups of cases and controls without disease (WHO, 2002).

It is important to identify the correct source of disease and to avoid going public with unconfirmed hypotheses. Pressure to identify sources quickly should not be allowed to compromise accuracy. Failure to identify the correct source can lead to expensive and ineffective interventions.

Control and prevention

A priority in all investigations is to identify and implement effective control measures. The aims are to:

- interrupt the chain of transmission and minimize the magnitude of the outbreak
- prevent future outbreaks.

The selection of control measures will require consultation with appropriate experts such as environmental microbiologists and water-treatment specialists. Outbreak investigations should assess the success of control measures, while ongoing disease surveillance should be implemented to monitor continued effectiveness. This type of surveillance will include monitoring of disease and the efficacy of the control measure. In the long term, monitoring of preventive control measures will take precedence.

Communication

During investigations, timely and accurate information should be provided to public health authorities (if not leading the investigation), building owners and managers, patients and, where appropriate, the public. Where there is uncertainty—for example, in the identification of sources—this should be communicated.

Full reports should be prepared at the end of outbreaks, describing events, interventions, lessons learnt and recommendations to prevent further occurrence. These reports should be made available to appropriate agencies, authorities, and building owners and managers involved in operation of water supplies.

5.2.6 Lessons learnt from disease surveillance and investigations

Results of disease-surveillance activities and outbreak investigations must be used to inform practices, and measures applied to reduce waterborne disease. The decrease in drinking-water waterborne outbreaks in the United States of America since the 1980s has been attributed to more stringent regulation (NRC, 2006). Events such as the Milwaukee outbreak of cryptosporidiosis in 1993 (MacKenzie et al., 1994) contributed to the development of regulations. At the same time, the proportion of outbreaks and illness associated with buildings has increased (Blackburn et al., 2004; Yoder et al., 2004, 2008ab; Djiuban et al., 2006; Liang et al., 2006). Water supplies in buildings are typically not included within the scope of national drinking-water regulations.

However, lessons learnt from disease surveillance and outbreak investigations have been used to reduce risks associated with building water supplies. The clearest example of this is the development of guidelines and regulations for controlling waterborne legionellosis (see *Legionella and the prevention of legionellosis*; WHO, 2007). Other examples include increased attention on cross-connection control and backflow prevention (USEPA, 2002; NRC, 2004) and the development of guidelines for preventing waterborne disease in health-care facilities (WHO, 2002; Sehulster et al., 2004).

On a national, regional and local level, it is important to learn from the application of control measures to deal with waterborne disease. Documentation, reporting and communication networks should support cataloguing of incidents and the sharing of experience in detecting deficiencies and implementing responses. Where appropriate, these can be translated into guidance and regulation to minimize risks of disease.

5.3 Regulatory and policy frameworks

National governments, together with regional and local authorities, are generally deemed to be responsible for ensuring that consumers are provided with safe and wholesome water in sufficient quantity. Typically, this responsibility will lie within the ministry of health, although sometimes other agencies, such as those responsible for environmental protection, may play a role. The actions and responsibilities of these authorities and agencies need to be supported by legislative and regulatory tools. However, the diversity of constitutional and legal systems makes it impossible to define a single accepted way for developing and implementing legislation. Nevertheless, there are a number of common principles that should be applied.

5.3.1 Purpose of legislation

Legislation should define responsibilities, functions and obligations of agencies charged with ensuring compliance with drinking-water quality requirements. Legislation should also provide these agencies with necessary powers to administer laws and regulations. For instance, the requirements of surveillance within buildings can be hindered by difficulties for national, regional or local authorities in gaining access to undertake inspections and audits. This needs to be considered in regulatory frameworks. Responsibilities for water quality also need to be identified. This should include responsibilities of drinking-water suppliers and the managers, operators or owners of water systems in buildings.

A48235836

As discussed throughout this document, the most effective way of assuring drinking-water safety in buildings is the application of WSPs that cover all issues, from planning and construction to surveillance of tapwater quality. The central role of WSPs should be reinforced and supported by regulatory and policy frameworks.

In addition to drinking-water legislation, many countries have established standard-setting bodies and certification systems. Standards and codes of practice can apply to a broad range of activities that can influence construction and management of drinking-water systems in buildings. These can include standards relating to construction of buildings, installation of plumbing, water systems and sewage systems, as well as the design, installation, maintenance and operation of devices such as cooling towers and evaporative condensers, swimming pools, hot-tub pools, hot-water systems and plumbing devices. Standards could also apply to sampling, testing and accreditation of technical experts (e.g. plumbers) and auditors.

Tables 5.1–5.3 summarize the tools needed by legislators for addressing WSP implementation in accordance with national legislation, technical regulations, standards and codes of practice.

A48235836

Table 5.1 Management legislation

Area of management legislation	Issues for legislator or regulator	Issues for standard-setting and certification agencies
Building construction and commissioning (as far as the water distribution system is concerned)	• Award the right of inspection entry, at building stages, to those responsible for regulating and certifying water systems • Enforce the WSP-in-building approach • Enforce by law the certification scheme for everyone involved, and their role	• Provide construction and plumbing standards • Provide codes of good practice for each category of work • Provide commissioning procedures and testing methods for water distribution systems and individual components, as required • Establish training and certification programmes for everyone involved
Maintaining required water quality	• Enforce mandatory WSPs for buildings of specified characteristics (size; kind of occupancy; public or open to public, etc.) • Identify responsibilities for at least the following: – owners – building managers – WSP managers • Identify independent regulatory agencies for performing technical inspection • Establish procedures for monitoring and reporting for health protection (implemented by the building manager and an independent health authority; for health-care premises, this is implemented by infection-control teams)	• Prepare general and specific WSPs according to the characteristics of the building (size; type); these should include definitions of major risks (microbiological, chemical, hydraulic) and responses to major events (natural catastrophes) • Provide a training and certification programme for those involved (identified in legislation) • Develop standards, guidance and a code of good practice for the operation and maintenance of water distribution systems in general, and for individual components and devices, as required
Surveillance	• Set the minimum surveillance requirements for WSPs • Identify independent entities for implementing the surveillance programme (public and/or third party) and specify their scope and given authority • Ensure independent entity has right of access and inspection of WSPs • Ensure the independent entity has the authority to order actions deemed necessary for protecting consumer health and safety	• Define WSP surveillance programmes (frequency, required analyses, etc.) • Establish accreditation scheme for independent entities performing surveillance of WSPs • Establish accreditation schemes for laboratories

WSP, water safety plan.

Table 5.2 Technical regulations

Area of technical regulation	Issues for legislator or regulator	Issues for standard-setting and certification agencies
Building permission	• Set minimum requirements for water supplies and specifications in buildings (e.g. pressure, flow rate) • Set minimum requirements for the sewage system connection • Set requirements for alternative water sources (private wells, etc.)	• Set standards for water supplies • Set standards for sewage systems
Materials and products intended for contact with drinking-water	• Define criteria based on: – mechanical characteristics related to safety and performance (durability, energy consumption, noise) – fitness for contact with drinking-water	• Set standards for testing: – mechanical characteristics – fitness for contact with drinking-water (migration or release of hazardous chemicals, support of microbial growth, etc.)
Surveillance of water quality at the consumer tap	• Define water-quality standards, and keep them up to date • Define criteria for collecting representative water samples • Define appropriate analytical methods	• Identify methods for taking water samples for chemical, physical and microbial analyses
Installation of water systems inside buildings	• Define requirements per product standards, including, if available, those related to safety, hygiene, energy savings • Define requirements for preventing unintended cross-connection and installation of backflow prevention, where required	• Set standards for internal installations, including: – general requirements – design principles – piping system design – installation – operation and maintenance • Set standards for connecting appliances and equipment to water distribution systems (washing and dishwashing machines, humidifiers, etc.) • Set standards for PoE and PoU devices, including operation and maintenance instructions
Installation of swimming pools, hot tubs, and other recreational water devices	• Define and update the water-quality standards • Define safety rules • Identify roles and responsibilities • Define “public” and “private” swimming pools • Ensure rights of inspection to regulatory entities for public pools	• Set standards for designing, operating and maintaining pools and accessories • Set standards for water treatment (filters, disinfection, etc.)

Table 5.2 Technical regulations *continued*

Area of technical regulation	Issues for legislator or regulator	Issues for standard-setting and certification agencies
Installation of systems conveying water for special purposes (e.g. in health-care facilities, child care)	• Define criteria for assessing the compatibility of activities within buildings with occupancy • Set general requirements for water systems intended for special purposes (e.g. increased safety levels and protection) • Set specific requirements, as needed or advisable	• Develop quality standards for each type of special water • Set standards for water-treatment devices
Hot-water and cold-water storage within dwellings	• Define requirements for independent technical inspection	• Set standards for storage tanks and associated equipment, including design, operation and maintenance
Hot-water systems	• Define requirements for preventing health risks (e.g. from *Legionella*) and suitable water specifications (e.g. temperature) • Define requirements for independent technical inspection	• Set standards for designing, operating and maintaining heating, storage and delivery, including temperature control
Water-using cooling devices (cooling towers, evaporative condensers)	• Define requirements for preventing health risks (e.g. from *Legionella*) • Define requirements for independent technical inspection	• Set standards for designing, operating and maintaining cooling systems

PoE, point of entry; PoU, point of use.

A48235836

Table 5.3 Links between legislation, regulations and standards

Area of regulation	Major issues for legislators	Major issues for standard-setting and certification agencies
Suitability of equipment for purpose	• Define requirements for establishing and operating certification schemes	• Define and manage certification scheme
Materials and products intended for the contact with drinking-water	• Establish a certification scheme	• Test schemes
Management of building system for safety, including maintenance and servicing	• Assign responsibilities of owner and manager	• Provide guidance and codes of good practice on cleaning, disinfection for systems and associated devices (e.g. swimming pools)
Independent oversight of building water safety	• Provide for independent oversight (surveillance) • Define scope of authority of independent agency (different types of building) • Ensure right of access and inspection for independent entity • Require analysis by accredited laboratories • Require that sampling and analyses comply with recognized methods	• Define frequency of inspections or audit • Define criteria for audits • Establish and operate accreditation schemes for inspectors and auditors • Establish and operate accreditation schemes for laboratories • Establish processes for accrediting sampling and analytical methods
System installation and commissioning	• Oversee licensing or industry self-regulation of plumbers	• Set standards and codes of good practice for plumbing • Set accreditation scheme for plumbers
Construction of buildings, including requirements for ensuring water-related environments are safe	• Set requirements for an entity to establish and update construction standards	• Establish a body to provide and maintain standards
Health-care settings	• Identify special provisions in high-risk environments • Identify responsibilities of health service providers	• Establish a body to provide and maintain standards and ongoing guidance on good practice
Drinking-water quality standards	• Assign authority to a suitable body to establish and update standards • Specify consultation requirements • Assign enforcement requirements	• Develop criteria for standard setting • Oversee the consultation process • Process enforcement

5.4 Capacity building and training

A wide range of responsibilities is associated with ensuring safety of water within buildings. The principles, including WSPs, are captured within the *Framework for safe drinking-water*. The risk-management principles described in the framework also apply to other devices, such as water-cooled air-conditioning plants, swimming pools and hot-tub pools (WHO, 2006a; Bartram et al., 2007).

All the stakeholders identified in section 3 need to have the appropriate skills to perform their specific functions related to provision of safe water supplies. This includes building commissioners and designers, building managers, employees, public health agencies, auditors, professional bodies and infection-control practitioners.

It is not practical or realistic to expect that all stakeholders will have the capacity to perform all functions. Training will need to be tailored for each group of stakeholders. Training provided to employees responsible for drinking-water systems will differ from training provided to employees responsible for water-cooled air-conditioning plants, swimming pools or hydrotherapy pools. However, all stakeholders need to have a basic understanding of risk-management principles associated with WSPs, including the identification of hazards, the assessment of risks and management strategies applied to control these risks. Each stakeholder should be aware of how their specific responsibilities fit within and contribute to the design and implementation of WSPs. They also need to be aware of the consequences of failure. Too often, this is not the case (Hrudey & Hrudey, 2005).

Overall, therefore, training programmes must be coordinated to ensure consistency of intent and understanding. In this way, all activities associated with water systems can contribute to a consistently high standard of design, construction, operation, maintenance and management.

General training should be available on:

- risk-management principles;
- development and application of WSPs; this should include training on applying WSPs in specialized settings (e.g. for infection control in medical and dental surgeries and renal dialysis clinics);
- risk assessment;
- control measures, including treatment;
- operational procedures, including monitoring and maintenance;
- emergency actions and responses.

In addition, specialized training may include the following components:

- For professionals involved in designing or modifying buildings and water networks
  - water-quality regulation, standards and guidelines
  - information on the importance of water quality and implications of failure
  - setting water-quality targets (e.g. environmental and building quality labels, certification)

A48235836

  - prevention of microbiological and chemical contamination, including major mistakes to be avoided (e.g. poor-quality water resources; accidental or unintended cross-connections; poor design of water distribution networks, waste systems and venting systems; poor design of storage systems)
  - maintenance and sampling requirements.
- For plumbers
  - water-quality regulations, standards and guidelines
  - responsibilities and legal obligations
  - evidence of links between construction practices and water quality at the tap (e.g. impacts of welding practices on resistance to corrosion, use of incompatible materials, inappropriate pipe diameters, accidental or unintended cross-connections)
  - water-system design, construction rules and good practices.
- For auditors
  - detailed knowledge of national and local water standards and guidelines applying to system design and construction
  - detailed knowledge of all aspects of WSPs
  - auditing practices applied to the domain of water quality.
- For regulators
  - understanding determinants of other disciplines that affect WSPs in their domain (e.g. health regulators should have an understanding of the main determinants of building design and construction)
  - building and plumbing regulations, standards and codes of practice.
- For building managers
  - importance of water quality and implications of failure
  - water-quality regulation, standards and guidelines
  - responsibilities and legal obligations
  - water-system design and construction
  - WSPs
  - maintenance and surveillance of water systems
  - supervision of water-system audits and risk assessments
  - event and incident management
  - audits of contractors' qualifications and competence.

- For employees responsible for specific installations (e.g. water-cooled air-conditioning plants, swimming pools, hydrotherapy pools)
  - importance of water quality and implications of failure
  - detailed knowledge of national and local design, construction, auditing and maintenance standards and guidelines for such installations
  - prevention of microbiological and chemical contamination specific to such installations
  - periodic feedback from others' field experience and major mistakes to be avoided (e.g. through specialist workshops, industry associations).

Mechanisms for providing this training and building capacity include formal courses that are accredited by national educational agencies, professional associations, industry-operated training courses, in-house training and mentor programmes, workshops, seminars and conferences. Training could be provided in stand-alone courses or within broader training programmes provided for specialists such as infection-control practitioners or plumbers. Where possible, training should be supported by provision of manuals, fact sheets and guidelines on websites. Contact details for appropriate experts or appropriate agencies should also be provided.

Feedback from field experience should be organized and documented to support training programmes, so that professionals can benefit from others' experience. Training and information sessions based on the presentation of field experience have been found to attract high levels of interest and increase the recognition and appreciation of water-quality issues and shared responsibilities. This type of networking and sharing of experiences can be valuable and effective. It should be encouraged.

Training should be documented, and records of all employees who have participated in training should be maintained. Skills and knowledge need to be maintained through attendance at refresher courses or at workshops and seminars that can reinforce existing qualifications.

A48235836

Annex 1 Model water safety plan—daycare facility for children

I Hazard identification, hazard assessment and risk characterization

Position	Potential hazard	Cause	Risk (likelihood and consequences)	Preventive or control measures
1.1	Contamination of the system with chemicals and/or microorganisms	Using cross-connections to other systems	High	• Avoid cross-connections • Design inspection records • Ensure that only appropriately qualified people are permitted to carry out connection work • Ensure that external professionals inspect or maintain the system
1.2		Flooding	Moderate–high	• Install adequate backflow-prevention devices • Establish an emergency plan • Train staff for flooding situation
1.3		Backflow resulting from reduced pipe pressure	Moderate	• Install adequate backflow-prevention devices • Ensure mandatory functionality check of backflow devices
1.4		Corrosion of pipes, valves, etc.	Moderate	• Install fine filter after water meter • Install adequate material, pipe dimension and system design
1.5		Do-it-yourself repairs in the system	Moderate	• Target educational activities to building owners or managers • Ensure that external professionals inspect or maintain the system

I Hazard identification, hazard assessment and risk characterization *continued*

Position	Potential hazard	Cause	Risk (likelihood and consequences)	Preventive or control measures
2.1	Microbial growth (e.g. *Legionella*, *Pseudomonas*) in the system	Stagnation of water in pipes with dead end	High	• Ensure a regular flushing of all pipes • Avoid dead pipes and long pipes • Identify areas at risk of stagnation • Reduce the length of tap pipes to minimize stagnation volume
2.2		Intermittent use (shower, hosepipe, social room, office, vacation)	High	• Ensure regular use of the system • Ensure regular flushing of the system • Construct shut-off valves near main pipes or near frequently used pipes and drainpipes after shut-off • Cut off unused pipes
2.3		Inadequate temperature in the warm-water system (heater temperature too low)	High	• Ensure adequate heater temperature and adequate supply of circulation pump • Construct adequate insulation of pipes and heaters
2.4		Inadequate temperature in cold-water system	High	• Ensure adequate cold-water temperature in the system • Separate cold-water pipes from heater and warm-water pipes • Ensure adequate insulation of pipes
2.5		Inadequate system material used	Moderate	• Use material according to current guidelines and standards
2.6		Warm-water flows are not hydraulically balanced	High	• Ensure adequate pipe dimension • Ensure that adequate flows are maintained through all parts of the distribution system • Replace simple valves with temperature-adjustable valves
2.7		Heater sludge (forces growth of microorganisms)	Moderate	• Inspect, maintain and clean the heater regularly

I Hazard identification, hazard assessment and risk characterization *continued*

Position	Potential hazard	Cause	Risk (likelihood and consequences)	Preventive or control measures
2.8	Local microbial contamination of the system	Inadequate tap hygiene (e.g. contaminated showerhead, aerator)	High	• Inspect and maintain tap hygiene • Ensure that work practices for maintenance comply with standard procedures
3.1	Leach-out of organic compounds into drinking-water	Inappropriate materials used, or stagnation	Moderate	• Use certified materials • Record material requirements
4.1	Biofilm growth	Water flow is too low, resulting in colonization of surfaces	Moderate	• Inspect the zones of concern, and put in place a plan to increase flows in these areas • Flush pipework
4.2		Poor chemical water quality leaving the treatment plant (e.g. post-treatment precipitation of floc, iron/manganese precipitation)	Moderate	• Ensure a regular cleaning and flushing programme is in place, especially through low-flow and dead-end areas
4.3		Poor microbial water quality leaving the treatment plant and introduced in the distribution system	Moderate	• Install filter to reduce some pathogens (e.g. protozoa) • Ensure a regular cleaning and flushing programme is in place, with additional chlorination especially through low-flow and dead-end areas
4.4		Inadequate material used	Moderate	• Use certified materials • Use materials according to current guidelines and standards
5.1	Sediment deposits	Inadequate cleaning programme	Moderate	• Install sediment filters to reduce sediments • Ensure an adequate cleaning programme is in place (particularly for fine filters, etc.)
5.2		Water velocity is too high	Moderate	• Ensure that pipes are of adequate dimension • Control the opening and closing valves, and starting pumps
6.1	Damage of the supply system	Natural disaster	Moderate	• Establish an emergency plan • Create an emergency communication schedule • Train staff for this situation

A48235836

II Operational monitoring and management

Position	Hazard	Cause	Monitoring procedures	Critical or operational limit (reference value)	Validation or verification	Management procedures, including corrective actions
1.1	Contamination of the system with chemicals or microorganisms	Cross-connections to other systems	• Provide job sheets and procedures to staff • Check security devices (safety valves like backflow prevention devices, etc.) at cross-connections	• Sufficient quality of job sheets • Security devices installed adequately	• Installation of cross-connections complies with guidelines, codes of practice and accepted standards • Backflow-prevention devices installed according to guidelines, codes of practice and accepted standards • Tapwater quality conforms with national drinking-water guideline values after cross-connection	• Maintenance procedures for backflow-prevention devices • Avoidance of cross-connections and removal of inadequate installation of cross-connections
1.2		Flooding	• Ensure that emergency plan is up to date and that responsible staff have been instructed on its use	• Update intervals of emergency plan (e.g. annual updating) are kept and responsibilities are checked	• Emergency plan complies with guidelines, accepted standards and references	• Emergency plan providing essential information for flooding situation (e.g. pipe materials, security devices, responsibilities, emergency numbers) • Review and update of emergency plan and assignment of responsibilities following incidents

II Operational monitoring and management *continued*

Position	Hazard	Cause	Monitoring procedures	Critical or operational limit (reference value)	Validation or verification	Management procedures, including corrective actions
1.3	Contamination of the system with chemicals or microorganisms (continued)	Backflow resulting from reduced pipe pressure	• Inspect and maintain the functionality and security of devices regularly (e.g. backflow-prevention devices) • Monitor pressure and flow in the system	• Inspection every six months; maintenance at least once a year • Backflow-prevention devices leak-proofed, functional • Normal fluctuation of pressure and water flow	• Installation and maintenance of backflow-prevention devices according to guidelines, accepted standards and references	• Maintenance procedures for backflow-prevention devices
1.4		Corrosion of pipes, valves, etc.	• Record pipe material and pipe dimension, date of installation • Inspect pipes for corrosion damage	• Inspection intervals are kept • Corrosion damage is not observable	• Recording and maintenance of pipe material comply with guidelines, accepted standards and references	• Purchasing specifications for pipes and fittings • Immediate inspection of pipes • Replacement of heavily damaged pipes with adequate pipe material
1.5		Do-it-yourself repairs in the system	• Inspect and maintain the system regularly • Provide regular training to building owners and managers	• Inspection or maintenance occurs at least once a year • Do-it-yourself repairs are well conducted • Certification of training	• Plumbers' certification complies with national standards • Installation, construction of pipes, as well as tapwater quality, comply with guidelines, accepted standards and references	• Procedures for inspection, management and training • Employment of only those plumbers with certification • Immediate shut-down of pipes and tap devices followed by reinstallation of pipes

II **Operational monitoring and management *continued***

Position	Hazard	Cause	Monitoring procedures	Critical or operational limit (reference value)	Validation or verification	Management procedures, including corrective actions
2.1	Microbial growth (e.g. *Legionella, Pseudomonas*) in the system	Stagnation of water in pipes with dead ends	• Record length of dead-end pipes and pipes at risk of stagnation • Monitor regular flushing programme	• The length of water pipes' dead ends are ≤10 times of the pipe diameter or ≤3 litres in volume	• Construction of pipes complies with guidelines, accepted standards and references	• Procedures and programmes for regular flushing • Disconnection of dead ends
2.2		Intermittent use (shower, hosepipe, social room, office, vacation)	• Ensure regular use of tap devices • Inspect and maintain shut-off valves regularly, and check drainage pipes • Monitor a regular flushing programme	• Tap devices are used at least every third day • System is flushed regularly (take pipe volume) if system is out of use for more than four weeks • Shut-off valves are inspected at least every six months, and maintenance occurs at least once per year	• Inspection, maintenance, installation and construction of pipes and tapwater quality comply with guidelines, accepted standards and references	• Inspection, maintenance and flushing programmes and procedures • Totally shut off areas with intermittent use
2.3		Inadequate temperature in warm-water system (e.g. temperature in heater too low)	• Monitor warm-water temperature	• Warm-water temperature in heater at least 60 °C and in the whole system only temporarily below 60 °C • Circulation system not more than 5 °C below heater temperature in backflow of circulation	• Construction of pipes (insulation) and water temperature comply with guidelines, accepted standards • Tapwater quality follows national guideline values for drinking-water quality	• Programme and procedures for temperature monitoring • Pipes, heater and valves are insulated • Increased heater temperature • Adequate circulation

II **Operational monitoring and management *continued***

Position	Hazard	Cause	Monitoring procedures	Critical or operational limit (reference value)	Validation or verification	Management procedures, including corrective actions
2.4	Microbial growth (e.g. *Legionella, Pseudomonas, Aeromonas*) in the system (continued)	Inadequate temperature in cold-water system	• Monitor cold-water temperature	• Cold-water temperature in the whole system below 20 °C, only temporarily below 25 °C (European standard)	• Construction of pipes (insulation) and water temperature comply with guidelines, accepted standards • Tapwater quality follows national guideline values for drinking-water quality	• Programme and procedures for temperature monitoring • Renew al of pipe insulation, or reinstall or pipes moved in the system
2.5		Inappropriate system material used	• Check and document pipe, valves and additional equipment material regularly, and update knowledge • Check microbial parameters and indicator parameters	• Regular check and documentation of pipe material is carried out	• Pipe material that complies with guidelines, accepted standards is used • Tapwater quality follows national guideline values for drinking-water quality	• Purchasing specifications for system materials • Immediate check and documentation of pipe material • Replacement of critical system components
2.6		Warm-water supply hydraulically unbalanced	• Inspect and maintain temperature of adjustable valves regularly • Monitor temperature in the system	• Inspect valves every six months, and maintain at least once per year • Keep temperature above 58 °C in the warm-water system	• Certification of temperature-adjustable valves • Water quality after valves follows national drinking-water guideline values	• Inspection, maintenance and monitoring programmes and procedures • Replacement of defective, damaged valves

II **Operational monitoring and management *continued***

Position	Hazard	Cause	Monitoring procedures	Critical or operational limit (reference value)	Validation or verification	Management procedures, including corrective actions
2.7	Microbial growth (e.g. *Legionella, Pseudomonas, Aeromonas*) in the system (continued)	Heater sludge (forces growth of microorganisms)	• Inspect and maintain the heater annually, and monitor the cleaning programme	• Inspect and maintain intervals at least once per year • Ensure that sediment deposit in heater is not observable	• Inspection and maintenance of heater comply with guidelines and accepted standards • Microbiological parameters and indicator parameters follow national guideline values after heater maintenance at heater exit	• Maintenance and cleaning programmes and procedures • Cleaning and removal of sludge • Thermal or chemical disinfection
2.8	Local microbial contamination of the system	Inadequate tap hygiene (e.g. contaminated showerhead, aerator)	• Inspect showerheads, aerators, etc. regularly • Check microbiological parameters and indicator parameters after maintenance of tapwater devices	• Inspection of showerheads, aerators, etc. at least once per year • Turbidity < 1 NTU; *E. coli*, coliforms = 0, normal trend of colony counts after tapwater devices	• Inspection complies with guidelines, accepted standards and references • Tapwater quality follows national guideline values for drinking-water quality	• Inspection, maintenance, cleaning and testing procedures and programmes • Thermal or chemical disinfection • Replacement of tap devices
3.1	Leach-outs of organic compounds from pipe materials into drinking-water	Inappropriate material used or stagnation	• Check material requirements • Authorize only experienced staff (checking job sheets)	• Sufficient knowledge of staff about material used in the system and update of knowledge about system materials	• Use of material complies with guidelines, accepted standards and references	• Purchasing specifications for system materials • Procedures for selecting staff (including qualifications) • Searching for experienced staff and replacement of inappropriate material

II Operational monitoring and management *continued*

Position	Hazard	Cause	Monitoring procedures	Critical or operational limit (reference value)	Validation or verification	Management procedures, including corrective actions
4.1	Biofilm growth	Water flow is too low, resulting in colonization of surfaces	• Monitor water flow and pressure in the system	• Adequate water flow in the system	• Water flow complies with references and national standards	• Procedures and programmes for monitoring water flows and pressures • Adjustment of pipe dimension to the system • Check of functionality of temperature-adjustable valves, and replacement of defective valves
4.2		Poor chemical water quality leaving the treatment plant (e.g. post-treatment precipitation of floc, iron/ manganese precipitation)	• Monitor the flushing programme of the system regularly • Monitor iron, manganese, chloride, etc.	• Electrical conductivity and pH are normal • Turbidity <1 NTU after flushing programme	• Water treatment solutions comply with guidelines, accepted standards and references • Tapwater quality follows national guidelines for drinking-water quality	• Flushing and monitoring programmes and procedures • PoU water treatment before entering installation system (activated carbon filter, pH regulation)
4.3		Poor microbiological water quality leaving the treatment plant and in the distribution system	• Inspect and maintain the filter regularly • Check microbiological parameters or indicators in the system	• Inspection or maintenance intervals at least every six months • Turbidity <1 NTU and *E. coli*, coliforms = 0	• Tapwater quality complies with national guidelines for drinking-water quality	• Inspection, maintenance and monitoring programmes and procedures • Thermal or chemical disinfection • Boiling of tapwater

II **Operational monitoring and management *continued***

Position	Hazard	Cause	Monitoring procedures	Critical or operational limit (reference value)	Validation or verification	Management procedures, including corrective actions
4.4	Biofilm growth (continued)	Inappropriate material used	• Check and document pipe, valves and additional equipment material regularly, and update knowledge • Check microbiological parameters and indicator parameters	• Regular check and documentation of pipe material is carried out	• Pipe material used complies with guidelines, accepted standards • Tapwater quality follows national guideline values for drinking-water quality	• Purchasing specifications for system materials • Immediate check and documentation of pipe material • Replacement of critical system components
5.1	Development of sediments	Inadequate cleaning programme (e.g. maintenance of filter)	• Check elements of cleaning programme according to current standards (e.g. regular maintenance of filters)	• Essential system elements in cleaning programme included	• Cleaning programme complies with guidelines, accepted standards and references	• Inspection, maintenance and monitoring programmes and procedures • Update of cleaning programme according to guidelines, accepted standards and references
5.2		Water velocity too high	• Check pipe dimension • Inspect or maintain controlled openings and closing valves and pumps	• Adequate system flow	• Inspection and maintenance comply with guidelines, accepted standards and references	• Design specifications • Inspection, maintenance and monitoring programmes and procedures • Removal of sediments by cleaning procedures • Replace pipe with inadequate dimensions

II **Operational monitoring and management *continued***

Position	Hazard	Cause	Monitoring procedures	Critical or operational limit (reference value)	Validation or verification	Management procedures, including corrective actions
6.1	Drainage of the supply system	Natural disaster	• Ensure that emergency plan is up to date, and that responsible staff have been instructed in its use	• Emergency plan completed and updated	• Emergency plan complies with guidelines, accepted standards and references	• Emergency plan providing essential information for disasters (e.g. responsibilities, emergency call numbers) • Update and audit of emergency plan

NTU, nephelometric turbidity unit; PoE, point of entry; PoU, point of use.

Annex 2 Potential biological and chemical hazards in building water supplies

Etiologic agent	Incubation period	Clinical symptoms	Source of exposure	Confirmation of waterborne disease
Bacteria				
Acinetobacter	Variable, depending on type of infection	Nosocomial infections, including urinary tract infections, pneumonia, bacteraemia, secondary meningitis and wound infections. Diseases are predisposed by factors such as malignancy, burns, major surgery and weakened immune systems, particularly in neonates and elderly people.	Free-living organisms that grow in distribution systems. Conditions such as low flows that promote biofilms are likely to support growth. Exposure through contact or inhalation of aerosols.	Cultures from cases and isolation from implicated water.
Campylobacter	1–10 days (usually 2–4 days)	Abdominal pain, diarrhoea (with or without blood or faecal leukocytes), vomiting, chills and fever. The infection is self-limited and resolves in 3–7 days. Relapses may occur in 5–10% of untreated patients. Other less common clinical manifestations of *C. jejuni* infections include reactive arthritis and meningitis. Several reports have associated *C. jejuni* infection with Guillain-Barré syndrome, an acute demyelinating disease of the peripheral nerves.	Contamination caused by ingress of faecal contamination through faults in treatment or distribution of water supplies. Exposure through ingestion of faecally contaminated water.	Cultures from stools and isolation from implicated water.

Etiologic agent	Incubation period	Clinical symptoms	Source of exposure	Confirmation of waterborne disease
Bacteria *continued*				
Escherichia coli (enteroinvasive or enterotoxigenic)	10–12 hours seen in outbreaks up to 24–72 hours	Profuse watery diarrhoea without blood or mucus; abdominal cramping and vomiting.	Contamination caused by ingress of faecal contamination through faults in treatment or distribution of water supplies.	Demonstration of *E. coli* isolates from stools that are enterotoxigenic or enterohaemorrhagic.
E.coli O157:H7 (enterohaemorrhagic)	2–10 days with a median of 3–4 days	Bloody or non-bloody diarrhoea, severe abdominal cramps and occasional vomiting, fever infrequent. Between 2% and 7% of cases can develop the potentially fatal haemolytic uraemic syndrome, which is characterized by acute renal failure and haemolytic anaemia. Children younger than five years are at most risk of developing haemolytic uraemic syndrome.	Exposure through ingestion of faecally contaminated water.	Demonstration of *E. coli* of same serotype in implicated water and stools in persons.
Klebsiella and other Gram-negative bacteria (*Serratia marcesans, Stentrophomonas maltophilia, Aeromonas, Burkholderia cepacia, Enterobacter*)	Variable depending on organism and type of infection	*Klebsiella* spp. and other Gram-negative bacteria can cause invasive infections in hospitals, involving the bloodstream, urinary tract, respiratory tract, eyes and wounds. On rare occasions, *Klebsiella* spp., notably *K. pneumoniae* and *K. oxytoca*, may cause serious infections, such as destructive pneumonia. Patients at highest risk are those with impaired immune systems, such as the elderly or very young, patients with burns or excessive wounds, those undergoing immunosuppressive therapy, or those with HIV infection.	Free-living organisms that grow in distribution systems. Conditions such as low flows that promote biofilms are likely to support growth. Exposure through contact or inhalation of aerosols.	Cultures from cases and isolation from implicated water.

Etiologic agent	Incubation period	Clinical symptoms	Source of exposure	Confirmation of waterborne disease
Bacteria *continued*				
Legionella spp.	2–10 days (usually 5–6 days) 5 hours to 3 days (usually 1–2 days)	Legionellosis (pneumonic illness). Fever, non-productive cough, headache, abdominal pain, nausea, diarrhoea, respiratory failure. Pontiac fever is a milder, self-limiting disease with a high attack rate and an onset (five hours to three days) and symptoms similar to those of influenza: fever, headache, nausea, vomiting, aching muscles and coughing.	Free-living organisms that grow in water between 25 °C and 50 °C. Growth promoted by low flows and development of biofilms. Sources include: • cooling towers, evaporative condensers; • domestic hot-water systems that include sections that operate between 25 °C and 50 °C; • humidifiers; • hot tubs and spas; • dental water lines at a temperature above 25 °C; • ice machines; • other water sources, including stagnant water in fire sprinkler systems that contain water between 25 °C and 50 °C. Exposure through inhalation of aerosols or aspiration.	Identification of urinary antigen, serum antibodies or *Legionella* from the case. Isolation of *Legionella* from implicated water matching the type found in the case.

Etiologic agent	Incubation period	Clinical symptoms	Source of exposure	Confirmation of waterborne disease
Bacteria *continued*				
Non-tuberculous or atypical *Mycobacterium* spp. (*M. gordonae, M. kansasii, M. marinum, M. xenopi, M. scrofulaceum, M. avium, M. chelonae, M. intracellulare* and *M. fortuitum*)	1 week to 2 months	Atypical *Mycobacterium* spp. can cause a range of diseases involving the skeleton, lymph nodes, skin and soft tissues, as well as the respiratory, gastrointestinal and genitourinary tracts. Manifestations include pulmonary disease, Buruli ulcer, osteomyelitis and septic arthritis.	High densities can form in biofilms on the insides of pipes and taps. Non-tuberculous *Mycobacterium* can colonize, survive, persist, grow and multiply in tapwater. Sources include distribution systems, hot- and cold-water taps, ice machines, heated nebulizers, hot tubs, footbaths and showerhead sprays. Multiple routes of transmission, including ingestion, inhalation and contact.	Cultures from cases and isolation from implicated water.

Etiologic agent	Incubation period	Clinical symptoms	Source of exposure	Confirmation of waterborne disease
Bacteria *continued*				
Pseudomonas aeruginosa	Ranges from 8 hours to 5 days, depending on type of infection	*Pseudomonas aeruginosa* can cause a range of infections, but rarely causes serious illness in healthy individuals without some predisposing factor. It predominantly colonizes damaged sites such as burn and surgical wounds, the respiratory tract of people with underlying disease, and physically damaged eyes. From these sites, it may invade the body, causing destructive lesions or septicaemia and meningitis. Cystic fibrosis and immunocompromised patients are prone to colonization with *P. aeruginosa*, which may lead to serious progressive pulmonary infections. Water-related folliculitis and ear infections are associated with warm, moist environments such as swimming pools and hot tubs. Diseases are predisposed by factors such as malignancy, burns, major surgery and weakened immune systems, and groups such as the elderly or neonates are particularly at risk.	Common environmental organism with growth promoted by conditions that support biofilm development (low flows or stagnant water). Commonly associated with poorly maintained and disinfected hot tubs, whirlpools, swimming pools or saunas. Multiple routes of transmission, including ingestion, inhalation and contact.	Isolation of *P. aeruginosa* from cases and implicated water or demonstration of presence by specific immunodiagnostic test (e.g. direct fluorescent antigen) or by PCR.
Salmonella *Salmonella* Typhi	6–72 hours (usually 12–36 hours) 3 to more than 60 days (usually 8–14 days)	Diarrhoea lasting three to five days accompanied by fever and abdominal pain. Usually the disease is self-limiting. Other less common manifestations include reactive arthritis, endocarditis, meningitis, pericarditis, pyoderma or pyelonephritis. Insidious onset of fever, headache, malaise, constipation or diarrhoea, anorexia.	Contamination caused by ingress of faecal contamination through faults in treatment or distribution of water supplies. Exposure through ingestion of faecally contaminated water.	Cultures from cases and isolation from implicated water. Cultures from cases and isolation from implicated water.

Etiologic agent	Incubation period	Clinical symptoms	Source of exposure	Confirmation of waterborne disease
Bacteria *continued*				
Shigella	12 hours to 1 week (usually 1–3 days)	Abdominal cramps, fever and watery diarrhoea occur early in the disease. All species can produce severe disease, but illness due to *S. sonnei* is usually relatively mild and self-limiting. In the case of *S. dysenteriae*, clinical manifestations may proceed to an ulceration process, with bloody diarrhoea and high concentrations of neutrophils in the stool. The production of Shiga toxin plays an important role in this outcome.	Contamination caused by ingress of faecal contamination through faults in treatment or distribution of water supplies. Exposure through ingestion of faecally contaminated water.	Cultures from cases and isolation from implicated water.
Vibrio cholerae 01 or 0139	A few hours to 5 days (usually 2–3 days)	The initial symptoms of cholera are an increase in peristalsis followed by loose, watery and mucus-flecked “rice-water” stools that may cause a patient to lose as much as 10–15 litres of liquid per day. Non-toxigenic strains of *V. cholerae* can cause self-limiting gastroenteritis, wound infections and bacteraemia.	Contamination caused by ingress of faecal contamination through faults in treatment or distribution of water supplies. Exposure through ingestion of faecally contaminated water.	Isolation of toxigenic *V. cholerae* 01 or *V. cholerae* 0139 from implicated water and from stool or vomit of ill persons, or significant rise (fourfold) in vibriocidal antibodies.
Viruses				
Adenoviruses	1–12 days, depending on illness	Adenoviruses cause a wide range of infections, including gastroenteritis, acute respiratory diseases, pneumonia, pharyngoconjunctival fever, cervicitis, urethritis, haemorrhagic cystitis, epidemic keratoconjunctivitis (“shipyard eye”), and pharyngoconjunctival fever (“swimming pool conjunctivitis”). Different serotypes are associated with specific illnesses; for example, types 40 and 41 are the main cause of enteric illness.	Contamination caused by ingress of faecal contamination through faults in treatment or distribution of water supplies. Multiple routes of exposure, including ingestion, inhalation or contact with faecally contaminated water.	Identification of virus in stools using culture-based methods. Identification using PCR, ELISA or latex agglutination. Identification in water using PCR or culture-based techniques.

Etiologic agent	Incubation period	Clinical symptoms	Source of exposure	Confirmation of waterborne disease
Viruses *continued*				
Calicivirus *Norovirus* and *Sapovirus*	10–96 hours (usually 24–48 hours)	Nausea, vomiting and abdominal cramps. Usually about 40% of infected people present with diarrhoea; some have fever, chills, headache and muscular pain. Since some cases present with vomiting only and no diarrhoea, the condition is also known as “winter vomiting disease”.	Contamination caused by ingress of faecal contamination through faults in treatment or distribution of water supplies. Ingestion of faecally contaminated water.	Identification of virus in stools by PCR, ELISA or radioimmunoassay. Positive detection (electron microscopy) of virus in vomit or stool in ill people, or by serology. Identification in water using PCR.
Enteroviruses	12 hours to 35 days, depending on illness	The spectrum of diseases is broad and ranges from a mild febrile illness to myocarditis, meningoencephalitis, poliomyelitis, herpangina, hand-foot-and-mouth disease and neonatal multi-organ failure. The persistence of the viruses in chronic conditions such as polymyositis, dilated cardiomyopathy and chronic fatigue syndrome has been described.	Contamination caused by ingress of faecal contamination through faults in treatment or distribution of water supplies. Ingestion or inhalation of faecally contaminated water.	Identification of virus in stools using culture-based methods or PCR. Identification in water using culture-based methods or PCR.
Hepatitis A virus	15–50 days (median 28–30 days)	Severe damage to liver cells. In general, the severity of illness increases with age. The damage also results in the failure of the liver to remove bilirubin from the bloodstream, causing the typical symptoms of jaundice and dark urine. After a relatively long incubation, there is a characteristic sudden onset of illness, including symptoms such as fever, malaise, nausea, anorexia, abdominal discomfort and eventually jaundice. Although mortality is generally less than 1%, repair of the liver damage is a slow process that may keep patients incapacitated for six weeks or longer.	Contamination caused by ingress of faecal contamination through faults in treatment or distribution of water supplies. Ingestion of faecally contaminated water.	Positive anti-HAV IgM test, or liver function tests compatible with hepatitis in people who drank implicated water. Detection of HAV RNA in blood and stools. Identification in water using PCR.

Etiologic agent	Incubation period	Clinical symptoms	Source of exposure	Confirmation of waterborne disease
Viruses *continued*				
Rotavirus	24–72 hours	Acute infection has an abrupt onset of severe watery diarrhoea with fever, abdominal pain and vomiting; dehydration and metabolic acidosis may develop, and the outcome may be fatal if not appropriately treated.	Contamination caused by ingress of faecal contamination through faults in treatment or distribution of water supplies. Ingestion of faecally contaminated water.	Identification of virus in stools by PCR, ELISA or latex agglutination. Positive detection (electron microscopy) of virus in vomit or stool in ill people, or serology. Identification in water using PCR.
Protozoa				
Cyclospora cayetanensis	1–11 days (median 7 days)	Watery diarrhoea, abdominal cramping, weight loss, anorexia, myalgia and occasionally vomiting or fever. Relapsing illness often occurs.	Contamination caused by ingress of faecal contamination through faults in treatment or distribution of water supplies. Ingestion of faecally contaminated water.	Demonstration of *C. cayetanensus* in stools of two or more ill people.
Cryptosporidium parvum	1–12 days (median 7 days)	*Cryptosporidium* generally causes a self-limiting diarrhoea, sometimes including nausea, vomiting and fever, which usually resolves within a week in normally healthy people, but can last for a month or more.	Contamination caused by ingress of faecal contamination through faults in treatment or distribution of water supplies. Ingestion of faecally contaminated water.	Isolation of *C. parvum* oocysts from implicated water and from stools, or identification in intestinal fluid or small bowel biopsy specimen, or demonstration of *C. parvum* antigen in stools by a specific immunodiagnostic test (e.g. ELISA).

Etiologic agent	Incubation period	Clinical symptoms	Source of exposure	Confirmation of waterborne disease
Protozoa *continued*				
Entamoeba hystolytica	A few days to several months or more (commonly 2–4 weeks)	About 10% of infected people present with dysentery or colitis. Symptoms of amoebic dysentery include diarrhoea with cramping, lower abdominal pain, low-grade fever and the presence of blood and mucus in the stool. The ulcers produced by the invasion of the trophozoites may deepen into the classic flask-shaped ulcers of amoebic colitis. *Entamoeba histolytica* may invade other parts of the body, such as the liver, lungs and brain, sometimes with fatal outcome.	Contamination caused by ingress of faecal contamination through faults in treatment or distribution of water supplies. Ingestion of faecally contaminated water.	Isolation of *E. hystolytica* from stools of ill people, or demonstration of *E. hystolytica* trophozoite in tissue biopsy, culture or histopathology.
Giardia lamblia	3 to more than 25 days (median 7–10 days)	Symptoms generally include diarrhoea and abdominal cramps; however, in severe cases, malabsorption deficiencies in the small intestine may be present, mostly among young children. Giardiasis is self-limiting in most cases, but it may be chronic in some patients, lasting more than one year, even in otherwise healthy people.	Contamination caused by ingress of faecal contamination through faults in treatment or distribution of water supplies. Ingestion of faecally contaminated water.	Isolation of *G. lamblia* cysts from implicated water, or isolation of *G. lamblia* from stools of ill people, or demonstration of *G. lamblia* trophozoite in duodenal fluid or small bowel biopsy, or demonstration of *G. lamblia* antigen by specific immunodiagnostic test (e.g. DFA).
Chemicals				
Heavy metals (e.g. copper, lead, nickel and cadmium nickel)	Acute: <1 hour (5 min – 8 hours)	Range of chemical symptoms depending on the metal. Initial acute symptoms may include gastroenteritis (e.g. copper), but broader symptoms range from neurological impacts to kidney damage and cancer.	Ingestion of water containing excessive concentrations due to leaching associated with corrosion or stagnant water.	Demonstration of concentrations of metals in water exceeding guideline values.
Nitrite (e.g. in boiler treatment fluid)	1–2 hours	Methaemoglobinemia, nausea, vomiting, cyanosis, headache, dizziness, dyspnoea, trembling, weakness, loss of consciousness.	Ingestion of water contaminated by backflow or cross-connection of devices such as boilers to drinking-water supplies.	Demonstration of concentrations of nitrites in water exceeding guideline values.

Etiologic agent	Incubation period	Clinical symptoms	Source of exposure	Confirmation of waterborne disease
Chemicals *continued*				
Organic chemicals (e.g. benzo(a)pyrene, styrene, vinyl chloride)	Chronic, many years	Most likely symptom is cancer from long-term exposure.	Ingestion of water contaminated by inappropriate materials used in plumbing.	Demonstration of concentrations in water exceeding guideline values.
Water treatment chemicals (e.g. chlorine)	Acute (chlorine)	Substantial tastes and odours.	Ingestion of water containing excessive concentrations of chlorine.	Demonstration of concentrations in water exceeding guideline values.

DFA, direct fluorescent antigen; ELISA, enzyme-linked immunosorbent assay; HAV, hepatitis A virus; HIV, human immunodeficiency virus; IgM, immunoglobulin M; PCR, polymerase chain reaction; RNA, ribonucleic acid.
Source: Information adapted from Percival et al. (2004), Heymann (2008) and WHO (2008).

A48235836

Glossary

Accreditation	An official authorization or certification to a person, organization or laboratory that has the credential to deliver certain tasks; certification to a laboratory, institution or someone who has met the standard required by an official authority (WHO, 2009). Accreditation provides an independent assessment of competency that provides confidence to users of services.
Actor	Individuals, groups or organizations that influence the overall safe management of building water supplies, including those who design, construct, manage, operate, maintain and regulate building water systems.
Aerosol	A suspension of fine solid or liquid particles in a gas, such as air.
Backflow	The unintended reverse flow of water or other substances into distribution pipes of drinking-water from an unintended source that is capable of polluting the drinking-water (American Society of Sanitary Engineering, 2007).
Backflow protection	Devices that prevent backflow (e.g. one-way valves, air gaps).
Back-siphonage	The reverse flow of water within a water-supply system due to negative pressures in the pipe system, enabling atmospheric pressure to force the flow of water backwards through a siphon action (World Plumbing Council, 2008). The reversing of normal flow resulting from negative or subatmospheric pressures in the distribution piping of a drinking-water supply system (WHO and WPC, 2006).
Biocide	A diverse group of poisonous substances, including preservatives, insecticides, disinfectants and pesticides, used to control organisms that are harmful to human or animal health, or that cause damage to natural or manufactured products.
Biofilm	A slimy matrix produced and inhabited by bacteria, which enables the bacteria to adhere to a surface and carry out certain essential biochemical processes.
Certification (personnel)	A programme to substantiate the capabilities of personnel by documenting their experience and learning in a defined area of endeavour (Symons et al., 2000).
Community acquired	Cases of illness that are not acquired in a health-care, travel or domestic (i.e. the patient's home) setting (Bartram et al., 2007). Community-acquired cases of legionellosis can almost always be attributed to inhalation of aerosols from devices such as cooling towers, hot tubs, industrial equipment and indoor fountains.

Component	Appliance, equipment. A device in which potable water is used and/or modified (e. g. water heater, chemical dosing unit, coffee-machine, toilet).
Contamination	Presence of an infectious or toxic agent or matter on a human or animal body surface, in or on a product prepared for consumption, or on other inanimate objects, including conveyances, that may constitute a public health risk (WHO, 2005). Presence of a disease agent on or in food, or any object that may come into contact with food (WHO, 2007).
Control	In a case–control study, the control group is the group of people who do not have the disease or condition of interest, and who are used to compare with those people who do.
Control measure	Any action and activity that can be used to prevent or eliminate a water safety hazard or reduce it to an acceptable level.
Cooling tower	Heat-transfer device in which warm water is cooled by evaporation in atmospheric air. Cooling towers usually incorporate an air fan for forced air movement, a circulating water pump, a water spray system and a cooling coil (World Plumbing Council, 2008).
Corrective action	Any action to be taken when the results of monitoring at the control point indicate a loss of control.
Corrosion	A surface reaction causing a gradual erosion of the material affected (WHO & WPC, 2006). The gradual deterioration or destruction of a substance (usually a metal) or its properties as a result of a reaction with the substance's surroundings (Symons et al., 2000).
Cross-connection	Any connection, physical or otherwise, between a drinking-water system and non-drinking-water, where contamination can enter the drinking-water supply lines by back pressure, back-siphonage, and backflow occurring in the water-supply system (American Society of Sanitary Engineering, 2007). Any physical connection or arrangement between two otherwise separate piping systems or containment means, one of which contains potable water, and the other water or fluid of unknown or questionable safety (WHO & WPC, 2006).
Dead leg	A length of water-filled pipe where there is little or no flow.
Disinfectant	An agent that destroys or inactivates harmful microorganisms (Symons et al., 2000).

A48235836

Disinfection	The supply of safe drinking-water through the destruction of microbial pathogens (bacteria, viruses and protozoa), involving reactive chemical agents. It is used for surface waters and for groundwater subject to faecal contamination (WHO, 2008). The procedure whereby health measures are taken to control or kill the insect vectors of human diseases present in baggage, cargo, containers, conveyances, goods and postal parcels (WHO, 2005). The process of destroying or inactivating pathogenic organisms (bacteria, viruses, fungi and protozoa) by either chemical or physical means (Symons et al., 2000).
Disinfection by-product	The formation of chemical by-products (inorganic or organic) that results from the use of chemical disinfectants in water treatment (WHO, 2008).
Domestic water	Water used for all usual domestic purposes, including consumption, bathing and food preparation (WHO, 2008). Pertaining to municipal (household) water services as opposed to commercial and industrial water. The term is sometimes used to include the commercial component (Symons et al., 2000). Water that is delivered for normal personal use within a household, school or commercial premises (World Plumbing Council, 2008).
Enforcement	Administrative or legal procedures and actions to require compliance with legislation or associated rules, regulations or limitations (Symons et al., 2000).
Exposure	Concentration or amount of a particular agent that reaches a target organism, system or (sub)population in a specific frequency for a defined duration (WHO, 2004a). Contact between an agent and a target (WHO, 2004b).
Greywater	Water from the kitchen, bath or laundry, which generally does not contain significant concentrations of excreta (WHO, 2006b). Untreated household-used water, such as wash or rinse water from a sink, bathtub, or other household plumbing fixture, except a toilet (Symons et al., 2000).
Guidelines	Minimum requirements of safe practice to protect health or derive numerical guideline values.

Hardness	Hardness in water is caused by dissolved calcium and, to a lesser extent, magnesium. It is expressed as the equivalent quantity of calcium carbonate. Hardness above about 200 mg/litre can result in scale deposition, particularly on heating. No health-based guideline value is proposed for hardness (WHO, 2008). Hardness is caused mainly by the presence of calcium and magnesium in the water. Scale formation and excessive soap consumption are the main concerns. When heated, hard waters have a tendency to form scale deposits, which shorten the life of water heaters and other appliances (Health Canada, 2009).
Hazard	In the context of this document, a hazard is a biological, chemical or physical agent in water, or a condition of water, with the potential to cause an adverse health effect.
Hazard identification	The identification of the type and nature of adverse effects that an agent has an inherent capacity to cause in an organism, system, or (sub)population.
Hazardous event	An event that introduces hazards to, or fails to remove them from, the water supply (Bartram et al., 2009).
Health-based target	Target based on critical evaluation of health concerns.
Hot tub	Facilities that are designed for sitting in (rather than swimming); contain water usually above 32 °C; are generally aerated; contain treated water; and are not drained, cleaned or refilled for each user. Hot tubs are also called spa pools, whirlpools, whirlpool spas and heated spas.
Infection	The entry and development or multiplication of an infectious agent in a host. Infection may or may not lead to disease symptoms (e.g. diarrhoea) (WHO, 2006b). The entry and development or multiplication of an infectious agent in the body of humans and animals that may constitute a public health risk (WHO, 2005). The presence in the body of viruses or organisms, such as bacteria, protozoa, fungi or helminths, which multiply or develop, completing all or part of their lifecycle within the tissues of an animal or human host (infection may or may not lead to a disease state) (WHO et al., 1996).
Legislation (primary and secondary)	Law enacted by a legislative body or the act of making or enacting laws (WHO, 2006b). Primary legislation is the law-making legislation, which is also known as enabling legislation, and can be found in the form of an Act, a statute or a bill. Subordinate legislation is legislation that is subordinate to the primary law-making legislation. It cannot make laws or change Acts, statutes or bills (World Plumbing Council, 2008).

A48235836

Maintenance	Activities aimed at keeping existing capital assets in serviceable condition (e.g. by repairing water-distribution pipes, pumps and public taps) (WHO, 2000).
Material	The substance from which a product is made.
Monitoring	The act of conducting a planned sequence of observations or measurements of control parameters, to assess whether a control point is operating within design specifications.
Multiple barrier approach	The multiple barrier approach in drinking-water is the concept of using more than one type of protection or treatment in series in a water-treatment process to control contamination (Symons et al., 2000).
Operational monitoring	The act of conducting a planned sequence of observations or measurements of control parameters to assess whether a control measure is operating within design specifications (e.g. for wastewater turbidity treatment) (WHO, 2008).
Outbreak	An epidemic limited to localized increase in the incidence of a disease (e.g. in a village, town or closed institution) (McMichael et al., 2003). A waterborne outbreak is a situation in which at least two people experience a similar illness after exposure to water (and possibly food) and the evidence suggests a probable water source (WHO, 2007).
Pathogens	Any microorganisms that cause disease in an organism, through direct interaction (infection) (Schmoll et al, 2006).
pH	The pH of a solution is the negative common logarithm of the hydrogen ion activity (WHO, 2008): $pH = -\log (H+)$ An expression of the intensity of the basic or acid condition of a liquid (WHO, 2006b).
Plumbing	The piping, fixtures and appliances within a property; and all the work associated with the design, installation, removal, alteration or repair of piping, fixtures and appliances in connection with drinking-water supply, non-drinking-water supply and drainage systems that flow in and out of buildings and between given connection points to points of use or disposal (World Plumbing Council Working Group, 2008).
Point of consumption	Draw-off point. Those points in the potable water installation from which water can be drawn.
Point-of-entry (PoE) treatment	A treatment device applied to the drinking-water entering a house or building for reducing contaminants in the drinking-water distributed throughout that house or building (Symons et al., 2000).
Policy	The set of procedures, rules and allocation mechanisms that provide the basis for programmes and services (WHO, 2006b).

Recycled water	Water that has been treated so that its quality is suitable for particular specified purposes, such as irrigation, toilet flushing or possibly drinking (WHO, 2006b). Sources of recycled water include sewage and greywater.
Risk	The probability of an adverse effect in an organism, system, or (sub)population caused under specified circumstances by exposure to an agent (WHO, 2008). The likelihood of a hazard causing harm in exposed populations in a specified time frame, including the magnitude of that harm (WHO, 2008).
Risk assessment	A process intended to calculate or estimate the risk to a given target organism, system, or (sub)population, including the identification of attendant uncertainties, following exposure to a particular agent, taking into account the inherent characteristics of the agent of concern, as well as the characteristics of the specific target system. The overall process of using available information to predict how often hazards or specified events may occur (likelihood) and the magnitude of their consequences (adapted from AS/NZS 4360:1999).
Risk management	Decision-making process involving considerations of political, social, economic and technical factors with relevant risk-assessment information relating to a hazard so as to develop, analyse, and compare regulatory and non-regulatory options, and to select and implement appropriate regulatory response to that hazard. Risk management comprises three elements: risk evaluation, emission and exposure control, and risk monitoring (WHO, 2004a). The systemic evaluation of the water-supply system, the identification of hazards and hazardous events, the assessment of risks, and the development and implementation of preventive strategies to manage risks (WHO, 2006b).
Sensitive or vulnerable population	Vulnerable groups or populations are people who might be vulnerable to the effects of exposure because of their development stage (e.g. children) or because of pre-existing health conditions (e.g. asthmatics and air pollution).
Spa pool	A facility that is designed for sitting in (rather than swimming); contains treated water usually above 32 °C; is usually aerated; and is not drained, cleaned or refilled for each user. Also known as a hot tub, whirlpool, whirlpool spa, heated spa, bubble bath or jacuzzi.
Stakeholder	Person or entity with an interest or 'stake' in the outcome of a particular action or policy (McMichael et al., 2003).
Storage (cistern)	Tank or storage container in which water is stored (American Society of Sanitary Engineering, 2007).

A48235836

Surveillance	The systematic ongoing collection, collation and analysis of data for public health purposes and the timely dissemination of public health information, for assessment and public health response as necessary (WHO, 2005).
Thermostatic mixing valves	Tempering valves that are typically temperature-activated. Used to mix hot and cold water to achieve a predetermined outlet temperature, and that are fitted between the water heater and the point of use to control the distribution temperature. Slightly different temperature ranges are used in some countries.
Turbidity	Cloudiness caused by the presence of suspended matter in water (WHO, 2008).
Validation	The process of obtaining accurate and reliable evidence that a water safety plan is effective.
Verification	The application of methods, procedures, tests and other evaluations, in addition to monitoring, to determine compliance with a water safety plan.
Water safety plan	A comprehensive risk-assessment and risk-management approach that encompasses all steps in water supply, from catchment to consumer.
Water system (external or building-specific)	An external system is one that provides multiple users and can be either publicly or privately owned. A building-specific supply is defined as an individual and isolated drinking-water system that is distinct from any external water system.

Extensive experience shows that poor design and management of water systems in buildings can cause outbreaks of disease. The types of building, water uses, disease outcomes and individuals affected are diverse. The health risks are preventable and can be readily controlled. However, evidence from outbreak detection suggests that the overall trend is increasing. With increasing global urbanization, the overall exposure of the human population to poorly designed or managed water systems in buildings is increasing rapidly. Consequently, the risk of disease outbreaks is also increasing. Actions to reduce the risk of disease should be considered a public health priority.

This document provides guidance for managing water supplies in buildings where people may drink water; use water for food preparation; wash, shower, swim or use water for other recreational activities; or be exposed to aerosols produced by water-using devices, such as cooling towers. These uses occur in a variety of buildings, such as hospitals, schools, child and aged care facilities, medical and dental facilities, hotels, apartment blocks, sport centres, commercial buildings and transport terminals.

This text is one of a series of supporting documents that provide guidance on implementing the World Health Organization's *Guidelines for drinking-water quality* (WHO, 2008). It is intended to support the improvement of water safety within buildings.

The target audience for this document includes the full range of "actors" who influence the overall safe management of building water supplies. In particular, it is directed at those who design, construct, manage, operate, maintain and regulate building water systems. This document is intended to be a useful resource for the development of training and information material.

Chapter 41. Preventing Health Care–Associated Infections

Amy S. Collins

Background

The occurrence and undesirable complications from health care–associated infections (HAIs) have been well recognized in the literature for the last several decades. The occurrence of HAIs continues to escalate at an alarming rate. HAIs originally referred to those infections associated with admission in an acute-care hospital (formerly called a nosocomial infection), but the term now applies to infections acquired in the continuum of settings where persons receive health care (e.g., long-term care, home care, ambulatory care). These unanticipated infections develop during the course of health care treatment and result in significant patient illnesses and deaths (morbidity and mortality); prolong the duration of hospital stays; and necessitate additional diagnostic and therapeutic interventions, which generate added costs to those already incurred by the patient's underlying disease. HAIs are considered an undesirable outcome, and as some are preventable, they are considered an indicator of the quality of patient care, an adverse event, and a patient safety issue.

Patient safety studies published in 1991 reveal the most frequent types of adverse events affecting hospitalized patients are adverse drug events, nosocomial infections, and surgical complications.[1, 2] From these and other studies, the Institute of Medicine reported that adverse events affect approximately 2 million patients each year in the United States, resulting in 90,000 deaths and an estimated $4.5–5.7 billion per year in additional costs for patient care.[3] Recent changes in medical management settings have shifted more medical treatment and services to outpatient settings; fewer patients are admitted to hospitals. The disturbing fact is that the average duration of inpatient admissions has decreased while the frequency of HAIs has increased.[4, 5] The true incidence of HAIs is likely to be underestimated as hospital stays may be shorter than the incubation period of the infecting microorganism (a developing infection), and symptoms may not manifest until days after patient discharge. For example, between 12 percent and 84 percent of surgical site infections are detected after patients are discharged from the hospital, and most become evident within 21 days after the surgical operation.[6, 7] Patients receiving followup care or routine care after a hospitalization may seek care in a nonacute care facility. The reporting systems are not as well networked as those in acute care facilities, and reporting mechanisms are not directly linked back to the acute care setting to document the suspected origin of some infections.

Since the early 1980s HAI surveillance has monitored ongoing trends of infection in health care facilities.[8] With the application of published evidence-based infection control strategies, a decreasing trend in certain intensive care unit (ICU) health care-associated infections has been reported through national infection control surveillance[9] over the last 10 years, although there has also been an alarming increase of microorganism isolates with antimicrobial resistance. These changing trends can be influenced by factors such as increasing inpatient acuity of illness, inadequate nurse-patient staffing ratios, unavailability of system resources, and other demands that have challenged health care providers to consistently apply evidence-based recommendations to maximize prevention efforts. Despite these demands on health care workers

and resources, reducing preventable HAIs remains an imperative mission and is a continuous opportunity to improve and maximize patient safety.

Another factor emerging to motivate health care facilities to maximize HAI prevention efforts is the growing public pressure on State legislators to enact laws requiring hospitals to disclose hospital-specific morbidity and mortality rates. A recent Institute of Medicine report identified HAIs as a patient safety concern and recommended immediate and strong mandatory reporting of other adverse health events, suggesting that public monitoring may hold health care facilities more accountable to improve the quality of medical care and to reduce the incidence of infections.[3] Since 2002, four States (Florida, Illinois, Missouri, and Pennsylvania) set legislation mandating health care organizations to publicly disclose HAIs.[10, 11] In 2006, the Association for Professionals in Infection Control and Epidemiology (APIC) reported that 14 States have mandatory public reporting, and 27 States have other related legislation under consideration.[12] Participation in public reporting has not been regulated by the Federal sector at this time. Some hospital reporting is intended for use solely by the State health department for generating confidential reports that are returned to each facility for their internal quality improvement efforts. Other intentions to utilize public reporting may be aimed at comparing rates of HAI and subsequent morbidity and mortality outcomes between different hospitals. This approach is problematic as there is currently a lack of scientifically validated methods for risk adjusting multiple variations (e.g., differences in severity of illnesses in each population being treated) in patients' intrinsic and extrinsic risks for HAIs.[13–15] Moreover, data on whether public reporting systems have an effective role in reducing HAIs are lacking.

To assist with generating meaningful data, process and outcome measures for patient safety practices have been proposed.[13, 14, 16] Monitoring both process and outcome measures and assessing their correlation is a model approach to establish that good processes lead to good health care outcomes. Process measures should reflect common practices, apply to a variety of health care settings, and have appropriate inclusion and exclusion criteria. Examples include insertion practices for central intravenous catheters, appropriate timing of antibiotic prophylaxis in surgical patients, and rates of influenza vaccination for health care workers and patients. Outcome measures should be chosen based on the frequency, severity, and preventability of the outcome events. Examples include intravascular catheter-related blood stream infection rates and surgical-site infections in selected operations. Although these occur at relatively low frequency, the severity is high—these infections are associated with substantial morbidity, mortality, and excess health care costs—and there are evidence-based prevention strategies available.[17, 18]

Definitions of Health Care-Associated Infections

The Centers for Disease Control and Prevention (CDC) developed baseline definitions for HAIs that were republished in 2004.[19] HAIs were defined as those that develop during hospitalization but are neither present nor incubating upon the patient's admission to the hospital; generally for those infections that occur more than 48 to 72 hours after admission and within 10 days after hospital discharge. Some hospitals use these definitions exactly as written; other hospitals may use some but not all of the CDC definitions; and other health care facilities may need to modify or develop their own definitions. Whatever definition is used, it should be consistent within the institution and be the same or similar to those developed by CDC or those used by other investigators. Having standard definitions is useful if the health care facility wants

to compare surveillance results or performance measures within its various medical/surgical specialties, against those of other health care institutions, or with national published data.

Patient Risk Factors for Health Care–Associated Infections

Transmission of infection within a health care setting requires three elements: a source of infecting microorganisms, a susceptible host, and a means of transmission for the microorganism to the host.

Source of Microorganisms

During the delivery of health care, patients can be exposed to a variety of exogenous microorganisms (bacteria, viruses, fungi, and protozoa) from other patients, health care personnel, or visitors. Other reservoirs include the patient's endogenous flora (e.g., residual bacteria residing on the patient's skin, mucous membranes, gastrointestinal tract, or respiratory tract) which may be difficult to suppress and inanimate environmental surfaces or objects that have become contaminated (e.g., patient room touch surfaces, equipment, medications). The most common sources of infectious agents causing HAI, described in a scientific review of 1,022 outbreak investigations,[20] are (listed in decreasing frequency) the individual patient, medical equipment or devices, the hospital environment, the health care personnel, contaminated drugs, contaminated food, and contaminated patient care equipment.

Host Susceptibility

Patients have varying susceptibility to develop an infection after exposure to a pathogenic organism. Some people have innate protective mechanisms and will never develop symptomatic disease because they can resist increasing microbial growth or have immunity to specific microbial virulence properties. Others exposed to the same microorganism may establish a commensal relationship and retain the organisms as an asymptomatic carrier (colonization) or develop an active disease process.

Intrinsic risk factors predispose patients to HAIs. The higher likelihood of infection is reflected in vulnerable patients who are immunocompromised because of age (neonate, elderly), underlying diseases, severity of illness, immunosuppressive medications, or medical/surgical treatments. Patients with alterations in cellular immune function, cellular phagocytosis, or humoral immune response are at increased risk of infection and the ability to combat infection. A person with a primary immunodeficiency (e.g., anemia or autoimmune disease) is likely to have frequently recurring infections or more severe infections, such as recurrent pneumonia.[21] Secondary immunodeficiencies (e.g., chemotherapy, corticosteroids, diabetes, leukemia) increase patient susceptibility to infection from common, less virulent pathogenic bacteria, opportunistic fungi, and viruses. Considering the severity of a patient's illness in combination with multiple risk factors, it is not unexpected that the highest infection rates are in ICU patients. HAI rates in adult and pediatric ICUs are approximately three times higher than elsewhere in hospitals.[22]

Extrinsic risk factors include surgical or other invasive procedures, diagnostic or therapeutic interventions (e.g., invasive devices, implanted foreign bodies, organ transplantations, immunosuppressive medications), and personnel exposures. According to one review article, at least 90 percent of infections were associated with invasive devices.[23] Invasive medical devices bypass the normal defense mechanism of the skin or mucous membranes and provide foci where

pathogens can flourish, internally shielded from the patient's immune defenses. In addition to providing a portal of entry for microbial colonization or infection, these devices also facilitate transfer of pathogens from one part of the patient's body to another, from health care worker to patient, or from patient to health care worker to patient. Infection risk associated with these extrinsic factors can be decreased with the knowledge and application of evidence-based infection control practices. These will be discussed in further detail in Chapter 42, "Targeting Health Care–Associated Infections: Evidence-Based Strategies."

Prolonged hospitalization, due to a higher acuity of illness, contributes to host susceptibility as there is more opportunity to utilize invasive devices and more time for exposure to exogenous microorganisms. These patients are also more susceptible to rapid microbial colonization as a consequence of the severity of the underlying disease, depending on the function of host defenses and the presence of risk factors (e.g., age, extrinsic devices, extended length of stay). Exposure to these colonizing microorganisms is from such sources as (1) endemic pathogens from an endogenous source, (2) hospital flora in the health care environment, and (3) hands of health care workers. A study related to length of hospitalization examining adverse events in medical care indicated that the likelihood of experiencing an adverse event increased approximately 6 percent for each day of hospital stay. The highest proportion of adverse events (29.3 percent) was not related to surgical procedures but linked instead to the subsequent monitoring and daily care lacking proper antisepsis steps.[24]

Means of Transmission

Among patients and health care personnel, microorganisms are spread to others through four common routes of transmission: contact (direct and indirect), respiratory droplets, airborne spread, and common vehicle. Vectorborne transmissions (from mosquitoes, fleas, and other vermin) are atypical routes in U.S. hospitals and will not be covered in this text.

Contact transmission. This is the most important and frequent mode of transmission in the health care setting. Organisms are transferred through direct contact between an infected or colonized patient and a susceptible health care worker or another person. Patient organisms can be transiently transferred to the intact skin of a health care worker (not causing infection) and then transferred to a susceptible patient who develops an infection from that organism—this demonstrates an indirect contact route of transmission from one patient to another. An infected patient touching and contaminating a doorknob, which is subsequently touched by a health care worker and carried to another patient, is another example of indirect contact. Microorganisms that can be spread by contact include those associated with impetigo, abscess, diarrheal diseases, scabies, and antibiotic-resistant organisms (e.g., methicillin-resistant *Staphylococcus aureus* [MRSA] and vancomycin-resistant enterococci [VRE]).

Respiratory droplets. Droplet-size body fluids containing microorganisms can be generated during coughing, sneezing, talking, suctioning, and bronchoscopy. They are propelled a short distance before settling quickly onto a surface. They can cause infection by being deposited directly onto a susceptible person's mucosal surface (e.g., conjunctivae, mouth, or nose) or onto nearby environmental surfaces, which can then be touched by a susceptible person who autoinoculates their own mucosal surface. Examples of diseases where microorganisms can be spread by droplet transmission are pharyngitis, meningitis, and pneumonia.

Airborne spread. When small-particle-size microorganisms (e.g., tubercle bacilli, varicella, and rubeola virus) remain suspended in the air for long periods of time, they can spread to other people. The CDC has described an approach to reduce transmission of microorganisms through

airborne spread in its *Guideline for Isolation Precautions in Hospitals.*[25] Proper use of personal protective equipment (e.g., gloves, masks, gowns), aseptic technique, hand hygiene, and environmental infection control measures are primary methods to protect the patient from transmission of microorganisms from another patient and from the health care worker. Personal protective equipment also protects the health care worker from exposure to microorganisms in the health care setting.

Common Vehicle. Common vehicle (common source) transmission applies when multiple people are exposed to and become ill from a common inanimate vehicle of contaminated food, water, medications, solutions, devices, or equipment. Bacteria can multiply in a common vehicle but viral replication can not occur. Examples include improperly processed food items that become contaminated with bacteria, waterborne shigellosis, bacteremia resulting from use of intravenous fluids contaminated with a gram-negative organism, contaminated multi-dose medication vials, or contaminated bronchoscopes. Common vehicle transmission is likely associated with a unique outbreak setting and will not be discussed further in this document.

Responsibility for Risk Reduction

Infection Control Department's Program Responsibilities

In 1985, the Study of the Efficacy of Nosocomial Infection Control (SENIC) project was published, validating the cost-benefit savings of infection control programs.[8] Infection control programs were proven to be effective as hospitals with certain practices reduced their infection rates by 32 percent, compared with an *increase* of 18 percent in hospitals without these components over a 5-year period.[8, 26] Essential components of effective infection control programs included conducting organized surveillance and control activities, a trained infection control physician, an infection control nurse for every 250 beds, and a process for feedback of infection rates to clinical care staff. These programmatic components have remained consistent over time and are adopted in the infection control standards of the Joint Commission (formerly the Joint Commission on Accreditation of Healthcare Organizations, JCAHO). The evolving responsibility for operating and maintaining a facility-wide effective infection control program lies within many domains. Both hospital administrators and health care workers are tasked to demonstrate effectiveness of infection control programs, assure adequate staff training in infection control, assure that surveillance results are linked to performance measurement improvements, evaluate changing priorities based on ongoing risk assessments, ensure adequate numbers of competent infection control practitioners, and perform program evaluations using quality improvement tools as indicated.

Infection Control Personnel

It has been demonstrated that infection control personnel play an important role in preventing patient and health care worker infections and preventing medical errors. An infection control practitioner[27] (ICP) is typically assigned to perform ongoing surveillance of infections for specific wards, calculate infection rates and report these data to essential personnel, perform staff education and training, respond to and implement outbreak control measures, and consult on employee health issues. This specialty practitioner gains expertise through education involving infection surveillance, infection control, and epidemiology from current scientific publications

and basic training courses offered by professional organizations or health care institutions.[28, 29] The Certification Board of Infection Control offers certification that an ICP has the standard core set of knowledge in infection control.[30, 31, 32]

Over time, the workload responsibilities of the ICP have significantly increased to encompass additional administrative functions and regulatory compliance reporting, sometimes covering prevention of infection activities in other facilities that belong to the health care system (e.g., long-term care, home care, and outpatient settings). The expanding scope of ICP responsibilities being performed with limited time and shrinking resources has created an imbalance in meeting all tasks, leading to regular completion of only essential functions and completing less essential functions when time permits. In a 2002 ICP survey examining resource allocations, the activity consuming the greatest amount of mean estimated time was surveillance, followed by education, prevention strategies to control transmission, infection control program communication, and outbreak control. In examining the tasks and the time allocations necessary to complete essential infection control responsibilities, a recent expert review panel recommended new and safer staffing allocations: 1 full-time ICP for every 100 occupied beds. Further staffing levels and recommendations are included for different types of health care facilities by bed size.[33] To maximize successful completion of current reporting requirements and strategies for the prevention of infection and other adverse events associated with the delivery of health care in the entire spectrum of health care settings, infection control personnel and departments must be expanded.[34]

Nursing Responsibilities

Clinical care staff and other health care workers are the frontline defense for applying daily infection control practices to prevent infections and transmission of organisms to other patients. Although training in preventing bloodborne pathogen exposures is required annually by the Occupational Safety and Health Administration, clinical nurses (registered nurses, licensed practical nurses, and certified nursing assistants) and other health care staff should receive additional infection control training and periodic evaluations of aseptic care as a planned patient safety activity. Nurses have the unique opportunity to directly reduce health care–associated infections through recognizing and applying evidence-based procedures to prevent HAIs among patients and protecting the health of the staff. Clinical care nurses directly prevent infections by performing, monitoring, and assuring compliance with aseptic work practices; providing knowledgeable collaborative oversight on environmental decontamination to prevent transmission of microorganisms from patient to patient; and serve as the primary resource to identify and refer ill visitors or staff.

Prevention Strategies

Multiple factors influence the development of HAIs, including patient variables (e.g., acuity of illness and overall health status), patient care variables (e.g., antibiotic use, invasive medical device use), administrative variables (e.g., ratio of nurses to patients, level of nurse education, permanent or temporary/float nurse), and variable use of aseptic techniques by health care staff. Although HAIs are commonly attributed to patient variables and provider care, researchers have also demonstrated that other institutional influences may contribute to adverse outcomes.[35, 36] To encompass overall prevention efforts, a list of strategies are reviewed that apply to the clinical

practice of an individual health care worker as well as institutional supportive measures. Adherence to these principles will demonstrate that you H.E.L.P. C.A.R.E. This acronym is used to introduce the following key concepts to reduce the incidence of health care–associated infections. It emphasizes the compassion and dedication of nurses where their efforts contribute to reduce morbidity and mortality from health care–associated infections.

Hand Hygiene

…so they shall wash their hands and their feet, that they die not:
and it shall be a statute for ever to them…
Exodus 30:21 Revised Standard Version

Overview. For the last 160 years, we have had the scientific knowledge of how to reduce hand contamination and thereby decrease patient infections from the seminal work on hand washing by the Hungarian obstetrician, Ignaz Semmelweis. Epidemiologic studies continue to demonstrate the favorable cost-benefit ratio and positive effects of simple hand washing for preventing transmission of pathogens in health care facilities.[37, 38] The use of antiseptic hand soaps (i.e., ones containing chlorhexidine) and alcohol-based hand rubs also effectively reduce bacterial counts on hands when used properly. Even though the clear benefits of hand washing have been proven in multiple settings, the lack of consistent hand-washing practices remains a worldwide issue. In a resource-poor area of Pakistan, a recent household hand-washing campaign demonstrated a 50 percent lower incidence of pneumonia in children younger than 5 years compared to households that did not practice hand washing. Children under 15 years in hand-washing households had a 53 percent lower incidence of diarrhea and a 34 percent lower incidence of impetigo. Hand washing with plain soap prevented the majority of illnesses causing the largest number of childhood deaths globally.[39] The World Alliance for Patient Safety, formed by the World Health Organization, has adopted infection reduction programs—in both developed and developing countries—as its first goal.[40, 41] The World Alliance for Patient Safety advocates a “clean care is safer care” program, in which health care leaders sign a pledge to take specific steps to reduce HAIs in their facilities. Hand hygiene is the first focus in this worldwide initiative.

Understaffing and hand hygiene. Hospitals with low nurse staffing levels and patient overcrowding leading to poor adherence to hand hygiene have been associated with higher adverse outcome rates and hospital outbreak investigations.[34, 42, 43] In an ICU setting,[44] it was demonstrated that understaffing of nurses can facilitate the spread of MRSA through relaxed attention to basic infection control measures (e.g., hand hygiene). In a neonatal ICU outbreak,[45] the daily census was above the maximum capacity (25 neonates in a unit designed for 15), and the number of assigned staff members was fewer than the number necessitated by the workload, which resulted in relaxed attention to basic infection-control measures (use of multidose vials and hand hygiene). During the highest workload demands, staff washed their hands before contacting devices only 25 percent of the time, but hand washing increased to 70 percent after the end of the understaffing and overcrowding period. Ongoing surveillance determined that being hospitalized during this period was associated with a fourfold increased risk of acquiring an HAI. These studies illustrate an association between staffing workload, infections, and microbial transmission from poor adherence to hand hygiene policies.

Time demands. A perceived obstacle is that time to complete patient care duties competes with time needed for hand washing, particularly in technically intense settings such as an ICU. Hospital observational studies demonstrate that the frequency of hand washing varies between

hospital wards and occurs an average of 5 to 30 times per shift, with more hand washing opportunities in an ICU.[46] With time limitations due to patient acuity demands or nurse-patient ratios and limited availability of sinks, the use of waterless, alcohol-based hand rubs has been shown to improve health care workers' compliance with hand hygiene practices in the ICU.[47]

Hand washing behaviors. Observational studies have found that on average, health care workers adhere to recommended hand hygiene procedures 40 percent of the time (with a range of 5 to 80 percent).[44] These studies implemented various interventions to improve hand washing, but summarized effects by measuring responses over a short time frame, without demonstrating long-lasting behavioral improvements. Two studies demonstrated the use of multidisciplinary interventions to change the organizational culture on frequency of hand washing that resulted in sustained improvements during a longer followup time period.[48, 49]

Behavioral theories that examine the relationship of multiple factors affecting behavioral choices have been applied to the complex issue of hand washing compliance. These theories illustrate the influence of the individual *intention* to perform hand washing and organizational influences that affect the outcome behavior. The Theory of Planned Behavior has been studied in this context, acknowledging that the intention to wash hands involves a person's (1) attitude whether or not the behavior is beneficial to themselves, (2) perception of pressure from peers, and (3) perceived control on the ease or difficulty in performing the behavior.[50–53] These perceptions are also influenced by the strength of the person's beliefs about the significance of the outcomes of the behavior; the normative beliefs, which involve the individual evaluation of peer expectations; and control beliefs, which are based on a person's perception of their ability to overcome obstacles that obstruct their completion of the behavior.

Monitoring compliance. Although standards for hand hygiene practices have been published with an evidence-based guideline[44] and professional collaborations have produced the *How-to-Guide: Improving Hand Hygiene,*[54] there is no standardized method or tool for measuring adherence to institutional policy. Varying quality improvement methodologies and a lack of consensus on how to measure hand hygiene compliance have made it difficult to determine the effectiveness of hand hygiene expectations within and across health care settings. The Joint Commission has instituted a partnership with major infection control leadership organizations in the United States and abroad to identify best approaches for measuring compliance with hand hygiene guidelines in health care organizations though its Consensus Measurement in Hand Hygiene (CMHH) project. The participating organizations include APIC, CDC, the Society for Healthcare Epidemiology of America, the World Health Organization World Alliance for Patient Safety, the Institute for Healthcare Improvement, and the National Foundation for Infectious Diseases. The final product of this project, due to be completed in early 2008, will be an educational monograph that recommends best practices for measuring hand hygiene compliance.[55]

Summary. Hand hygiene adherence and promotion involve multiple factors at the individual and system level to provide an institutional safety climate for patients and health care staff. Methods used to promote improved hand hygiene require multidisciplinary participation to identify individual beliefs, adherence factors, and perceived barriers. Program successes have been summarized and should be reviewed to establish improved hand hygiene as a priority program at your facility.[44, 56, 57]

Hand Hygiene: Key Points

- The practice of appropriate hand hygiene and glove usage is a major contributor to patient safety and reduction in HAIs. It is more cost effective than the treatment costs involved in a health care–associated infection.
- Joint Commission infection control standards include hand washing and HAI sentinel event review, which are applicable to ambulatory care, behavioral health care, home care, hospitals, laboratories, and long-term care organizations accredited by the Joint Commission.
- Hand hygiene is the responsibility of the individual practitioner and the institution. Developing a patient safety culture backed by administrative support to provide resources and incentives for hand washing is crucial to a successful outcome.
- Hand hygiene promotion should be an institutional priority.
- Select methods to promote and monitor improved hand hygiene. Monitor outcomes of adherence to hand hygiene in association with reduced incidence of HAI.
- Establish an evaluation model to recognize missed opportunities for appropriate hand hygiene.

Environmental Cleanliness

The health care environment surrounding a patient contains a diverse population of pathogenic microorganisms that arise from a patient's normal, intact skin or from infected wounds. Approximately 10^6 flat, keratinized, dead squamous epithelium cells containing microorganisms are shed daily from normal skin,[58] and patient gowns, bed linens, and bedside furniture can easily become contaminated with patient flora. Surfaces in the patient care setting can also be contaminated with pathogenic organisms (e.g., from a patient colonized or infected with MRSA, VRE, or *Clostridium difficile*) and can harbor viable organisms for several days. Contaminated surfaces, such as blood pressure cuffs, nursing uniforms, faucets, and computer keyboards,[59, 60] can serve as reservoirs of health care pathogens and vectors for cross-contamination to patients. Studies have demonstrated that health care workers acquire microorganisms on gloved hands without performing direct patient contact and when touching surfaces near a colonized patient.[59, 61] Another study determined that a health care worker's hand became contaminated after entering a regular patient's room (one who was not on contact precautions) and only touching common surfaces close to the patient (bed rails, bedside table), without direct patient contact. The same hand contact was done by other personnel in unoccupied rooms that had been terminally cleaned after patient discharge. Ungloved hands became contaminated with low levels of pathogenic microorganisms more than 50 percent of the time, even from surfaces in rooms that had been terminally cleaned after patient discharge.[62] It is important to consider this likelihood of hand contamination could occur (contamination would also apply to the external surface of gloves, if worn) and to perform routine hand hygiene to bare hands or ungloved hands to reduce hand contamination before touching clean**,** general-use surfaces (e.g., computer keyboard, telephone, med cart, medical record, cleaning supplies, etc.). Proper disinfection of common surfaces and proper hand hygiene procedures (after direct contact to surfaces or contact with glove usage) is also critically important to reduce direct or indirect routes of transmission.[63] Persistence of environmental contamination after room disinfection can occur and has been recently demonstrated to increase the risk of transmission to the next susceptible room occupants.[64–66]

Thus, patients with known colonization or diseases with multi-drug-resistant organisms or *Clostridium difficile* require Contact Precautions in addition to the Standard Precautions to reduce the risk of transmission from the patient and the contaminated environment to others.

Nurses can ensure clean medical equipment is used between patients and can work with environmental services personnel to maximize clean conditions in and around patient rooms. It is necessary to consistently perform hand hygiene after routine patient care or contact with environmental surfaces in the immediate vicinity of the patient. Infection control procedures are recommended to reduce cross-contamination under the following situations:[67]

1. Use EPA-registered chemical germicides for standard cleaning and disinfection of medical equipment that comes into contact with more than one patient.
2. If *Clostridium difficile* infection has been documented, use hypochlorite-based products for surface disinfection as no EPA-registered products are specific for inactivating the spore form of the organism.
3. Ensure compliance by housekeeping staff with cleaning and disinfection procedures, particularly high-touch surfaces in patient care areas (e.g., bed rails, carts, charts, bedside commodes, doorknobs, or faucet handles).
4. When contact precautions are indicated for patient care (e.g., MRSA, VRE, *C. difficile*, abscess, diarrheal disease), use disposable patient care items (e.g., blood pressure cuffs) wherever possible to minimize cross-contamination with multiple drug-resistant microorganisms.
5. Advise families, visitors, and patients regarding the importance of hand hygiene to minimize the spread of body substance contamination (e.g., respiratory secretions or fecal matter) to surfaces.

A patient safety goal could be to adopt a personal or an institutional pledge, similar to the following: I (or name of health care facility) am committed to ensuring that proper infection control and environmental disinfection procedures are performed to reduce cross-contamination and transmission so that a person admitted or visiting to this facility shall not become newly colonized or infected with a bacterium derived from another patient or health care worker's microbial flora.

Leadership

Health care workers dedicate enormous effort to providing care for complex medical needs of patients, to heal, to continuously follow science to improve the quality of care—all the while consciously performing to the best of their ability to *Primum non nocere* (First, do no harm). Though medical errors and adverse events do occur, many can be attributed to system problems that have impacted processes used by the health care worker, leading to an undesired outcome. Health care workers evaluate their professional impact based on outcomes that demonstrate that medical and nursing orders are completed properly, that a sentinel event did not occur, clinical judgment was properly utilized to improve patient care, and that most patients leave in stable or better health than when they arrived. With all the complicated patient care administered, if the patient did not acquire an infection during a hospitalization, is that an indication that all patient care interactions were practiced aseptically? Or could the lack of infection be attributed to some process interactions where the patient received a microbial exposure that was less than the threshold needed to acquire an infection or, fortuitously, the patient had enough natural immunity to ward off a potential infection? Although success is measured by an outcome with or without infection, we should consistently practice in such a manner to reduce patient exposure to exogenous microorganisms, which would consequently reduce the risk of infection.

Responsibility for risk reduction involves the institution administrators, directors, and individual practitioners. It is clear that leaders drive values, values drive behaviors, and

behaviors drive performance of an organization. The collective behaviors of an organization define its culture. The engagement of nursing leaders to collaborate with coworkers and hospital administrators in safety, teamwork, and communication strategies are critical requirements to improve safe and reliable care. Developed and applied concurrently, they weave a supporting framework for the effective implementation of new technologies and evidence-based practices.[68] If patients are not receiving all the evidence-based care that is indicated (regardless of a noninfectious outcome measure), then we have a professional obligation to demonstrate leadership to develop the methods to improve that care. The challenge is how to develop and sustain the change necessary to translate infection prevention knowledge into everyday clinical practice. As each person accepts his or her role in that responsibility, that leadership and role model example will influence a standard culture and expectation for all health care workers and support personnel to implement best practices.

Each institution must communicate the evidence-based practices to health care staff, have access to expertise about infection control practices, employ the necessary resources and incentives to implement change, and receive real-time feedback of national and comparative hospital-specific data.

> Health care institutions simply must expect more reliable performance of essential infection-control practices, such as hand hygiene and proper use of gloves. It is no longer acceptable for hospitals with substandard adherence to these basic interventions to excuse their performance as being no worse than the dismal results in published reports. Most institutions still tolerate defect or failure rates in hand hygiene of 40 percent or more—levels that would be considered shocking in any other industry[69] (p. 274).

Institution improvements should focus on process improvements that sustain best practices, using multifactorial approaches, and a commitment from the top administration through all levels of staff and employees to implement best practices.[70]

Proper Use of Personal Protective Equipment

Infection control practices to reduce HAI include the use of protective barriers (e.g., gloves, gowns, face mask, protective eyewear, face shield) to reduce occupational transmission of organisms from the patient to the health care worker and from the health care worker to the patient. Personal protective equipment (PPE) is used by health care workers to protect their skin and mucous membranes of the eyes, nose, and mouth from exposure to blood or other potentially infectious body fluids or materials and to avoid parenteral contact. The Occupational Safety and Health Administration's Bloodborne Pathogens Standard states that health care workers should receive education on the use of protective barriers to prevent occupational exposures, be able to identify work-related infection risks, and have access to PPE and vaccinations.[71]

Proper usage, wear, and removal of PPE are important to provide maximum protection to the health care worker. However, PPE may not be 100 percent protective, individual work practices may lead to exposure (e.g., needlestick injury), breaches in PPE might occur, and some breaches may go unrecognized. All PPE should be removed when leaving the patient care area.[25] Gloves prevent gross contamination of the hands when touching body fluids, reduce the likelihood that microorganisms present on the hands of personnel will be transmitted to patients during invasive or other patient care procedures, and reduce the likelihood that hands of personnel contaminated with microorganisms from a patient or a fomite can transmit these microorganisms to another

patient. Gloves may have small, unapparent defects or may be torn during use, and hands can become contaminated during removal of gloves,[72–75] thus hand hygiene is essential before donning another pair of gloves.

Various types of masks, goggles, and face shields are worn alone or in combination to provide barrier protection. A surgical mask protects a patient against microorganisms from the wearer and protects the health care worker from large-particle droplet spatter that may be created from a splash-generating procedure. When a mask becomes wet from exhaled moist air, the resistance to airflow through the mask increases. This causes more airflow to pass around edges of the mask. The mask should be changed between patients, and if at anytime the mask becomes wet, it should be changed as soon as possible. Gowns are worn to prevent contamination of clothing and to protect the skin of health care personnel from blood and body fluid exposures. Gowns specially treated to make them impermeable to liquids, leg coverings, boots, or shoe covers provide greater protection to the skin when splashes or large quantities of potentially infective material are present or anticipated. Gowns are also worn during the care of patients infected with epidemiologically important microorganisms to reduce the opportunity for transmission of pathogens from patients or items in their environment to other patients or environments. When gowns are worn, they must be removed before leaving the patient care area and hand hygiene must be performed.

Improper use and removal of PPE can have adverse health consequences to the health care worker. During the 2003 severe acute respiratory syndrome (SARS) outbreak in Canada, 44 percent of the probable SARS cases were in health care workers. After institutional implementation of SARS-specific infection control precautions, 17 workers developed disease. Fifteen were interviewed to determine their knowledge and work practices that could have contributed to their infection. Only 9 (60 percent) reported they had received formal infection control training; 13 (87 percent) were unsure of the proper order in which to don and remove PPE; 6 (40 percent) reused items (e.g., stethoscopes, goggles, and cleaning equipment) elsewhere on the ward after initial use in the room of a SARS patient; and 8 (54 percent) were personally aware of a breach in infection control precautions. Fatigue and multiple consecutive shifts may have contributed to the transmission.[76]

From the experiences observed during the SARS outbreak, CDC developed training materials to increase the safety of the health care worker environment through improved use of PPE by health care personnel. Posters (bilingual), slides, and video information are available on the CDC Web site: http://www.cdc.gov/ncidod/dhqp/ppe.html.

Consistent Evidence-Based Practices

Professional organizations for infection control and health care epidemiology publish evidence-based guidelines regarding the practice of health care infection control, strategies for surveillance and prevention, and control of HAIs in U.S. health care facilities. These consensus-based scientific publications provide priority recommendations on the basis of the existing scientific data; theoretical rationale; and applicability of well-designed experimental, clinical, or epidemiologic studies to prevent HAIs in different patient care settings. Additionally, the Joint Commission's initiative, Shared Visions—New Pathways 2004 accreditation process, focuses on continuous compliance with its standards, which contributes to health care organizations' maintenance of safe, quality care and improved organizational performance.[77]

Despite the high educational level of health care workers and knowledge of aseptic practices, adherence to published infection control precautions is not consistently applied.[78] In one study, a

self-reported questionnaire demonstrated that although all health care providers knew the appropriate protective barrier equipment required for a particular patient care interaction, their reasons for nonadherence included perceived time constraints (64 percent), inconvenience (52 percent), and presumption that the patient was not infected (34 percent).[79] The observed rate of compliance was inversely related to the years of health care experience.

Translation of evidence-based guidelines into clinical practice may require more than reliance on an individual practitioner's knowledge and intentions. Organizational interventions may be necessary to better understand the barriers that impede the process of effectively reviewing and implementing evidenced-based practices into daily clinical practice.[80–83] Standard policies and standards of practice should be time specific, measurable, and should also define the specific population of patients that will be affected. When the institution implements an evidence-based guideline that updates the current policy, a multidisciplinary intervention should be planned to ensure staff concurrence with the change; agreement that the new approach is crucial; an assurance that there will be adequate staff, knowledge, and resources to implement the change; and a method to evaluate the impact of the change.[84]

Antimicrobial-Resistance Campaign

"In theory, there is no difference between theory and practice. But in practice, there is."
Jan L. A. van de Snepshceut, computer scientist and educator

Background. After the first use of penicillin in the 1950s, antibiotic resistance developed rapidly in some bacteria such as *Staphylococcus aureus.* Over the last several decades, a shift in the etiology of more easily treated pathogens has increased toward more antimicrobial-resistant pathogens with fewer options for therapy. Infections from antimicrobial-resistant bacteria increase the cost of health care, cause higher morbidity and mortality, and lengthen hospital stays compared to infections from organisms susceptible to common, inexpensive antimicrobials. Antimicrobial resistance has continued to emerge as a significant hospital problem affecting patient outcomes by enhancing microbial virulence, causing a delay in the administration of effective antibiotic therapy, and limiting options for available therapeutic agents. In a 2003 Institute of Medicine report, antimicrobial resistance was noted as a paramount microbial threat of the 21st century.[85]

Burden of organisms. Rates of antimicrobial resistance among hospital and community pathogens have increased considerably during the past decade. More than 70 percent of the bacteria that cause hospital-associated infections are resistant to at least one of the drugs most commonly used to treat these infections.[86] According to 2003 National Nosocomial Infections Surveillance System data from ICU patients, 60 percent of *Staphylococcus aureus* isolates were resistant to methicillin, oxacillin, or nafcillin (MRSA)—an 11 percent increase from data reported the year before.[87] There was a nearly 50-percent increase in nonsusceptible *Klebsiella pneumoniae* isolates to 3rd generation cephalosporins between 2002 and 2003. Although the rate of vancomycin-resistant enterococcus (VRE) has shown a less drastic increase than previous years, it still increased 12 percent in 2003 (for a total of 28.5 percent of all enterococci isolates).

Another recent national survey of antimicrobial resistance trends and outbreak frequency was performed among U.S. hospitals (those hospitals having at least 50 beds, both general medical and surgical services, and accreditation by the Joint Commission) using the American Hospital Association annual survey data set.[88] A total of 494 of the 670 hospital laboratories (74 percent) responded. Antimicrobial resistance rates were highest for oxacillin-resistant *Staphylococcus*

aureus (ORSA, also referred to as MRSA) (36 percent); two-thirds of the hospitals reported increasing MRSA rates, 4 percent reported decreasing rates, and 24 percent reported MRSA outbreaks.

Mechanism of antibiotic resistance. The treatment of bacterial infections is not a straightforward process. Bacterial microorganisms are initially susceptible to a new antibiotic, but over time, as use of the antibiotic increases, new generations of the organism will selectively adapt by developing antibiotic resistance. These organisms have the ability to undergo protective spontaneous mutation within themselves or acquire an exogenous antibiotic-resistant gene through genetic transfer from another organism, which enables it to inactivate an antibiotic or nullify its killing activity. The human microbial population includes a combination of susceptible bacteria and antibiotic-resistant bacteria. Antimicrobial usage changes the competitive balance of the microbial population by decreasing the amount of susceptible bacteria, providing an opportunity for resistant bacteria to flourish. Areas within hospitals such as ICUs that have high rates of antimicrobial usage also have the highest rates of antimicrobial resistance.

Patients can acquire an antibiotic-resistant organism through other mechanisms. Increased antibiotic treatments received in community settings can lead to the presence or colonization of antimicrobial-resistant organisms in the community population, which can be introduced into the hospital by patients on admission. These colonized organisms may not be detected if the patient is admitted for noninfectious reasons. This underscores the need for routine hand hygiene after all patient care, not just after care to patients on Contact Precautions. Often, it becomes apparent that silent transmission has occurred when the newly discovered presence of a resistant organism can be traced back to another patient who is later found to have been infected or colonized with the resistant organism. More frequently, however, the exact source of resistant organisms or the source of transmission within the institution remains undetermined.

Prevention of antibiotic-resistant organisms. Authors of evidence-based guidelines on the increasing occurrence of multidrug-resistant organisms propose these interventions: stewardship of antimicrobial use, an active system of surveillance for patients with antimicrobial-resistant organisms, and an efficient infection control program to minimize secondary spread of resistance.[89–91] Antimicrobial stewardship includes not only limiting the use of inappropriate agents, but also selecting the appropriate antibiotic, dosage, and duration of therapy to achieve optimal efficacy in managing infections. A prospective study on hospital mortality due to inadequate antimicrobial treatment demonstrated that the infection-related mortality rate for patients receiving inadequate antimicrobial treatment (42 percent) was significantly greater than the infection-related mortality rate of patients receiving adequate antimicrobial treatment (17.7 percent) in a medical or surgical ICU setting.[92]

Earlier guideline recommendations by professional organizations were published between 1995 and 1997 for the prevention of antimicrobial resistance in hospitals.[93–95] To evaluate the application of the recommendations, a cross-sectional survey was performed to determine what types of antimicrobial-use programs were being used among 47 U.S. hospitals participating in the ICU component of the CDC's National Nosocomial Infections Surveillance System.[96] All 47 hospitals had some established programs, although their practices did not meet all of the published recommendations. For example, one programmatic practice was to consult with an infectious disease physician or pharmacist (used 60–70 percent of the time) to discuss initial antimicrobial options; however, only 40 percent reported a system to measure compliance with administering the recommended antimicrobial agent. The Cochrane Collaboration reviewed 66 published papers to develop "interventions to improve antibiotic prescribing practices for

hospital inpatients."[97] Interventions were aimed at varying outcomes (e.g., increase/decrease treatment, regimen, timing of dosing, restrictive or persuasive methods to reduce unnecessary antibiotic use). Studies showed that about half of the time, hospital physicians were not prescribing antibiotics properly. Nonetheless, most interventions demonstrated some improvement in antibiotic prescribing to reduce antimicrobial resistance or hospital-acquired infections. Hospital campaigns to prevent antimicrobial resistance include steps to (1) employ programs to prevent infections, (2) use strategies to diagnose and treat infections effectively, (3) operate and evaluate antimicrobial use guidelines (stop orders, restrictions, and criteria-based clinical practice guidelines), and (4) ensure infection control practices to reduce the likelihood of transmission.[98] Nurse practitioners have a role as part of the health care team diagnosing and treating infections appropriately and should be familiar with strategies to improve antimicrobial use. All health care workers play a critical role in reducing the risk of transmission.

Based on the factors contributing to antibiotic resistance in health care settings that were identified through data collection, guidelines, professional recommendations, and scientific research, the CDC compiled several tools in 2002 to increase awareness in health care settings. The Campaign to Prevent Antimicrobial Resistance in health care settings utilizes four strategies to increase awareness and encourage the best practices for antibiotic use and interventional programs to prevent resistance: prevent infection, diagnose and treat infection effectively, use antimicrobials wisely, and prevent transmission. Laminated cards, posters, slide sets, and fact sheets that can be used in a health care setting to promote recognition and utilization are listed at http://www.cdc.gov/drugresistance/healthcare/default.htm. A summary of the CDC's 12-step program and specific nursing interventions is provided in Appendix 2.

Summary of key concepts. A program that only scrutinizes and monitors antimicrobial use will not be effective to reduce antimicrobial resistance; it must also implement proper infection control measures and have laboratory, surveillance, and administrative support. The optimal strategy for control of antibiotic-resistant organisms is not the same for every health care facility as this individually depends on the levels of endemic colonization, presence of one or more resistant organisms, and levels of infection (low or outbreak levels). The ICP and hospital epidemiologist at each facility are valuable resources to provide programmatic education and recommend targeted infection control measures (e.g., use of personal protective barriers, hand hygiene resources, patient placement/segregation, and admission surveillance cultures). Similar to the example of antibiotic consultation practices and outcome measures, this plan will have little effect or opportunity to reduce the morbidity and mortality of infectious complications unless there is committed organizational support, including expert recommendations that are adopted into daily practice routines. Nursing personnel have the most patient contact and the most opportunity to interrupt the chain of transmission through adherence to consistent aseptic practices.

Respiratory Hygiene and Cough Etiquette

Respiratory viruses are easily disseminated in a closed setting such as a health care facility and can cause outbreaks that contribute to the morbidity of patients and health care staff. Personnel and patients with a respiratory illness commonly transmit viruses through droplet spread. Droplets are spread into the air during sneezing, talking, and coughing and can settle on surfaces. Transmission occurs by direct contact with mucous membranes or by touching a contaminated surface and self-inoculating mucous membranes. Respiratory viruses can sometimes have aerosol dissemination.

Precautions to prevent the transmission of all respiratory illnesses, including influenza, have been developed.[99] The following infection control measures should be implemented at the first point of contact with a symptomatic or potentially infected person. Occupational health policies should be in place to guide management of symptomatic health care workers.

1. Post visual alerts (in appropriate languages) at the entrance to outpatient facilities instructing patients and escorts (e.g., family, friends) to notify health care personnel of symptoms of a respiratory infection when they first register for care.
2. Patients and health care staff should consistently practice the following:
   a. Cover the nose/mouth when coughing or sneezing.
   b. Use tissues to contain respiratory secretions and dispose of them in the nearest waste receptacle after use.
   c. Perform hand hygiene after having contact with respiratory secretions and contaminated objects or materials.
3. During periods of increased respiratory infection activity in the community or year-round, offer masks to persons who are coughing. Either procedure masks (i.e., with ear loops) or surgical masks (i.e., with ties) may be used to contain respiratory secretions. Encourage coughing persons to sit at least 3 feet away from others in common waiting areas.
4. Health care personnel should wear a surgical or procedure mask for close contact (and gloves as needed) when examining a patient with symptoms of a respiratory infection. Maintain precautions unless it is determined that the cause of symptoms is not an infectious agent (e.g., allergies).

Evaluation

The ICP or a nurse on a specific patient care unit should design a periodic evaluation program of infection control practices, including aseptic technique practices. Evaluation methods include a self-assessment survey of intended practices, direct observational assessments by another health care worker or a patient, and self-completion of checklists that review work practices and identify opportunities for improvement within the health care operations. If deficiencies or problems in the implementation of standardized infection control procedures are identified, further evaluation activities (e.g., root-cause analysis) may be indicated to identify and rectify the contributing factors to the problem.[100]

Most evaluation reviews are generated after a major, life-threatening error occurs, which usually happens infrequently. Historically, when an evaluation determined that a process completed by personnel was deficient, problem-solving efforts focused on the identification of the specific individual(s) who “caused” the problem. Later, quality improvement efforts focused on developing a culture of safety and recognized that additional contributions to errors were due to complex, poorly designed systems. The advantage of an evaluation that reviews system problems is that it encourages health care professionals to report adverse events and near misses that might be preventable in the future, while balancing the identification of system problems with holding individual providers responsible for their everyday practices. Improvement is impossible without evaluation reports to provide data on the factors that contribute to mistakes and lead to subsequent individual and system changes that support safer practices.[101]

An evaluation strategy examining process measures include the following examples:

- Document staff use of maximum sterile barriers (cap, mask, sterile gown, sterile gloves, large sterile sheet) and aseptic technique for the insertion of central intravenous catheters or guidewire exchange.
- Document timing of antibiotic prophylaxis when used in surgical patients (e.g., within 1 hour of incision).
- Document if hand hygiene is performed and clean or sterile gloves are worn before assessing a catheter insertion site or changing a dressing on intravascular catheters.
- Document time elapsed from when patient culture (microbiology and susceptibility) results are reported and when the appropriate isolation precautions are instituted (patient room placement, signs, PPE used, disposable equipment used, medical record documentation, etc.).
- Ensure that staff (nurses, doctors, and housekeeping) enter a contact isolation room using the specified personal protective barriers (e.g., gloves, gown) on each entry.
- Ensure that staff properly remove PPE after leaving a patient's room.
- Assess the annual rates of influenza vaccination for health care workers and other personnel eligible to receive vaccination; assess the rates of influenza vaccination for patients.
- Ensure that needle disposal containers are no more than three-quarters full at time of disposal.
- Periodically monitor and record adherence with the hand hygiene guidelines: the number of times personnel washed their hands divided by the number of hand-hygiene opportunities, computed by ward or by service. Provide feedback to personnel regarding their performance.
- Monitor the volume of alcohol-based hand rub (or detergent used for handwashing or hand antisepsis) used per 1,000 patient days.
- When outbreaks of infection occur, assess the adequacy of health care worker hand hygiene.
- When a patient with a known colonization or infection with a multidrug-resistant organism (e.g., MRSA, VRE) is transferred to your facility, evaluate effectiveness of system notification to health care personnel in the receiving facility.
- Record compliance with hospital policy for catheter-site dressing changes.

Research Implications[*]

1. Research and apply behavioral and management sciences to achieve implementation of evidence-based clinical guidelines and compliance with infection prevention policies.
2. Develop methods to improve the appropriateness of antimicrobial use based on identified antimicrobial control measures and institution microbial susceptibility patterns.
3. Collect data for the economic impact of HAIs and other adverse effects and resulting return of investment for prevention methods.
4. Identify specific components of infection prevention and control programs and staffing in health care institutions that are effective (and cost effective) in reducing rates of infection.

[*] Adapted from Lynch et al. 2001[104] and Aboelela et al. 2006.[105]

5. Improve health care institution information systems for seamless review of appropriateness of infection control-related care based on patient diagnosis.
6. Determine standard indices for measurement of effectiveness and cost of infection control measures.
7. Measure effect of staffing changes (reduced personnel, prolonged work hours, varying levels of formal education) on patient outcomes related to infectious outcomes of morbidity and mortality (e.g., colonization of microorganisms, postoperative wound infections, and catheter-related infections).
8. Design studies so that independent effects of specific interventions can be identified.
9. Monitor the implementation of interventions in a multicenter study to examine a cause-and-effect response and differentiate between efficacy and effectiveness.
10. Develop interdisciplinary research teams to improve the rigor and sophistication of studies conducted.

Conclusions

It is the responsibility of all health care providers to enact principles of care to prevent health care–associated infections, though not all infections can be prevented. Certain patient risk factors such as advanced age, underlying disease and severity of illness, and sometimes the immune status are not modifiable and directly contribute to a patient's risk of infection. Depending on the patient's susceptibility, a patient can develop an infection due to the emergence of their own endogenous organisms or by cross-contamination in the health care setting. Benefits of antimicrobial therapy will alter the microbial flora by reducing one microbial presence but may allow the emergence of another, causing a new infection (e.g., antibiotic-associated diarrhea).

Nurses can reduce the risk for infection and colonization using evidence-based aseptic work practices that diminish the entry of endogenous or exogenous organisms via invasive medical devices. Proper use of personal protective barriers and proper hand hygiene is paramount to reducing the risk of exogenous transmission to a susceptible patient. For example, microorganisms have been found in the environment surrounding a patient and on portable medical equipment used in the room. Environmental surfaces around a patient infected or colonized with a multidrug-resistant organism can also become contaminated. Health care workers should be aware that they can pick up environmental contamination of microorganisms on hands or gloves, even without performing direct patient care. Proper use and removal of PPE followed by hand hygiene will reduce the transient microbial load that can be transmitted to self or to others. Identified aseptic and infection control practices have been proven to reduce the dissemination of organisms to a single patient, to prevent repeated transmissions that contribute to an outbreak situation among multiple patients, or to become established in the health care environment as endemic hospital flora.

Nursing has many complicated scopes of practice, which challenge time management, priority setting, and efficiency of practice. Although system and administrative support is beneficial to supporting aspects of nursing care, direct care is performed by individuals. Every individual nurse focuses on making a difference throughout the daily workloads and enormous responsibilities but changes in a patient's medical condition can become overwhelming. One nurse comes to mind who found the resolve to make significant strides within the patient ward dealing with chronically overwhelming situations. She was administratively responsible for

directing and addressing the challenges of all patients' chronic wound infections, ongoing cross-contamination, lack of needed medical supplies and equipment, severe understaffing, working extra shifts, and still finding time to provide care and comfort to patients. By her personal efforts to improve wound care, aseptic practices, and hand hygiene among all nursing and medical staff, mortality dropped in a dramatic decline from 33 percent to 2 percent within a 9-month period.[102] These sustained and dedicated efforts to reduce patient infections and improve patient care in light of overwhelming adversity set a standard of practice for all nurses to follow. That nurse was Florence Nightingale, defining the art of nursing in the 1850s. Although medical care is more advanced and technically more complex since that time, it was the dedication of a nurse (like you) to ensure aseptic practices despite the significant nursing demands of patient care that makes the difference for the patients—then and now.

National surveys of the public have repeatedly found nursing to be one of the most trusted professions. The public trusts us to provide safe care and employ best practices by following certain principles: (1) to not work while having an infectious illness, (2) to be knowledgeable about the methods to protect our patients from transmission of disease, (3) to perform aseptic practice and monitor patient infections, (4) to participate in quality improvement initiatives to reduce infections, and (5) to provide care even if it means self-risk from infection. As nurses we have an ethical obligation to meet that trust and uphold the highest standards for our patients and the public, whether we are providing direct care, teaching about proper health care, or overseeing nursing practice.[103]

It has been demonstrated that nursing and medical practices can pick up transient microorganisms from intact patient skin and from environmental surfaces. Although the amount of contamination is not quantified and the exact incidence is not apparent, it does occur. Hand hygiene and aseptic practices before caring for a susceptible patient can reduce the transient carriage and transfer of microorganisms. The protective benefits of infection control using evidence-based practices are cost effective and numerous: they not only contribute to the best individual patient care outcome, but also protect health care workers, increase public awareness in all health care settings about infection control issues, and maintain the highest standards in nursing, which positively contributes to our goal for the best possible patient and public health outcomes.

Appendix 2. Campaign To Prevent Antimicrobial Resistance in Health Care Settings

Centers for Disease Control and Prevention

Adapted from information on http://www.cdc.gov/drugresistance/healthcare/default.htm

Strategy	Steps	Related Fact	Nursing Actions
Prevent Infection	1. Influenza and Pneumococcal vaccinations	Predischarge immunizations of at-risk hospital patients and health care personnel will prevent infections.	♦ Give influenza and *pneumococcal* vaccine to at-risk patients before discharge. ♦ Receive annual influenza vaccinations.
	2. Get the catheter out	Catheters and other invasive devices are the # 1 exogenous cause of hospital-onset infections.	Use catheters— ♦ Only when essential. ♦ With proper insertion and care protocols. ♦ Only as long as needed.
Diagnose and Treat Infection Appropriately	3. Target the pathogen	Appropriate therapy (correct regimen, timing, dosage, route, and duration) saves lives.	♦ Culture the patient. ♦ Verify empiric therapy is to a likely pathogen and definitive therapy is treating a known pathogen.
	4. Access the experts	Infectious disease expert collaboration improves the outcome of serious infections.	Incorporate guidance from infectious disease experts into daily care plan. All full-time, part-time, and contract staff should know and utilize recommendations.
Use Antimicrobials Wisely	5. Practice antimicrobial control	Programs to improve antibiotic use are effective.	Know your pharmacy policies on ordering, restrictions, switching, and stopping. Utilize or develop online ordering with computerized decision support/rationale.
	6. Use local data	The prevalence of resistance can vary by time, locale, patient population, hospital unit, and length of stay.	Know the common organisms in your clinical area and the effective antibiotics used to treat each infection.
	7. Treat infection, not contamination	A major cause of antimicrobial overuse is “treatment” based on results of patient cultures that become contaminated.	Utilize proper protocols to collect patient blood and other specimens for culture. Submit to laboratory in proper medium/collection containers and within the recommended time.
	8. Treat infection, not colonization	A major cause of antimicrobial overuse is “treatment” based on colonization.	Be familiar with practice guidelines for clinical assessments of new symptoms (i.e., fever) in critically ill patients and when cultures are warranted.
	9. Know when to say “no” to vanco	Vancomycin overuse promotes emergence, selection, and spread of resistant pathogens.	Be familiar with hospital policy on proper vancomycin utilization and when it should be discouraged (e.g., routine surgical prophylaxis and the exceptions, etc.).

Strategy	Steps	Related Fact	Nursing Actions
	10. Stop antimicrobial treatment	Failure to stop unnecessary antimicrobial treatment contributes to overuse and resistance.	Be aware of the patient's infection status and need for an antibiotic. Stop or don't use antibiotics when ♦ The infection is cured; ♦ Cultures are negative and infection is unlikely; and ♦ Infection is not diagnosed.
Prevent Transmission	11. Isolate the pathogen	Patient-to-patient spread of microorganisms can be prevented.	Practice strict aseptic technique to prevent transmission of organisms. Strict oversight of proper contact precautions when used and proper room disinfection.
	12. Break the chain of contagion	Health care personnel can spread antimicrobial-resistant pathogens from patient to patient.	Clean hands can pick up and transfer microorganisms. Hand hygiene is essential—set an example for others.

Whole-genome sequencing

SUMMARY

Background: Haemato-oncology patients are at increased risk of infection from atypical mycobacteria such as *Mycobacterium chelonae* which are commonly found in both domestic and hospital water systems.
Aims: To describe the investigation and control measures following two patient cases of *M. chelonae* and positive water samples in the study hospital.
Methods: Water testing was undertaken from outlets, storage tanks and mains supply. Whole-genome sequencing (WGS) was used to compare patient and positive water samples. The subsequent infection control measures implemented are described.
Findings: The WGS results showed two main populations of *M. chelonae* within the group of sampled isolates. The results showed that the patient strains were unrelated to each other, but that the isolate from one patient was closely related to environmental samples from water outlets, supporting nosocomial acquisition.
Conclusions: WGS was used to investigate two patient cases of *M. chelonae* and positive water samples from a hospital water supply. Relevant control measures and the potential for chemical dosing of water systems to enhance proliferation of atypical mycobacteria are discussed.

Introduction

Mycobacterium chelonae is an environmental opportunistic mycobacterium found in hospital water systems and household plumbing [1]. It belongs to the non-tuberculous (atypical) group of mycobacteria (NTM) and is classified as a rapid grower [2]. Clinically, it can cause cutaneous lesions, bacteraemia, and invasive infections of bone and lung.

This study used whole-genome sequencing (WGS) to analyse *M. chelonae* isolates from patients and hospital water samples

following investigation of *M. chelonae* infection in two paediatric haemato-oncology patients over a 12-month period. One patient presented with a bacteraemia and the other presented with skin lesions in proximity to a Hickman line site. Both children are now in remission from the original disease, and do not require treatment for infection. Analysis of data for the preceding 10 years for all Glasgow hospitals revealed four other cases of *M. chelonae* bacteraemias in haemato-oncology patients (one in each of 2011, 2013, 2016 and 2018). Three of these cases were from a different city hospital campus.

Methods

Water testing

In response to a second case of *M. chelonae* infection in a 12-month period, water testing of outlets (pre- and post-flush) was undertaken in wards and departments where patients had been nursed. Water was also taken from basement storage tanks and the incoming mains supply. One hundred millilitres of water was filtered on to Middlebrooks agar and incubated aerobically at 35°C for 42 days. Plates were examined weekly for evidence of bacterial growth. If bacteria were present, smear microscopy using pre- and post-flush staining was performed. Acid-fast bacilli smear-positive samples were sent to the Scottish Mycobacteria Reference Laboratory for identification. Clinical and water isolates were identified using GenoType Mycobacteria CM v2.0 (Hain Lifescience, Nehren, Germany) after Genolyse extraction, in accordance with the manufacturer's instructions.

Whole-genome sequencing of patient and environmental isolates

There is no recognized molecular typing scheme available for *M. chelonae* to assess genetic relatedness. The mutation rate for *M. chelonae* is unknown, and published literature on the utility of WGS for investigation of *M. chelonae* is difficult to find, so this investigation was performed on a research basis alone.

Briefly, genomic DNA was extracted from heat-inactivated mycobacteria using a modified QIAamp DNA Mini Kit (Qiagen, Hilden, Germany) protocol using silica glass beads (adapted from Köser et al., 2013) [3]. Following Nextera XT DNA library preparation (Illumina, Cambridge, UK), paired-end sequencing was performed using 500 v2 Illumina MiSeq kits producing 2 x 250-bp reads.

Reference-based mapping was used to determine the genetic relationship between different strains based on single-nucleotide polymorphism (SNP) analysis. To identify SNPs, sequence reads were aligned to a reference genome of *M. chelonae* CCUG47445 (accession number CP007220) [4] using SMALT (http://www.sanger.ac.uk/science/tools/smalt-0). The default mapping parameters and SNP filtering were as described previously [5]. Recombination was detected in the genomes using Gubbins (http://sanger-pathogens.github.io/gubbins/) [6]. The Gubbins results were used to filter out the SNPs predicted to be associated with recombination and identify core-genome SNPs. Phylogenetic reconstruction using core SNPs was performed using RAxML Version 8.2.8 [7], using a GTR model with a gamma correction for intra-site rate variation.

To look more closely at the genetic relationship between each of the clades, reads were mapped to a de-novo genomic assembly of a representative of each clade (i.e. a more similar sequence than *M. chelonae* CCUG47445). Fastq files from MiSeq sequencing were assembled *de novo* with Velvet [8]. This has been done in WGS investigations of other mycobacteria to increase the number of successfully mapped reads, thus improving the accuracy of mapping [9].

Results

In total, 147 unfiltered water samples from outlets (taps and showers) in two paediatric haemato-oncology inpatient wards and an operating theatre complex were tested between 16th April 2019 and 24th June 2019. Atypical mycobacteria, subsequently identified as *M. chelonae*, were detected from all three areas. Sixty-eight of 147 (46%) water samples from outlets tested positive, with 34 of 68 (50%) having counts >100 colony-forming units/mL. An additional five samples were taken from water storage tanks (post-filtration) and all were negative. Three mains samples were taken by Scottish Water, and one of these tested positive for *M. chelonae*. Multiple other Gram-negative isolates (predominantly *Cupriavidus pauculus*) and fungi were also isolated from water, as described previously [10]. WGS was undertaken on 31 isolates.

The WGS results showed that there were two clonal populations within the group (Clades 1 and 2; Figure 1). The pairwise core-genome SNP distance distinguishing the two clades was ~20,000 SNPs, illustrating that they do not share a recent common ancestor and are genetically distinct. Isolates within each clade appeared to be closely related (<100 SNPs; SNP differences distinguish the isolates in each clade), which suggests that each population had separate recent common ancestors. The isolate from Patient 1 was genetically diverse from the isolates in Clade 1 and Clade 2, and was therefore considered unrelated. The SNP distance distinguishing Patient 1 from Clade 2, the genetically closest clade, was approximately 2000 SNPs. In Clade 1, the isolate from Patient 2 was firmly placed amongst the isolates sampled from the environment, although on a longer branch. The environmental isolates appear to be closely related (in terms of SNP differences), with some shown to be indistinguishable from each other. The maximum pairwise SNP distance distinguishing isolates in this clade was 19 SNPs. In addition, a number of environmental isolates (3854, 3123, 3856, 3800, 3846, 3862 and 3808) were closely related to Patient 2, as shown by SNP distances of six to eight SNPs on the tree (Figure 2). The positive water sample from the mains supply was in Clade 1, and was unrelated to patient isolates.

Discussion

M. chelonae was first discovered from the lung tissue of sea turtles by Friedmann in 1903 [11]. The organism is ubiquitous in the environment but is a rare cause of infection. Most commonly, it is associated with skin lesions, but immunosuppressed patients such as haemato-oncology patients may present with bacteraemias and disseminated infections. *M. chelonae* has been found in rivers, lakes, seawater, wastewater from

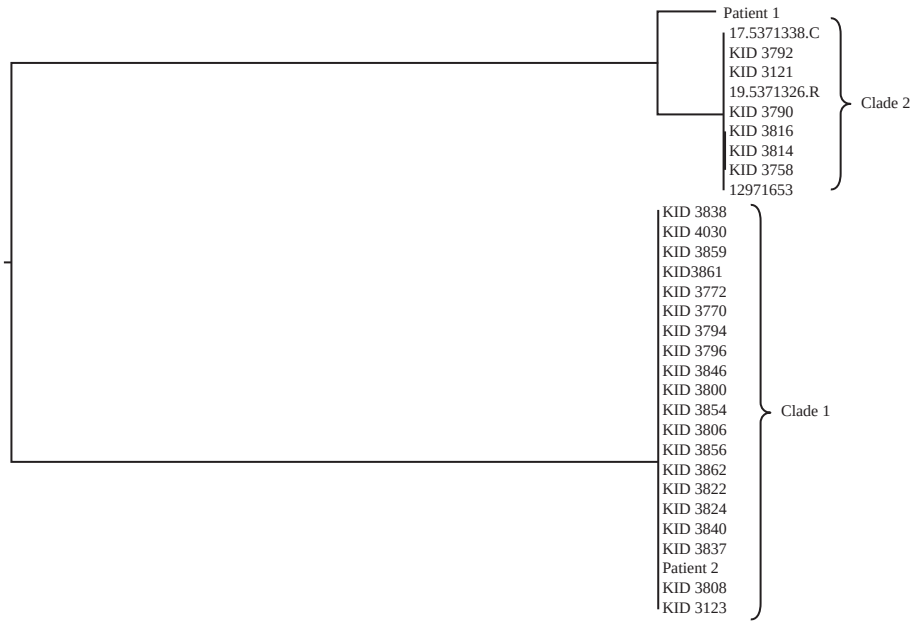

Figure 1. Diversity of the sampled *Mycobacterium chelonae* population. The maximum likelihood phylogenetic tree was built using core single-nucleotide polymorphisms (SNPs) with SNPs in regions of recombination removed. Sequence data were mapped to the *M. chelonae* CCUG47445 reference. The tree is midpoint rooted, and two clades were identified that are distinguished by less than 100 SNPs. The approximate SNP distance that distinguishes the two clades is approximately 38,000 SNPs.

hospitals, and drinking water samples [12]. Atypical mycobacteria in water systems are more resistant to chlorine, chlorine dioxide and chloramine than other organisms [13]. Warm water in premise plumbing is ideal for their proliferation, and there are extensive surfaces available for biofilm formation [13].

In some studies, water samples obtained from homes had lower rates of cultures yielding NTM than hospitals. Rates of atypical mycobacterial colonization of potable water systems ranged from 60% to 100% in hospitals, haemodialysis units and dental offices [14]. In one study in Berlin which tested two hospitals and four homes, mycobacteria were isolated predominantly from hospitals. Over 50% of samples from both hospitals contained mycobacteria, compared with only 9% from a home environment [15]. *M. gordonae* was the most common atypical mycobacterium isolated, and *M. chelonae* was also found.

With regards to virulence factors, *M. chelonae* and other NTM have a lipid-rich outer membrane which aids survival in the environment [16]. This membrane also protects against the effects of high temperature and disinfectants. NTM demonstrate surface hydrophobicity, enabling attachment to surfaces where they will grow in biofilm. The surface hydrophobicity also means that they are readily aerosolized, which is one of the routes of transmission to patients [16]. Direct contact with contaminated water can also lead to infection.

Few nosocomial outbreaks of *M. chelonae* have been reported. The first reported outbreak of nosocomial infection with an identified source was in patients undergoing liposuction in the USA [17]. Twelve patients were infected, and the organism was traced to plumbing in the procedure room. Multiple sources of contamination were identified, involving rinsing of instrumentation in tap water and inadequate disinfection/sterilization processes [17]. In another large outbreak involving 35 patients with laparoscopy port site infections, the source of *M. chelonae* was traced to water stored for rinsing instruments [18]. The organism was found in biofilm in the base of disinfectant trays and in the outer sleeves of re-usable instruments. No further cases were detected following dismantling and manual cleaning of laparoscopic equipment followed by ethylene oxide gas sterilization [18]. A contaminated humidifier was implicated in four cases of *M. chelonae* eye infections in patients who had undergone a LASIK (laser eye) procedure. Three of the four patient isolates were indistinguishable on pulsed-field gel electrophoresis from the humidifier isolate, with the fourth isolate being closely related. No further cases were detected after disposal of the humidifier and upgrading of the air-handling system [19].

In patients with cancer, atypical mycobacteria can cause exit-site infections, tunnel infections or catheter-related bacteraemias, some of which can lead to disseminated infection [20]. Outbreaks and isolated cases of atypical mycobacteria have been described in haemato-oncology patients with links to the hospital water. Five patients in one adult haemato-oncology ward developed bloodstream infection secondary to atypical mycobacteria, four cases with *M. mucogeniucm* and one with *M. canariasense*. Both of the organisms were identified in the water supply to the ward, and were identical to patient isolates on 16S-rRNA sequencing [21].

In another paediatric setting, a 20-year review of oncology patients in a US children's hospital, combined with a literature review of other reported cases, described 85 atypical mycobacteria infections in this patient group. Eighteen cases were disseminated infections and 42 cases were central-line-associated bloodstream infections (CLABSIs). Thirty-one percent of CLABSIs were associated with hospital outbreaks [22].

In a paediatric haemato-oncology ward, five patients developed *M. mucogenicum* bloodstream infection over a 6-

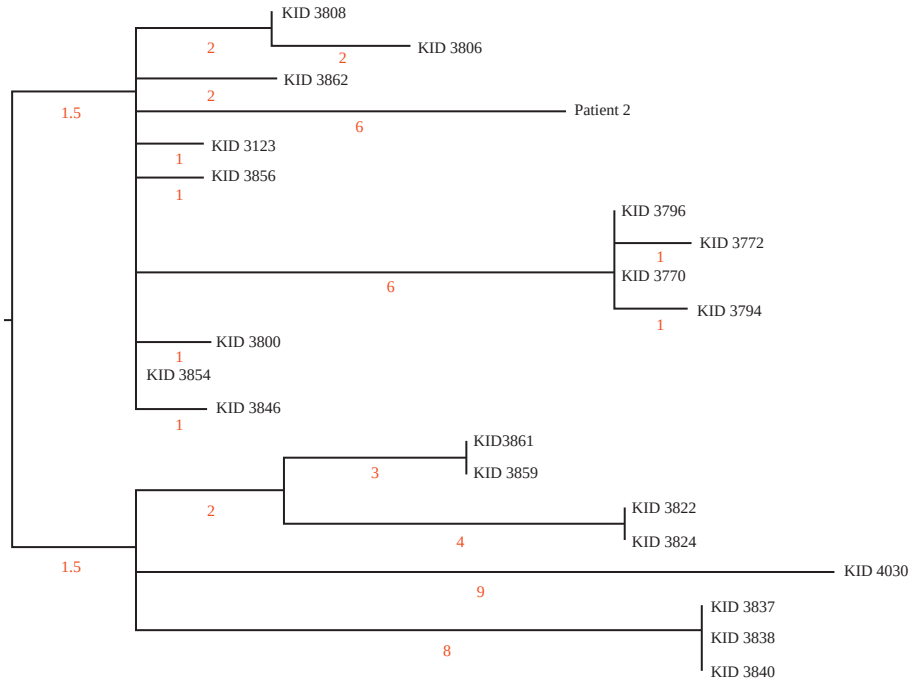

Figure 2. Diversity of Patient 2 and the environmental *Mycobacterium chelonae* population. The maximum likelihood phylogenetic tree was built using core single-nucleotide polymorphisms (SNPs). Sequence data were mapped to a de-novo assembly of Patient 2 isolate reference. The tree is midpoint rooted, and the SNP distances associated with the branch lengths are indicated in red text.

month period. Samples of water from taps indicated that they were the likely source, and this was confirmed by typing [2]. In this incident, levels of chlorine in the water were intermittently low and may have contributed to bacterial growth. A review of exit sites of central lines revealed that these were not covered properly during bathing, which may have facilitated colonization [2]. Similarly, following a cluster of atypical mycobacterial infections in haemato-oncology patients, no more cases were identified following the introduction of central venous catheter control measures, despite the bacteria continuing to be identified in the water system [23]. These control measures included new connectors and a line dressing which could remain *in situ*, covering the line site whilst patients showered [23]. A single case of disseminated *M. fortuitum* infection in a patient with leukaemia was investigated and linked to showerhead water in one hospital [24].

Increasingly, WGS has been used for investigation of mycobacterial relatedness, proving more discriminatory than MIRU-VNTR typing for *M. tuberculosis* [25], and allowing global comparisons of *M. abscessus* complex [26] and *M. chimaera* [27] in the investigation of possible mycobacterial transmission. In these studies, five, 20 and 13 SNP differences were associated with possible epidemiological linkages, respectively. Although well-defined reference strains in many NTM such as *M. chelonae* are lacking, the present study demonstrated a useful role that allows comparisons with isolates elsewhere.

Control measures for atypical mycobacteria in water systems include: increasing the water temperature to 55°C; application of point-of-use filters (POUFs); replacement of showerheads to those with large holes; and monthly disinfection of showerheads. Aerators should also be removed from taps [16]. In the study hospital, POUFs were *in situ* on the haemato-oncology wards following a previous water incident, and these were subsequently extended to all areas that patients might visit in the hospital. A programme of regular disinfection of showerheads was also undertaken. Quarterly cleaning and disinfection of showerheads and hoses was undertaken via a service exchange procedure. Following removal, parts were dismantled and physically cleaned. They were then submerged in a solution of Showerhead Plus Legionella specific descaler and biocide for a minimum contact time of 2 min.

Showerheads, in particular, offer a moist, warm and nutrient-rich environment for atypical mycobacteria to proliferate and form biofilms [28]. In one study, biofilms from showerheads were highly contaminated with atypical mycobacteria, 100-fold above background water contents [20].

The study hospital is a new-build hospital which opened in 2015. It is not clear whether atypical mycobacteria were present prior to testing in 2019, or whether their presence and detection were enhanced by the introduction of a chlorine dioxide dosing system in late 2018 to control a widespread water contamination issue [10]. On completion of each stage of the installation, chemical treatment of the domestic cold-water system commenced at a level of 1.0 mg/L for 24—48 h. Once the residual level of chlorine dioxide reached 0.1 mg/L in each part of the system, microbiological monitoring commenced. Once the residual level reached 0.2 mg/L in each part of the system, the associated plant output was reduced in stages until the residual level was 0.4 mg/L and the plant output was between 0.5 and 0.7 mg/L as a final continual water treatment baseline value. The domestic hot-water system presented an additional challenge of chlorine dioxide when exposed to high temperature gasses off. Therefore, the treatment was set at 2—4mg/L centrally to achieve a residual level of 0.5—1.0mg/l at hot water outlets peripherally.

The WGS results show that there were two main populations of *M. chelonae* within the group of sampled isolates. The limited number of SNP differences observed within each population suggests that the diversification may have happened fairly recently, but it is not possible to confirm the time scale over which this has occurred without understanding the mutation rate of the organism and/or the time of sampling. These WGS results suggest that the isolate from one patient (Patient 2) was closely related to environmental isolates from water outlets. Epidemiologically this fitted, with the patient linked in time and place to these outlets. Whilst no link with Patient 1 was established, no contemporaneous water results were available from the time this patient developed infection, so a water source in the hospital cannot be excluded completely. Whilst there were POUFs on outlets in wards, there were none in the theatre anaesthetic rooms where patients underwent procedures such as line insertions. Therefore, there was a splash risk from the proximity of sinks. This highlights the importance of applying POUFs throughout the full patient pathway.

In conclusion, haemato-oncology patients are at increased risk of infection from atypical mycobacteria such as *M. chelonae*. Atypical mycobacteria are a common finding in hospital water systems, and a single case of atypical mycobacteria infection should prompt consideration of water as a source. Water systems which are being treated with disinfectants may be of particular risk as they remove competing organisms and enable atypical mycobacteria to proliferate. WGS is a promising adjunct for the investigation of outbreaks due to atypical mycobacteria.

The role of water in healthcare-associated infections

Brooke K. Decker[a] *and Tara N. Palmore*[a,b]

Purpose of review
The aim is to discuss the epidemiology of infections that arise from contaminated water in healthcare settings, including Legionnaires' disease, other Gram-negative pathogens, nontuberculous mycobacteria, and fungi.

Recent findings
Legionella can colonize a hospital water system and infect patients despite use of preventive disinfectants. Evidence-based measures are available for secondary prevention. Vulnerable patients can develop healthcare-associated infections with waterborne organisms that are transmitted by colonization of plumbing systems, including sinks and their fixtures. Room humidifiers and decorative fountains have been implicated in serious outbreaks, and pose unwarranted risks in healthcare settings.

Summary
Design of hospital plumbing must be purposeful and thoughtful to avoid the features that foster growth and dissemination of *Legionella* and other pathogens. Exposure of patients who have central venous catheters and other invasive devices to tap water poses a risk for infection with waterborne pathogens. Healthcare facilities must conduct aggressive clinical surveillance for Legionnaires' disease and other waterborne infections in order to detect and remediate an outbreak promptly. Hand hygiene is the most important measure to prevent transmission of other Gram-negative waterborne pathogens in the healthcare setting.

Keywords
biofilm, healthcare-associated infection, Legionnaires' disease

INTRODUCTION

The complexity of modern healthcare facilities and increasing proportion of immunologically vulnerable patients make prevention of healthcare-associated waterborne infections a high priority. Several factors make hospital buildings suitable for colonization with bacteria and molds: large, complex water systems with areas of low flow predispose to stagnation and biofilm formation; water temperatures that are optimal for healthcare use may also be ideal for bacterial growth. Whereas these conditions exist in other buildings, the fragility of hospitalized patients and the presence of invasive devices put them at risk for infection with organisms that grow in hospital water. This article reviews the recent epidemiology of waterborne, healthcare-associated infections in the developed world.

LEGIONELLA

Legionnaires' disease is an important infection acquired from hospital water, and the one for which detection of a single nosocomial case should prompt an immediate investigation. The disease is typically transmitted to patients through aerosols of water that arise from showers, ice machines, decorative fountains, humidifiers, and other water sources in hospitals. The first documented nosocomial outbreak occurred nearly a decade before the discovery of the disease and its microbial cause. When McDade *et al.* [1] identified a fastidious thin-walled bacteria, *Legionella pneumophila,* as the cause of pneumonia among 182 people attending the 1976 American Legion Convention, the antibody test developed during the investigation was applied to serum specimens from a hospital outbreak. The

KEY POINTS

- Healthcare facilities must conduct careful clinical surveillance for legionellosis, including diagnostic testing specific for *Legionella* in all patients who develop nosocomial pneumonia.
- Hospitalized patients who are highly immunocompromised or have invasive devices are most susceptible to infections with waterborne pathogens that can evade the body's normal defenses.
- Devices that aerosolize water in the presence of patients, such as room humidifiers and decorative fountains, pose a risk of infection with waterborne pathogens and are not recommended for use in hospitals.

1965 outbreak at a Washington, D.C. psychiatric facility comprised 81 cases of pneumonia of unknown cause [2]. Testing demonstrated antibody responses to *Legionella* in 21 out of 23 patient sera [1]. This hospital outbreak of Legionnaires' disease thus became the first of many documented over the past 50 years.

The incidence of Legionnaires' disease in the United States nearly tripled from 2000 to 2009, with only 4% of cases associated with a known cluster [3▪▪]. More than 80% of cases are attributable to *L. pneumophila,* and a large majority of those belong to serogroup 1 [4,5]. The urine antigen assay, which detects only serogroup 1, was responsible for 97% of diagnoses, whereas culture was performed in only 5% of cases [3▪▪]. The challenges of culturing the organism make identification of other serogroups and other species uncommon. Pontiac fever is a self-limited hypersensitivity illness that occurs in immunocompetent hosts who are exposed to *Legionella*-containing aerosols, and who can have positive urine antigen assays, but do not develop pneumonia [6].

Many components of water systems have been implicated in *Legionella* transmission, including cooling towers, evaporative condensers, water heaters, and the potable water distribution system. When *L. pneumophila* is present in a hospital water system, the patients who acquire the infection generally have medical conditions that contribute to infection susceptibility [7–9], including organ or stem cell transplantation [10], chronic obstructive pulmonary disease [11], and immunosuppressive therapy [e.g. corticosteroids and tumor necrosis factor (TNF) inhibitors] [10–12]. Healthcare personnel are exposed and may seroconvert, but do not usually become ill [13]. Acquiring *Legionella* pneumonia in the hospital conveys an increased mortality risk; the case fatality rate for nosocomial infections in Spain was 31.7% compared to 6.8% for community-acquired disease [14].

L. pneumophila organisms are well suited to the waterworks of hospitals. They multiply between 25 and 42°C and thrive at 35°C, a frequently occurring temperature in manmade systems [4]. They thrive in the stagnant water, scale, or sediment that is found in the dead legs of complex plumbing systems. They flourish in biofilms when a column of water stagnates, as when a hospital fountain is turned off for repairs [9], or when material provides contaminated biofilms with protection from water currents and decontamination measures [15▪]. Point-of-use plumbing fixture selection may affect risk for colonization; at some hospitals, hands-free faucets have been shown to have higher *Legionella* contamination rates than manual faucets, and may be more likely to fail disinfection attempts [16–18]. Immunosuppressed patients may acquire the bacteria from hospital water sources via exposure to aerosols from bathing [8,19–21], steam-heated towels [22], decorative hospital fountains [9,15▪,23], and possibly aspiration of contaminated water [7], among others. Even the distilled water system can become colonized with *Legionella*, as documented in a Quebec City outbreak of *L. dumoffii* acquired via respiratory therapy equipment and a room humidifier [24].

Although pediatric legionellosis is very uncommon, neonates have developed *Legionella* pneumonia from delivery in a hospital birthing pool [25] and, more recently, use of a cool mist humidifier filled with contaminated water in a newborn nursery [26]. An additional challenge with pediatric disease is the treatment delay and poor outcome that may result if clinicians do not suspect the infection in this patient population [25,26].

In nature, *Legionella* grows in association with protozoa, including *Acanthamoeba* spp., *Hartmannella* spp., and *Naegleria* spp., all commonly found in fresh water. Some have suggested that culturing for free-living amoebae from a suspected water source may increase the sensitivity of *Legionella* detection [27].

Early initiation of therapy for Legionnaires' disease is associated with improved survival, but physicians must consider the diagnosis in order to pursue appropriate empiric therapy [28]. Aggressive pursuit of diagnosis in patients who develop hospital-acquired pneumonia is essential for instituting appropriate treatment and recognizing a nosocomial cluster. As part of their evaluation, patients should undergo *Legionella* urine antigen testing, and, if negative, *Legionella* culture and molecular

testing from respiratory specimens to detect infection with nonserogroup 1 *L. pneumophila* and less common *Legionella* species [4].

Because preventing and remediating *Legionella* colonization are of utmost concern, guidelines for hospital construction prioritize *Legionella* risk reduction [29,30]. Some hospitals use systemic disinfection measures such as copper–silver ionization, chlorine dioxide, or monochloramine. These disinfection systems are reviewed thoroughly by Lin *et al.* [31▪▪] and Stout *et al.* [32]. Of note, monochloramine use in municipal water has been shown to reduce *Legionella* infection risk in hospitals [33,34].

Breakthrough *Legionella* has been reported with every modality of disinfection. A recent outbreak involving 21 patients and 5 attributable deaths at the Veterans Affairs Pittsburgh Healthcare System was notable in that 29 out of 44 water samples (66%) were positive for *Legionella* [23]. This proportion far exceeded the 30% threshold of 'heavy colonization' proposed by Yu and colleagues above which nosocomial cases of Legionnaires' disease occur more frequently [35,36]. Some water isolates matched the outbreak strain, despite appropriate copper and silver levels [23]. A filter and ozone generator failed to prevent contamination of a decorative wall fountain that caused infection in stem cell transplant recipients [9]. A larger outbreak stemmed from contamination of another hospital fountain despite the presence of a regularly maintained copper–silver ionizer [15▪].

When a water system is already contaminated with *Legionella*, options include super-heating and flushing the system with or without shock chlorination [20]. These methods have been effective in terminating existing outbreaks [19,31▪▪,32]. Preventing back-flow of heated water into the cool water system limits the possibility of producing ideal temperature conditions for *Legionella* growth [20,37]. Hospitals that utilize a systemic disinfection modality should monitor the intervention (e.g., ion levels) and consider periodic cultures to establish its effectiveness [31▪▪].

Hospitals providing care for immunocompromised patients must conduct close clinical surveillance for Legionnaires' disease among that patient population [10,38]. The US Centers for Disease control (CDC) recommends that facilities that have had a nosocomial outbreak of Legionnaires' disease conduct ongoing microbiologic surveillance to detect recontamination of their water supply [10,38]. The use of environmental surveillance for primary prevention, when there has been no outbreak, remains an area of controversy [36].

OTHER GRAM-NEGATIVE BACTERIA

Several clinically important Gram-negative bacterial species are well adapted to colonize the biofilms of water systems, and their presence has been associated with sporadic infection and outbreaks in hospitalized patients. Many genera are associated with transmission via hospital water, including *Pseudomonas, Stenotrophomonas*, *Acinetobacter*, *Sphingomonas*, *Burkholderia*, and *Achromobacter*. Most Gram-negative waterborne infections likely go unrecognized unless they occur in a cluster.

Pseudomonas species are commonly associated with biofilms in hospital water sources [39]. Therapy pools, tubs, and daily bathing in bed can be sources of transmission [38,40–42]. *Stenotrophomonas*, *Chryseomonas*, and other waterborne bacteria have caused outbreaks in neonates with intravenous lines or other invasive devices who were bathed in tap water [43,44]. In one neonatal ICU in Belgium, pseudomonal infection and colonization in four newborns was linked to the thawing of frozen blood products in a contaminated water bath [45]. In the presence of surgical incisions, invasive devices, or significant immune compromise, an exposure that would normally be deflected by the body's surface defenses may cause invasive infection. In order to reduce the risk of transmission from these sources, sinks and wash basins should be cleaned and disinfected regularly as part of routine hospital environmental cleaning [38]. There are not yet data to support use of chlorhexidine baths to reduce the risk of infection with waterborne bacteria.

Hand hygiene of healthcare personnel is the most important measure to prevent Gram-negative hospital-acquired infections [38]. Ironically, transmission in the setting of appropriate hand hygiene may occur when hands become contaminated during hand-washing in a sink with a contaminated aerator, faucet, or drain. This method of transmission has been reported in several outbreaks [16,18,46–55]. A hospital in Toronto recently identified hand-washing sinks as a key reservoir for nosocomial transmission of multidrug-resistant *Klebsiella oxytoca* following an outbreak among 66 patients [56]. Hota *et al.* [57] reported contamination of an ICU sink with an outbreak strain of multidrug-resistant *Pseudomonas*; fluorescein injection into sink drains demonstrated splash-back up to 1 m from the sink when the water was running [57]. Remediation of outbreaks due to sink contamination may require disassembly and replacement of plumbing components [56], redirection of the faucet water jet [57,58], replacement of the sink [48], or rearrangement of the surrounding space [57]. Hospital waste water can also lead to outbreaks when blockages and

A48235836

leaks occur, as occurred in one hospital due in part to a sharp-angled pipe junction; splash-back from shower drains and toilets may have caused contamination of patient materials placed nearby [59].

Patients can acquire waterborne bacteria from healthcare devices that contain liquid but with which they do not have direct contact. Contamination of the water used in hemodialysis equipment has frequently been reported as a cause of bloodstream infections in dialysis patients [60]. A blood gas analyzer with a contaminated water reservoir was linked to a prolonged ICU outbreak of *Burkholderia cepacia* [61]. Room humidifiers have been implicated in transmission of Gram-negative organisms, in some cases despite use of sterile water. Colonization occurs after about 5 days of continuous use, possibly from room particles and from hand contamination during filling [62]. Cool mist humidifiers, which are difficult to clean and disinfect properly, have caused outbreaks of Legionnaires' disease [24,26], *Pseudomonas*, *Acinetobacter* [63,64], and other Gram-negative organisms, with little actual rise in room humidity [63]. The evidence suggests a highly unfavorable risk–benefit ratio of room air humidifier use in hospitals.

MYCOBACTERIA

Nontuberculous mycobacteria (NTM) are hardy organisms that are present in municipal water, survive in hot water systems, and resist chlorination [65,66]. Plumbing features that encourage the growth of *Legionella* species, such as dead legs, stagnation, and warm water, also foster proliferation of NTM. Because the organisms occur frequently in hospital tap water [67–70], many true outbreaks and several pseudo-outbreaks with NTM have been reported. Hospital-associated outbreaks and sporadic cases have included central line infections, sternal wound infections, cosmetic surgery-associated soft tissue infections, and bloodstream infections related to dialysis [71–80]. Most reported outbreaks involved exposure of invasive devices or nonintact skin to tap water. Wallace *et al.* [80] reported eight outbreaks involving 71 patients with NTM infections after cardiac bypass surgery. Eighty per cent of isolates were from southern US coastal states, where NTM infections have the highest incidence [81]. Sources of transmission included tap water used to cool the cardioplegia solution and ice machines; in both cases, contamination was thought to originate from the municipal water supply [80]. A cluster of 34 patients who underwent liposuction developed *Mycobacteria chelonae* cutaneous abscesses. Patient isolates matched those of bacteria detected in water pipes in the physician's office, and the investigation suggested that surgical instruments rinsed in that water were inadequately disinfected [78]. Five hemodialysis patients developed *M. chelonae-abscessus* infections linked to high-flux dialysis machines in a single center, where a contaminated water spray was used for reprocessing dialyzers and the disinfectant solution had inadequate germicidal activity against mycobacteria [77]. Pseudo-outbreaks with NTM are typically due to tap water rinsing or contamination of diagnostic testing equipment. In one hospital, the bronchoalveolar lavages of nine patients over a month grew *M. chelonae* in the absence of typical symptoms; investigation revealed that the incoming water line of an automated bronchoscope cleaner was the source of this pseudo-outbreak [74].

PROTOZOA

Nosocomial transmission of intestinal protozoa has become uncommon in developed countries with sanitary hospital water supplies. Poor sanitation increases risk of waterborne infection, but some organisms are hardy enough to survive even in the presence of disinfection [82]. An unusual outbreak of *Cyclospora cayetanensis* was traced to a contaminated rooftop water supply and caused diarrheal illnesses among 17 medical residents and three staff members in a Chicago hospital [83]. After *Cryptosporidium parvum* caused a massive community outbreak in Milwaukee, Wisconsin, that disproportionately affected immunocompromised persons [84], water treatment regulations implemented in the wake of that outbreak have successfully prevented further municipal water-related outbreaks in the United States [85]. *Cryptosporidium* can be spread in hospitals to elderly or immunocompromised patients through contaminated food or water, although a number of reports implicate transmission via contact [86]. In one outbreak in Denmark, a patient who had HIV/AIDS and *Cryptosporidium* infection contaminated a hospital ice machine, leading to 19 infections [87].

FUNGI

Fungal contamination of water in the healthcare environment is considered a potential source of nosocomial infection. The presence of opportunistic molds such as *Aspergillus* and *Fusarium* has been reported in hospital water and plumbing fixtures [88–90]. Although airborne spores are thought to be the primary mode of nosocomial transmission, those spores may derive in part from water sources within the hospital [91]. Molecular typing has

A48235836
Copyright © Lippincott Williams & Wilkins. Unauthorized reproduction of this article is prohibited.

been used to link waterborne isolates with patient infections in a few cases. An investigation of fusariosis in a Texas hospital demonstrated *Fusarium* species in a majority of environmental samples; two water isolates matched patient isolates, suggesting nosocomial acquisition from water or a plumbing fixture [89]. *Phialemonium* bloodstream infections in dialysis patients were linked to reflux of contaminated fluid from a waste water line into the patient dialysis circuit during priming [92], a mechanism that has also been implicated in bacterial bloodstream infections and transmission of hepatitis C in this population [93,94]. Because the role of water contamination with molds in the epidemiology of patient infections remains unclear, current guidelines do not recommend reducing exposure of vulnerable patients to hospital water, but rather focusing on using best practices in structural and engineering controls to limit transmission to patients [29,38,95].

CONCLUSION

No single approach guarantees that hospital water will be safe for vulnerable patients, but a combination of engineering and hygiene measures and clinical strategies can minimize the risk. Engineering measures in the built environment include avoidance of features in plumbing systems that predispose to stagnation, maintenance of separate cold and hot water systems until near the point of use, and thoughtful construction of wastewater pipes to avoid blockages. Decorative fountains should not be placed inside healthcare facilities [9,29]. Careful planning should be given to sink design, avoiding high flow over drains, proximity to critical patient care areas, and possibly hands-free faucets. Hygiene measures include routine cleaning and disinfection of sinks and plumbing fixtures, proper disinfection of equipment that is rinsed in tap water, and, most importantly, healthcare personnel hand hygiene to prevent transmission of pathogens derived from moist sources to patients. Clinical strategies include aggressive surveillance for nosocomial waterborne infection, including testing patients who develop nosocomial pneumonia for *Legionella* species, and conducting prompt investigations if a single hospital-acquired case is suspected. Protection of central venous catheter sites from exposure to tap water, as recommended by current guidelines [96▪], may prevent some bathing-related outbreaks. Water disinfection systems can be implemented as a primary or secondary preventive measure, but even expensive, potent systems have been documented to fail. Most essentially, infection control specialists should be quick to respond to increases in rates of known and emerging waterborne pathogens.

SUMMARY

Background: Healthcare-associated infection (HAI) is associated with increased morbidity and mortality resulting in excess costs.
Aim: To investigate the impact of all types of HAI on the inpatient cost of HAI using different approaches.
Methods: The incidence, types of HAI, and excess length of stay were estimated using data collected as part of the Evaluation of Cost of Nosocomial Infection (ECONI) study. Scottish NHS reference costs were used to estimate unit costs for bed-days. Variable (cash) costs associated with infection prevention and control (IPC) measures and treatment were calculated for each HAI type and overall. The inpatient cost of HAI is presented in terms of bed-days lost, bed-day costs, and cash costs.
Findings: In Scotland 58,010 (95% confidence interval: 41,730–74,840) bed-days were estimated to be lost to HAI during 2018/19, costing £46.4 million (19m–129m). The total annual cost in the UK is estimated to be £774 million (328m–2,192m). Bloodstream infection and pneumonia were the most costly HAI types per case. Cash costs are a small proportion of the total cost of HAI, contributing 2.4% of total costs.
Conclusion: Reliable estimates of the cost burden of HAI management are important for assessing the cost-effectiveness of IPC programmes. This unique study presents robust economic data, demonstrating that HAI remains a burden to the UK NHS and bed-days capture the majority of inpatient costs. These findings can be used to

Introduction

Healthcare-associated infection (HAI) represents a major issue for health services, patients, and public authorities [1]. These potentially avoidable events are associated with increased morbidity and mortality, resulting in excess management costs [1—3]. The Evaluation of Cost of Nosocomial Infection (ECONI) study estimated HAI incidence of 0.76% (95% confidence interval (CI): 0.72—0.81) with 7437 (7021—7849) HAI cases in teaching and large general hospitals in NHS Scotland in 2018/19 [4].

Many studies have examined the costs associated with HAIs but comparisons among estimates can be challenging due to the differences between settings, patient groups, and methods of attributing costs [5]. Few studies have examined the whole-hospital incidence and all HAI types. The last study to do this for the UK by Plowman *et al.* found HAI to be a considerable burden, equivalent of 9.1% of the total 1994/5 inpatient acute, obstetric, and geriatric programme budget in England [6]. These cost estimates arose from methods that did not account for the time-varying nature of HAI and are likely to have been overestimated [7]. In the intervening period the UK and other countries established national infection prevention and control (IPC) programmes focused on HAI prevention [8,9]. Since the 1990s there have been significant changes in the age and frailty of the hospital population, complexity of treatments, use of invasive devices, antimicrobial resistance (AMR) and targeted IPC measures, all of which have affected the incidence and impact of HAI. Accurate and current information is needed to optimize decision-making when selecting between competing IPC programmes to ensure the most efficient programmes are implemented [10,11].

The aim of this study was to estimate the costs of different types of HAI in acute hospitals in NHS Scotland using a variety of approaches, and to extrapolate to the whole of the UK. One of the major costs of HAI can be shown by the number of bed-days released by its prevention. Released hospital beds can be valued in monetary terms by examining how much they historically cost the hospital to supply, the accounting cost. Bed-days include a high proportion of fixed costs and some variable costs [11]. When HAI cases are prevented, releasing bed-days, resources represented by fixed costs can be redeployed for other uses but not recovered, whereas variable costs can be recovered as cash savings. The cost of HAI is presented as natural units of bed-days lost due to HAI and bed-days valued using accounting costs. The accounting costs represent valuations of resources for alternative uses. The cash or variable costs related to the treatment of HAI in NHS hospitals are also calculated separately. The cash costs of treating HAI represent potential savings if HAI cases were prevented [11].

This study presents new information for healthcare decision-makers which can inform economic decision-making for competing IPC programmes locally and nationally.

Methods

To estimate the inpatient cost of HAI on the health service, the incidence rates and estimates of excess length of stay (LOS) derived from the ECONI study were combined [4,12]. ECONI was a two-centre, prospective observational incidence study with a nested case—control study [13]. ECONI took place in one teaching hospital and one large general hospital in NHS Scotland in 2018/2019. The cost of HAI to the NHS acute care sector was estimated by taking the following steps. First, the expected number of annual HAI cases was estimated. Second, the extra resources used to treat the average case were identified. Third, those resources used for the treatment of HAI were valued in monetary terms. The costs from the ECONI study were extrapolated to produce an estimate for the UK.

Expected annual HAI cases

The expected number and types of annual HAIs were estimated using data collected as part of the ECONI study [4]. ECONI reported the incidence of HAI using standard case definitions of the European Centre for Disease Prevention and Control [13]. Incidence rates of HAI per 100,000 acute occupied bed-days (AOBD) in the study hospitals were used to estimate HAI incidence in NHS Scotland. National estimates of HAIs were derived by applying the incidence within each specialty group to the total annual overnight admissions within NHS Scotland [4]. The nested case—control sample included ~5% of the HAI cases and was used to calculate the cash cost of antibiotic treatment only (see Appendix) [14].

Resources used to manage the average HAI case

HAI cost is mainly driven by excess LOS in the hospital [15]. During these extra days in hospital, HAI patients consume a mix of resources represented by fixed and variable costs. Fixed costs do not change with the number of patients treated and, in the NHS, represent buildings and staff; variable costs change with the number of patients treated and include consumables such as drugs and disposable equipment. Estimates of excess LOS due to HAI were produced for each HAI type and all HAI using a multi-state modelling approach that took account of time-varying exposures and the competing risks of death and discharge [16,17]. The multi-state model estimated excess LOS, for each HAI type, that could have been spent in any clinical area inclusive of intensive care unit (ICU), high-dependency unit (HDU) or other wards. The methods and results for the multi-state model are described in detail elsewhere [12]. Estimates of annual bed-days lost to HAI depend on both estimated incidence and excess LOS due to HAI [4,12].

Table I
Bed-day unit costs (£)[a]

Unit cost	Mean	SD	Distribution
Bed-day total cost	799.17	535.37	Log–normal
Bed-day direct cost	519.38	344.27	Log–normal

SD, standard deviation.
[a] Source: Information Services Division (ISD) Scotland [26].

Valuing resources used in the treatment of HAI in monetary terms

To value bed-days lost due to HAI, the 'total' and 'direct' accounting unit costs were calculated. These are mostly fixed costs and are based on a top-down valuation approach with gross-costing methodology [18]. Total costs include capital, overheads, staff, pharmacy, and laboratory costs. The total and direct costs were calculated using routinely reported historical data from NHS Scotland [19]. Direct costs include staff and consumable costs outlined above and exclude capital and overhead costs. Direct costs can be directly attributed to patient care and have been used previously to estimate the costs of treating HAI [20–25]. Unit cost estimates were weighted by the total number of discharges across all specialties from April 2017 to March 2018 in Scottish teaching hospitals and large general hospitals (see Appendix). Unit costs were aggregated across ICUs, HDUs, and other wards to match the estimates of the multi-state model [12]. Unit cost raw data were assumed to be log–normally distributed. In cost estimation CIs were calculated by taking 5000 Monte Carlo draws from log–normal distributions fitted to the unit cost data. Bed-day unit costs were based on Scottish reference costs and are presented in Table I [26]. Standard deviations in Table I reflect the substantial variability in bed-day costs across specialties and hospitals in Scotland.

The excess variable or cash cost incurred for each type of HAI was also calculated separately. These cash costs excluded fixed staff costs and were grouped into diagnostic tests and IPC consumables (including cleaning materials and antibiotic drugs). Diagnostic tests were defined according to HAI type and causative organisms reported in the ECONI study [4]. IPC and cleaning consumable costs were calculated for each level of transmission-based precautions (TBP) required for treatment. This included mapping the proportion of each HAI type which required use of TBP based on the Scottish National IPC manual and consultation with IPC experts [27]. The unit costs of IPC consumables were based on a mix of existing literature and expert opinion (see Appendix for full details).

Data on antibiotic prescribing in hospital was collected from the nested case–control sample of the ECONI study. The British National Formulary was used to cost antibiotics [28]. The costs were recorded in the week after data collection had been completed. Cash costs were multiplied by the estimated annual number of HAIs to calculate cash treatment by HAI type and a total. All cash costs were calculated in 2019 pound sterling (£); further detail is presented in the Appendix.

UK extrapolation of bed-day HAI costs

The ECONI study estimated incidence 0.76% (95% CI: 0.72–0.81) was applied to the UK total elective and emergency patient admissions in the financial year April 2017 to March 2018 to produce national estimates of costs [29–32]. This extrapolation assumes that the two hospitals of the study were representative of other acute hospitals in Scotland and the UK in terms of specialties, excess LOS, and bed-day unit costs [19].

Estimation of lost bed-days and costs due to HAI

Estimates of annual bed-days lost, for each HAI type and overall HAI, along with bias-corrected confidence intervals, using 5000 non-parametric bootstrap samples, were based on incidence and excess LOS estimated elsewhere [4,12]. In this study the annual and per-case cost of HAI is defined as the product of vectors of unit costs and excess resources consumed due to HAI. Point estimates of annual and per-case bed-day costs, for each HAI type and overall HAI, were calculated using annual and per-case bed-days lost multiplied by bed-day unit costs and excess LOS multiplied by bed-day unit costs, respectively. To estimate 95% CIs of annual and per-case costs, 5000 Monte Carlo simulations were drawn from log–normal distributions fitted to the data shown in Table I [17].

Cash costs were calculated separately using a different analytical process (see Appendix). Due to the way cash costs were calculated, point estimates of the unit costs were used in the calculation of cash costs. Therefore, no CIs are provided for cash costs related to IPC and treatment of HAI.

Table II
Incidence, average excess LOS and bed-days lost by HAI type in Scotland

HAI	Incidence rates per 100,000 AOBD (95% CI)	Estimated annual number of HAI cases (95% CI)	Average excess LOS[a] per HAI (95% CI)	Total annual bed-days lost to HAI[b] (95% CI)

Ethics

This study was surveillance and therefore was confirmed as ineligible for ethical review (A. Bailey. Personal communication to S. Stewart, 2016, South East Scotland Research Ethics Service). The case–control study component of the study received a favourable ethical opinion from the Scotland A Research Ethics Committee on March 3rd, 2017 (Reference 16/SS/0199). It was approved by national information governance approvals: Public Benefit of Health and Social Care: Incidence study: 1617-0037.

Results

The incidence rate and average excess LOS from the ECONI study and total bed-days lost by HAI type for teaching and general hospitals in Scotland are shown in Table II. These are based on the total annual admissions to teaching and general hospitals in NHS Scotland in 2018/19.

Bloodstream infection (BSI) was the HAI type with the greatest total annual impact in terms of bed-days lost, followed by pneumonia and surgical site infection (SSI). Urinary tract infection (UTI) was shown to have a negative impact on LOS in the multi-state model. In practice this means that on average UTI did not increase LOS, and it was assumed that there were zero additional days for these patients. In total there were 58,010 bed-days (95% CI: 41,730–74,840) lost in a year due to all HAI types.

Cost per case and annual inpatient costs in Scotland are shown in Table III. The total cost attributable to HAI treatment annually in NHS Scotland is estimated to be £46.35 million (19.4m–128.8m). The direct cost due to HAI is estimated to be £30.11 million (14.1m–74.4m) per year.

The extrapolation of the costs for the whole of the UK is shown in Table IV. Total costs in the UK based on total admissions are estimated to be £774 million (328 million to 2.2 billion) annually. Direct costs are estimated to be £503 million (236 million to 1.2 billion) per year.

The costs of consumable items that could be saved in the short term are shown in Table V. The total cost of these items varies by HAI type. These costs are small in comparison to staff time and other fixed resources. The total annual estimate is approximately £1.1 million across acute hospitals in the Scottish NHS. Cash costs are ~2.4% of the estimated total cost of HAI and 3.7% of the direct cost of HAI in Scotland.

Table IV
Annual total inpatient cost of HAI in the UK[a]

Annual total cost in the UK (£ million per year)	Annual direct cost in the UK (£ million per year)
774 (328–2,192)	503 (236–1,217)

Annual UK total and direct costs are based on ECONI HAI incidence: 0.76% (0.72–0.81).
[a] Values are mean (95% confidence interval).

Discussion

The ECONI study is the first in the UK to report whole-hospital incidence of HAI since the study by Plowman *et al.*, which was based on data from more than 20 years ago [6]. It was estimated that in Scotland 58,010 (95% CI: 41,730–74,840) bed-days were lost due to HAI each year. These occupied beds are the main economic cost arising from HAI. The impact of lost bed-days in a system like the NHS results in an increase in waiting lists, which means that potential patients are delayed in accessing services. This size of the loss equates to 159 beds or a small general hospital of 180 beds (assuming average bed occupancy of 88%) being occupied for a whole year with HAI cases. Alternatively, the impact of HAI can be shown by the number of elective patients who could have been treated after a 10% reduction in HAI rates. Given that LOS for elective patients in NHS Scotland is on average 3.4 days, then 1700 additional elective patients could be treated annually if 10% of HAI is prevented [33]. Estimated lost bed-days represent the opportunity cost of HAI expressed in natural units. The opportunity cost of a bed-day can be defined as the forgone benefit of the best alternative use of the resource such as treating another patient. In the NHS high demand means that a released bed is very valuable since a new patient will always occupy it, but in situations of spare capacity the value would be lower if a bed remains empty. Bed-days are a unit of currency familiar to healthcare decision-makers who manage resources with a high proportion of fixed costs.

The total cost valuation of the lost bed-days due to HAI was £46.35 million (95% CI: 19m–129m) and the direct cost was £30.11 million (14m–75m). In 2018/19 the total acute inpatient expenditure in Scotland was about £4 billion [34]; this sets the total cost of HAI at ~1.1% of the total acute inpatient expenditure in NHS Scotland. These are mostly fixed costs that cannot be recovered as savings if HAI is prevented, since they are based

Table III
Cost per case for each HAI type and annual cost of HAI in NHS Scotland[a]

HAI	Cost per case for each HAI type and overall (£)		Annual cost in NHS Scotland (£ million)	
	Total cost per case	Direct cost per case	Total cost	Direct cost

IPC, infection prevention and control; HAI, healthcare-associated infection; BSI, bloodstream infection; GI, gastrointestinal infection; LRI, lower respiratory tract infection; PN, pneumonia; SSI, surgical site infection; UTI, urinary tract infection; 'Other' includes: skin/soft tissue; bone and joint; cardiovascular; eye, ear, nose, and throat; and systemic infection.
[a] Antibiotic costs were calculated from the case–control sample and not directly comparable with other results presented in this study.

on historical accounting unit costs. However, it is still important to consider costs in this way so that comparisons can be made with other NHS spending that is reported in similar terms. These costs also represent a monetary valuation of benefits from alternative uses of these resources when HAI is prevented. Direct costs are a representation of staff and consumable resources that could have been used to treat other patients if HAI rates were reduced.

The top three HAI types which had the greatest cost impact were BSI, pneumonia, and SSI (Table III). HAI cost is estimated as a combination of incidence and excess LOS, and the rank order of HAI type changes according to the impact on either incidence or LOS. For example, according to ECONI incidence, UTIs are the most common infections in Scotland but these are usually easily treated and thus have minimal impact on inpatient resources. This does not mean that IPC teams should disinvest in UTI prevention since these high-incidence infections frequently require antibiotic treatment, thus contributing to AMR. UTIs were also found to be one of the most common primary infection types leading to secondary BSI [4]. BSI is the second most common HAI type and has a relatively large impact on LOS (11.4 additional days on average). BSI is very costly, and targeting investment in IPC measures to reduce this type of HAI is likely to be cost-effective. Pneumonias also have serious consequences for the patients and can be difficult to treat, increasing LOS by more than 16 days on average, but they were less frequent than other HAIs. Nevertheless, IPC measures to prevent pneumonias could represent a good use of resources given the high cost per case of these infections. Outbreaks that would cause an increase in viral respiratory tract infection can be very costly for the health service and vigilance against these is required. SSIs have a lower cost per case than pneumonias but are more frequent, making these the second most costly HAI type annually in Scotland.

The cost of HAI was extrapolated to the whole of the UK and is estimated to be at £774 million (95% CI: 328m to 2,192m) and direct costs at £503 million (236m–1,217m) annually. The total cost of HAI is estimated to be at 0.62% of the NHS total spending in the four UK nations in 2018 and is associated with ~968,000 lost bed-days annually. This is much lower than the 9.1% and 3.64 million lost bed-days estimated by Plowman *et al.* more than 20 years ago [6]. Since the 1990s, changes in the hospital population, treatments, use of devices, antimicrobial resistance and IPC measures have affected the incidence and impact of HAI on the health service. The extrapolation results in this study should be interpreted with caution since they assume a similar mix of hospitals, specialties, and severity of illness across the UK.

Whereas total costs may represent historical spending to supply these beds, they do not necessarily represent their value in terms of opportunity costs, especially in situations of spare capacity. Opportunity costs are a more useful measure for decision-making under conditions of scarce resources but estimating these accurately may be difficult [35]. There have been attempts to estimate the opportunity cost of a bed-day using willingness-to-pay (WTP) surveys in other countries [36,37]. For example, Page *et al.* estimated opportunity costs using a WTP survey, for bed-days released by IPC programmes, elicited from CEOs of acute hospitals in Australia [37]. These estimates suggest that the total accounting cost to opportunity cost ratio is approximately equal to 3.7, which would imply an economic value of £216 for each bed-day in this study. A bed-day cost at this level would result in yearly opportunity costs in Scotland of up to £16 million, falling at the lower end of the estimated direct cost confidence interval (95% CI: 14m–75m). The true economic value or opportunity cost of the occupied bed-day in teaching and general hospitals in the UK is unknown, and using WTP estimates from another country or other types of hospitals would introduce sources of uncertainty. WTP can over- or underestimate the cost depending on demand for hospital beds, and estimates would be much higher in an infection outbreak or pandemic. In a WTP study in European tertiary hospitals Stewardson *et al.* recognized that a limitation of this approach is that WTP measures purchase intention, not actual cost [36]. Additionally, they found that WTP values depended on the type of hospital reimbursement [36]. Other studies also found that the hospital remuneration pro-cess had implications in how hospital executives view infection prevention [38,39].

This study values resource lost to HAI in total costs and direct costs using estimates of HAI incidence and excess LOS that are based on methodologies that minimize bias [4,12]. Most UK hospitals are operating close to full capacity with long waiting lists, which suggests that, when HAI is prevented, resources could be readily redeployed to treat other patients [40,41]. This means that the valuation of HAI cost in this study

represents resources with alternative uses. In addition, this study allows a comparison of the cost of different HAI types, and at the same time contrasts incidence with resource use, which is relevant to IPC planning. Another strength of this study is the probabilistic methodology that combined estimates of HAI incidence, excess LOS, and bed-day unit costs, and accounted for all types of uncertainty in the parameters. Previously in this literature studies have reported costs without fully accounting for all sources of uncertainty [38,42–45].

This study has several limitations. It was not conducted using a bottom-up micro-costing approach [18]. An example of this method is the patient-level information costing system (PLICS) but this was not routinely available during the study period. PLICS is a patient-level approach that can be used to standardize the method of reporting cost information across the health service. PLICS has the potential to be more accurate than gross-costing methods but is still limited by unit costs that do not reflect opportunity costs, and staff costing may occasionally be based on averages resembling a gross-costing methodology. A study in an English NHS hospital using PLICS to report the economic burden of SSI reported an attributable cost of SSI of £5,239 (95% CI: 4,622–6,719) [38]. This study estimates that the attributable direct hospital cost of SSI was £5,086 (2,095–14,433). Another limitation of this study is that the multi-state model estimates of excess LOS do not distinguish between facilities that have completely different cost profiles. For example, if 10% of the excess LOS took place in an ICU bed, this would increase estimated costs by ~14%. Heister *et al*. in a study of *C. difficile* show that multi-state models may also underestimate excess LOS, which means that the results of this study could be a conservative estimate of the true cost of HAI [46]. Furthermore, since antibiotic costs are based on a smaller sample, these costs may not be directly comparable with the rest of the results.

Bed-day costs reported previously in the literature mostly relate to capital costs, overheads, and fixed contracts that do not change in the short term [11]. Since the cost of facilities and staff are fixed under normal circumstances there is small potential for any annual saving that could be achieved by preventing HAI. Any savings would relate to the consumable items that are purchased as they are consumed. Gastrointestinal infections (GIs) and pneumonias had the highest IPC and laboratory cash costs per case, with GIs having the greatest annual impact. This study shows that pneumonias are highly resource intensive, both in terms of fixed costs and variable costs. While the results of this study have shown that Scottish annual cash costs for all HAI types are relatively small at approximately £1.1 million per year, this money could eventually be reinvested if HAI cases were prevented. Plowman *et al*. suggested that cash costs are 11% of the total costs [6]. The results of this study suggested that cash costs are a much smaller proportion of costs at 2.4% of the total and 3.8% of direct costs. This means that any expected cash savings from HAI prevention would be very small. Preventing HAI may only release relatively small funds as cash savings, but there is an additional benefit – that is not included in these monetary valuations – of reducing antibiotic consumption [47]. The human cost of HAI should also be taken into account when evaluating HAI prevention since it is also not included in these monetary costs.

A recent meta-analysis concluded that HAI reduction of between 35% and 55% may be possible with the implementation of multi-faceted interventions [48]. However, preventable proportions of HAI may decrease over time as IPC initiatives are successfully implemented. Reductions shown in some of the earlier studies within this meta-analysis would not be achievable today, as many of the proposed interventions have been implemented in some way. It is likely that realistic reductions in overall HAI numbers in Scotland would be lower than Schreiber *et al*. reported, especially given the low proportion of surgical and device-related HAIs identified in the ECONI study [4,48]. Exaggerated estimates of the cost of HAI and the potential benefits from prevention of HAI may lead policy-makers to be disappointed when IPC programmes turn out to be less efficient than expected.

Although considerable progress has been made in evaluating IPC measures with cost-effectiveness modelling approaches, these analyses rely heavily on unbiased information [49]. When seeking funding, 'attention grabbing' costs are frequently quoted in order to convince policy-makers to invest in IPC measures among other interventions. Within the literature there are also attempts to compare the cost of HAI with other conditions, e.g. cancers, with the intention to focus policy-makers' attention on IPC and HAI prevention. However, as discussed elsewhere, it is patients with these conditions who are most at risk of developing HAI [50]. Rather than promoting such competition for resources among patient groups, studies should include integration of IPC measures in order to maximize the efficacy of existing treatments for those most at risk of developing HAI. This study reports the cost of HAI using a variety of measures that can reliably inform future economic evaluations of IPC programmes.

Acknowledgements

Data collection could not have been completed without the enormous effort from the ECONI research nurses: N. Williamson, H. Thain, R. Boyle, A. McAlpine. and C. Beith. Thanks are extended to all members of the infection prevention and control teams, microbiology departments and research and development teams in the study sites for their support in initiating the study. The study was supported by the clinical staff in the study hospitals, particularly the infection control teams, laboratory staff, and research and development teams. The authors would like to specifically thank E.R. and L.R. for their advice and guidance on the costing of the IPC measures.

Author contributions

S.M. contributed to aspects of the study design and led data collection for economic analysis, calculated the total and direct costs and prepared the manuscript. S.S. led the study design, wrote study protocols and ethics and Public Benefit and Privacy Panel approvals, patient-facing materials, contributed to the design of the collection tools, contributed to the statistical analysis, developed the manuscript and the cash treatment costs. N.G. prepared the manuscript and contributed to the study design. H.M. contributed to the study design, led on health economic aspects of the study design and contributed to the manuscript. C.R. contributed to the concept of the study, study design, statistical analysis plan and the manuscript. S.K., J.P. and K.K., undertook the statistical analysis and prepared results. L.H. contributed to the development of study design, protocol and data management and contributed to the final manuscript. M.A. contributed to the final manuscript. S.D. and B.C. are the Principal Investigators at the recruiting sites and contributed to the final

manuscript. J.R. conceived the study, is Chief Investigator for the study and contributed to the manuscript.

Non-author collaborators

Abstract: Healthcare-associated infections (HAIs) are one of the most common patient complications, affecting 7% of patients in developed countries each year. The rise of antimicrobial resistant (AMR) bacteria has been identified as one of the biggest global health challenges, resulting in an estimated 23,000 deaths in the US annually. Environmental reservoirs for AMR bacteria such as bed rails, light switches and doorknobs have been identified in the past and addressed with infection prevention guidelines. However, water and water-related devices are often overlooked as potential sources of HAI outbreaks. This systematic review examines the role of water and water-related devices in the transmission of AMR bacteria responsible for HAIs, discussing common waterborne devices, pathogens, and surveillance strategies. AMR strains of previously described waterborne pathogens including *Pseudomonas aeruginosa, Mycobacterium* spp., and *Legionella* spp. were commonly isolated. However, methicillin-resistant *Staphylococcus aureus* and carbapenem-resistant Enterobacteriaceae that are not typically associated with water were also isolated. Biofilms were identified as a hot spot for the dissemination of genes responsible for survival functions. A limitation identified was a lack of consistency between environmental screening scope, isolation methodology, and antimicrobial resistance characterization. Broad universal environmental surveillance guidelines must be developed and adopted to monitor AMR pathogens, allowing prediction of future threats before waterborne infection outbreaks occur.

Keywords: antibiotic resistance; antimicrobial resistance; water; waterborne outbreak; healthcare associated infection; biofilm

1. Introduction

Healthcare-associated infections (HAIs) are defined as infections caused as a direct or indirect result of an individual receiving healthcare [1]. This may occur in hospitals, aged care facilities, dental clinics and long-term care facilities [2]. The United States (US) Centers for Disease Control and Prevention (CDC) have estimated that 1 in 25 hospital patients are diagnosed with a HAI each year [3]. Additionally, there are over 4 million HAIs in Europe, 1.7 million in the US and 165,000 in Australia annually [4]. HAIs result in unnecessary morbidity and mortality with estimates from the US indicating HAIs are responsible for approximately 99,000 unnecessary deaths every year [4]. Hospital patients and aged care residents are especially vulnerable to infection due to their potentially compromised immune systems [5]. HAIs are commonly associated with catheters, surgical sites and ventilators [6], where the causative organisms may originate from the patient's own microbial flora, other patients, staff or from the healthcare facilities physical environment [5]. The US CDC have identified a number of causative agents that pose serious threats to hospitalized patients including *Acinetobacter*

A48235836

spp., influenza, *Klebsiella* spp., methicillin-resistant *Staphylococcus aureus* (MRSA), *Clostridium difficile, Pseudomonas aeruginosa,* non-tuberculous mycobacteria (NTM) and norovirus [7]. The significance and severity of HAIs are increasing due to the rise in antimicrobial resistance and emergence of multidrug resistance (MDR) [8]. Thus, treatment for patients suffering HAIs resistant to traditional antibiotic therapies is more precarious, costly and, in the worst case scenario, unsuccessful [6]. The increase in antimicrobial resistance is driven, in part, by the inappropriate use of antibiotics and ineffective disinfectant protocols [9]. Understanding potential environmental reservoirs of infectious bacterial species is needed to develop and implement effective infection control [1]. Strategies for the prevention of person-to-person transmission are well defined, including disinfection procedures of dry surface fomites such as bed rails, doorknobs and light switches [1,10–12]. However, there are limited studies investigating the role of environmental microorganisms, including waterborne pathogens such as *Legionella* spp., *P. aeruginosa* and *Mycobacterium* spp. [13–27]. It has been estimated that 20% of nosocomial pneumonias are caused by waterborne *P. aeruginosa* in the US, resulting in a conservative annual mortality of approximately 1400 individuals [28]. An outbreak of *L. pneumophila* infection in the neonatal unit of a private hospital was linked to a cold-mist humidifier filled with contaminated tap water, resulting in nine infections and three deaths [29]. Transmission of these waterborne pathogens may occur via water related devices such as showers, drinking fountains, bathtubs, dental units, ice machine, humidifiers, sinks and toilets [27]. Notably, approximately 80% of chronic and recurrent microorganism infections are caused by biofilms [30], which are communities of microorganisms, providing protection from adverse environmental conditions and antimicrobial agents [30].

This systematic review examined the role of water in the transmission of AMR pathogens that are responsible for HAIs. Common waterborne devices, pathogens, and surveillance strategies are discussed. A greater understanding of the ecological niche of these pathogens is needed to develop improved management strategies for the prevention of waterborne HAIs.

2. Results

Two thousand, two hundred, and one papers were retrieved from SCOPUS and Web of Science using the search terms identified (Figure 1). After applying the inclusion and exclusion criteria described in Figure 1, a total of 88 papers were included for review. These were further divided such that 21 papers (presented in Table 1) described studies specifically investigating the presence of AMR bacteria in water and water-related devices including tap faucets, drains, showers, and baths. A further 67 papers that did not specifically investigate water but included some water sampling are presented in the Table S1. These include clinical outbreak investigations and other studies screening a range of environmental sources within healthcare facilities.

Table 1. Summary of reports and studies identifying antimicrobial resistant bacterial species within healthcare water sources and water-related devices.

Study Site	Reservoir	Organism	Country *	Bacterial Isolation Methods ◊	Antimicrobial Methods †	Antimicrobial Characteristics	Additional Comments ×	Reference
Hospital	Water	*Legionella* spp.	Greece *	ISO 11731 (filtration, untreated, heat and acid treatments) plated on GVPC agar	E-test strips	Five strains displayed low-level resistance to CIP and ERY	SGs 1–15 identified. Antibiotics tested: CIP, ERY	[31]
Hospital	Water	*Burkholderia cepacia* *Pseudomonas stutzeri* *Chryseobacterium meningosepticum* *Stenotrophomonas maltophilia* *Enterobacter cloacae* *Acinetobacter baumannii* *Escherichia coli* *Proteus mirabilis* *Alcaligenes xylosoxidans* *Pseudomonas aeruginosa* *Pseudomonas putida* *Serratia liquefaciens* *Moraxella osloensis* *Serratia plymuthica*	Greece	Membrane filtration and plated on m-endo medium and cetrimide agar	Agar dilution	*S. maltophila* isolate resistance: 37% resistant to CAZ 58% resistant to FEP 100% resistant to IPM *E. coli* isolates: 55% resistant to TIC *P. mirabilis*, *P. putida*, *S. liquefaciens*, *P. stutzeri* and *S. plymuthica* exhibited resistance to tetracycline 19% of the total enterobacteria and 35% of the total non-fermenting isolates were MDR	Antibiotics tested: AMK, CAZ, CIP, FEP, IPM, TET, TIC, SXT, TOB	[32]
Hospital	Water	*Acinetobacter haemolyticus* *B. cepacia* *Pseudomonas aeruginosa* *P. stutzeri*	Brazil	MPN, APHA 2000 plated on MacConkey agar	Disc diffusion	*B. cepacian* isolates showed resistance to 10/11 antibiotics *P. aeruginosa* isolates showed resistance to 11/11 antibiotics *A. haemolyticus* isolates showed resistance to 11/11 antibiotics *P. stutzeri* isolates showed resistance to 7/11 antibiotics	Antibiotics tested: AMK, CAZ, CCHL, CIP, FEP, GEN, IPM, TET, TMP, TOB, TZP	[33]
Hospital	Hot water system	*Legionella pneumophila*	Italy	Italian guidelines for prevention and control of Legionellosis	VITEK-2	MIC values of *L. pneumophila* SG 1 were higher than non-SG 1 isolates for AZI, CIP, LEV, MOX, and TIG No difference in MIC values between SGs for CEF, CLA, DOX, ERY, and RIF	Antibiotics tested: AZM, CIP, CLR, CTX, DOX, ERY, LVX, MXF, RIF, TGC	[34]

2.1. Study Sites

Of the 21 papers that specifically investigated the presence of pathogens associated with HAIs in water sources (Table 1), 15 studies were from Europe, 3 from North and South America, 2 from Africa and 1 from Asia. Seventeen studies sampled water sources from hospitals, one from a residential care home, one from dental chair units, one from a medical center and another from a sanatorium. AMR bacterial species were found in potable water samples (15 studies), followed by showers (2 studies) and building water distribution systems (2 studies), sinks (1 study), baths (1 study), haemodialysis water (1 study) and drains (1 study).

In those clinical outbreak investigations and studies examining a range of environmental sources (Table S1), there were 27 reports from Europe, 22 from Asia, 11 from the Americas, 6 from Africa and 1 published from Oceania. Of these studies, 30/67 found AMR bacterial contamination within a water source, including tap water, hydrotherapy pool water, nasogastric water, and incubator water. Taps and tap components such as aeration grids, tap handles, and hands-free taps had AMR bacterial contamination in 18/67 studies. Sink and sink components such as drain holes, sink surfaces, drainpipe leaks and sink traps were found to have multidrug resistant (MDR) bacterial contamination resistant to two or more antimicrobials in 45/67 studies (Table S1). Shower components such as the shower hoses, showerhead and outlets were contaminated with AMR bacteria in 11/67 studies. Baths were found to have MDR bacterial contamination in 4 studies and bath toys were identified as a source of contamination in 1 study [14,16,52–54].

2.2. Identified Pathogens Associated with HAIs

Seven of the studies used culture-based techniques to investigate the bacterial diversity in the water sources in healthcare facilities. The pathogens identified are detailed in Table 1 and include *Achromobacter* spp., *Acinetobacter* spp., *Acinetobacter anitratus, Acinetobacter baumannii, Acinetobacter haemolyticus, Acinetobacter lwoffi., Aeromonas* spp., *Alcaligenes xylosoxidans, Burkholderia cepacia, Chryseobacterium meningosepticum, Citrobacter* spp., *Citrobacter diversus, Citrobacter freundii, Enterobacter* spp., *Enterobacter aerogenes, Enterobacter agglomerans, Enterobacter cloacae, Erythrobacter* spp., *Escherichia coli, Flavobacterium* spp., *Klebsiella oxytoca, Klebsiella pneumoniae, Leclercia adocarboxylata, Moraxella* spp., *Moraxella osloensis, Mycobacterium* spp., *Novosphingobium* spp., *Pantoea agglomerans, Proteus mirabilis, Pseudomonas* spp., *Pseudomonas acidovorans, P. aeruginosa, Pseudomonas cepacia, Pseudomonas fluorescens, Pseudomonas putida, Pseudomonas stutzeri, Ralstonia picketti, Serratia* spp., *Serratia liquefaciens, Serratia marcescens, Serratia plymuthica, Sphingomonas* spp., *S. aureus,* and *Stenotrophomonas maltophila.*

Fourteen studies investigated the presence of one specific bacterial species or genus that may cause HAIs in water and water-related devices. Of these, seven papers investigated *P. aeruginosa* exclusively, three investigated *Legionella* spp. and two papers focused specifically on *L. pneumophila*. One paper focused on *Enterococci* spp. and another focused on *Sphingomonadacae* spp. (Table 1).

Twenty studies undertook comprehensive environmental bacterial screens of the study sites. These studies included additional pathogens such as *Acidovorax* spp., *Acinetobacter johnsonii, Aeromonas caviae, Aeromonas hydrophila, Alkaligenes faecalis, Bosea* spp., *Chryseobacterium* spp., *Chryseobacterium indologenes, Elizabethkingia meningoseptica, Enterobacter asburiae, Enterococci* spp., *Klebsiella ozenae, Methylobacterium* spp., *Mycobacterium chelonae, Pantoea calida, Proteus* spp., *Proteus vulgaris, Providencia stuartii, Raoultella ornithinolytica, Raoultella planticola, Sphingomonas paucimobilis, Staphylococcus citrus, Staphylococcus epidermidis* and *Staphylococcus* spp., as shown in Table S1. However, due to the design of some studies, it was not always clear whether these bacterial species were isolated from the water samples taken or from other environmental sources.

Thirty-five of 67 (Table S1) investigated bacterial clinical outbreaks in one or more healthcare facilities identified contamination of water and/or a water related device as the likely source of transmission via strain comparison. This included HAI outbreaks of *Achromobacter bacteraemia, Achromobacter denitrificans, Achromobacter xylosoxidans, Acinetobacter bereziniae, A. hydrophila,* carbapenem-resistant *Enterobacteriaceae* (CRE), carbapenem-resistant *E. coli, Citrobacter amalonaticus,*

C. freundii, Collinsella aerofaciens, Comamonas testosterone, E. cloacae complex, *Klebsiella* spp., *Pseudomonas medocina, Pseudomonas nitroreducens, Pseudomonas oleovorans* and *P. putida*. A surveillance review of waterborne diseases in the US from 2013 to 2014 found that there were 42 outbreaks from drinking water, resulting in 13 deaths all caused by *Legionella* spp. [55].

Nine studies compared clinical bacterial isolates and environmental isolates, including those from water samples for molecular epidemiology in non-outbreak settings. These studies included bacterial species such as *Aeromonas spp., Burkholderia spp., Klebsiella quasipneumoniae, P. aeruginosa* and *S. maltophila*, as shown in Table S1.

2.3. Antimicrobial Resistance of Identified Strains

Several AMR pathogens of concern, as classified by the US CDC, were identified by studies included in this review (Table 1 and Table S1). Specifically, three studies detected CRE, one from a plumbing fixture, one from a water sample and one sample site was unspecified [21,52,56]. MDR *P. aeruginosa* strains were also found in 12 studies, most commonly from potable water samples (7 studies), sinks (3 studies) and faucets (2 studies) [14–16,33,39,40,43,49,50,57–59]. Eight studies reported AMR *Acinetobacter* spp. of which five reported MDR isolates and one study identified the resistance genes *tetG, ermX* and *ermF* in bacteria within a biofilm sample [32,37,42]. Additionally, the resistance gene OXA-23 was found in *A. baumannii* sampled from hospital water which has been linked to β-lactam antibiotic resistance [60]. Specific genetic elements such as Opr protein-mediated resistance to fluoroquinolone antibiotics was also found in *P. aeruginosa* isolates [37]. MRSA was detected in every bathroom sink tap that was tested in a UK hospital. However, it is unclear which antibiotics this specific environmental isolate was resistant to [61]. Sixteen studies that investigated water and water-related devices found bacterial isolates that were resistant to two or more of the antibiotics that were tested (Table 1). One study investigating *P. aeruginosa, P. stutzeri, B. cepacian* and *A. haemolyticus* in hospital water samples found that all isolates were resistant to seven or more of the 11 antibiotics that were tested, including amikacin, ceftazidime, chloramphenicol, ciprofloxacin, cefepime, gentamicin, imipenem, tetracycline, trimethoprim, tobramycin and piperacillin-tazobactam [33]. One study into the presence of *L. pneumophila* in a hospital hot water system found that the minimum inhibitory concentration (MIC) values were higher in serogroup 1 isolates compared to non-serogroup 1 isolates for the antibiotics azithromycin, ciprofloxacin, levofloxacin, moxalactam and tigecycline [34]. Resistance to β-lactamase inhibitors such as tazobactam and clavulanic acid was identified in *K. oxytoca, P. calida, R. ornithinolytica* and *P. aeruginosa* isolated from hospital sinks, drains, shower heads, water and aerators [15,25,62]. Biofilm samples taken from hospital shower heads contained *Erythrobacter* spp., *Mycobacterium* spp., *Novosphingobium* spp. and *Sphingomonas* spp. isolates that carried the resistance genes *aac2Ib, aac2Ic, aph3Ic, bacA, bL2b, ceoB* and *mfpA* that have been linked to biofilm formation, virulence, peroxide resistance, DNA repair, antibiotic resistance, and antigenic variation traits [45].

2.4. Detection Methods

There was significant variation in the methods used for detecting bacterial species from the environment. Fifteen studies (Table 1) examined water using culture techniques. Specifically, eleven studies performed membrane filtration followed by plating onto selective agar media, nine of these studies used 0.45 µm pore diameter filters and two did not specify (Table 1). Of those that specifically investigated *Legionella* spp., two studies referenced the International Organization for Standardization (ISO) 11731—water quality enumeration of *Legionella* [31,36]. One study investigating *L. pneumophila* followed Italian guidelines for prevention and the control of legionellosis [34] and two studies used other culturing techniques [35,44]. Of the studies investigating *P. aeruginosa,* four papers used membrane filtration methods followed by plating onto selective media such as R2A, cetrimide, and Columbia with horse blood, one of which referenced the ISO 16266:2008—detection and enumeration of *P. aeruginosa* specifically [38,39,43,48]. One paper alternatively inoculated malachite-green broth with the individual environmental water sample and subcultured onto cetrimide agar to isolate *P. aeruginosa* [40]. Bacterial

species from biofilm and swab samples taken from water-related devices were isolated using a variety of methods including direct inoculation onto cetrimide, MacConkey, tegritol-7, or deoxycholate agar, and centrifugation to resuspend a pellet for inoculation onto selective agar, as shown in Table 1 [33,37,42,45,49]. Five studies used additional methods such as polymerase chain reaction (PCR), matrix-assisted laser desorption/ionization-time of flight (MALDI-TOF), VITEK-2, multiplex PCR and 16S gene sequencing to identify isolated bacterial species (Table S1) [63–65].

2.5. Antimicrobial Resistance Characterization Methods

A range of methods were used to determine the antimicrobial resistance characteristics of isolated strains. Seventy-one of 88 studies (Table 1 and Table S1) used traditional microbiological methods including disc diffusion (56 studies), agar dilution (4 studies), broth microdilution (5 studies) and E-test strips (6 studies). Other approaches for characterizing antimicrobial resistance included PCR (17 studies) and comparison to known AMR strains using VITEK-2 system (5 studies), pulse field gel electrophoresis (PFGE) (3 studies), microscan (2 studies), microarray (1 study) and multilocus sequencing typing (MLST) (1 study).

Comparing the antimicrobial resistance is challenging due to the varying approaches used in the different studies. A joint initiative by the European CDC and US CDC provided definitions for the terms MDR and XDR to standardize international terminology. To facilitate these definitions, lists of antimicrobial categories and breakpoints were developed from the Clinical Laboratory Standards Institute (CLSI), the European Committee on Antimicrobial Susceptibility Testing (EUCAST) and the United States Food and Drug Administration (FDA). MDR was defined as acquired non-susceptibility to at least one agent in three or more antimicrobial categories. XDR was defined as non-susceptibility to at least one agent in all but two antimicrobial categories [66]. The terms MDR and extensively drug resistant (XDR) were used by five studies and the terminology has been reported as stated in the papers (Table 1 and Table S1); however, it was unclear what specific antibiotics the isolates were resistant to [32,39,49,50,58]. Of the studies detailed in Table S1, 20/67 studies reported the environmental isolates as a whole data set rather than describing the phenotypes of each individual strain.

3. Discussion

3.1. Water as a Source of HAIs

Water sources and water-related devices are often contaminated with pathogens responsible for HAIs. This may occur when microorganisms survive treatment protocols or via end point contamination [67]. The design of a hospital or healthcare facility's water system can influence the risk of microbial contamination [68]. Complex infrastructure may have points of heat transfer and stagnation which can promote biofilm formation, microbial growth and the rise or transfer of antimicrobial resistance [69]. The CDC Antibiotic Resistance Threats Report estimated that there are more than 2.8 million AMR infections each year in the US resulting in approximately 35,000 deaths [8]. This review identified that water and water-related devices play a significant role in the transmission of AMR HAIs with subsequently an economic and health imperative to improve the control of hospital and healthcare water sources.

This review identified a range of waterborne pathogens present in the potable water supply and plumbing surfaces (such as drains and tap faucets). However, pathogens not typically considered waterborne were also detected, including *S. aureus*, *Moraxella* spp. and *E. aerogenes* [32,42,51,54,70–73]. For example, AMR pathogens of concern, extended-spectrum beta-lactamase-producing Enterobacteriaceae and MRSA, were located in a hospital sink bowl, hospital bathroom sink taps and a hospital bathtub [51,61,74]. This raises the hypothesis that end point contamination may be occurring from patient-to-water source. A study examining the influence of contaminated splash backs when handwashing in twenty faucet/sinks in hospital intensive care units found that the faucet spouts were more contaminated than the sink bowl and drains. Flawed sink design such as shallow bowls

enable splashing contaminated sink contents onto patient care items, healthcare workers hands and the patients' broader environment [75].

Numerous approaches are taken to ensure a facility's potable water supply is suitable for human use and consumption. The Healthcare Infection Control Practices Advisory Committee (HICPAC) has published guidelines to prevent the growth of bacterial species such as *Legionella* spp. [69]. This includes recommendations such as maintaining adequate water pressure, temperature and preventing stagnation. Some older healthcare facilities, built prior to such guidelines, often have plumbing infrastructure that doesn't meet these requirements. If infrastructure recommendations can't be met, additional measures such as chlorine treatment, copper-silver ionization or ultraviolet light can be used to ensure water quality [76]. As municipal water passes through the distribution network, the amount of residual disinfection agent can vary. If the facility is far away from the point of disinfection, the water the building receives may have disinfectant levels lower than the effective concentration [69]. The success of disinfection approaches may also be impacted by resistant species. For example, copper resistant *P. aeruginosa* was isolated from a French water system and tap aeration grids, and hydrogen peroxide and silver nitrate resistant *Legionella* spp. were isolated from a hospital's water supply [57,77]. Future work is needed to inform and improve HAI guidelines regarding the use of water and prevent the spread of AMR pathogens.

3.2. Biofilm Formation and Antimicrobial Resistance

Biofilms are secure, often heterogeneous, communities of microorganisms which colonize and grow on surfaces of medical implants, plumbing infrastructure and on patients [30]. They are comprised of dense microbial populations immobilized by an extracellular matrix comprised of bacterial secreted polymers such as exopolysaccharides (EPS), extracellular DNA and proteins [30]. Recently, point of use filters have been implemented in healthcare facilities as an additional form of protection from bacteria present in the water supply [78]. Even though *P. aeruginosa* and *Legionella* spp. were eliminated from taps in an intensive care unit in Hungary when point of use filters were installed, decreasing cases of infection to zero [79], they have been found to facilitate biofilm formation inside the filter when not maintained correctly, directly affecting the bacterial load in the water over time [78,80]. Within hospital water distribution systems and plumbing fixtures, biofilms provide a source of nutrients and protection from disinfection processes [30]. Biofilm growth is promoted in areas of low flow rate and stagnation which allows for bacterial attachment to the infrastructure surface [81].

The metabolic activity of the bacterial biofilm communities is different compared to planktonic bacteria, such as increased rates of EPS production, activation or inhibition of genes associated with biofilm formation and decreased growth rate [30]. The role of EPS has been linked to conferring tolerance to aminoglycosides by quenching their activity via a diffusion reaction inhibition [82]. An outbreak strain of aminoglycoside resistant *P. aeruginosa* was found on a contaminated bath toy in an Australian hospital [16]. Biofilm production confers protection to the microorganism communities from harmful pH, osmolarity, nutrient scarcity and shear forces [30]. Bacteria in biofilms are also more resistant to antimicrobial exposure by blocking the access of antibiotics, increasing the resistance by up to 1000-fold when compared to planktonic bacteria [45]. Once a biofilm community has reached maturation, species such as *L. pneumophila* may enter a viable non-culturable (VBNC) stationary phase as a way of surviving antibiotic stress [30,83]. Recent data suggests that hot water flushing and chlorination are not effective in eliminating *Legionella* spp. from plumbing systems over long periods of time [76,84]. This may be due to in part to bacterial species such as *Legionella* spp. being intracellular parasites of free living amoeba, resulting in conferred protection from disinfection by techniques when phagocytized [76].

One of the predominant mechanisms for acquiring antimicrobial resistance is uptake of resistance genes by horizontal gene transfer (HGT) [82]. The high cell density and presence of genetic elements from a highly heterogeneous community promotes this transfer via mechanisms such as conjugation, transformation or transduction [82]. Antimicrobial resistance may also be acquired via a mutation event in a bacterial chromosome [85]. Once the resistance mutation has stabilized in a generation,

it will be directly transmitted to all descendant cells by mitosis [86]. This process is known as vertical transmission. Under antimicrobial stress, resistance may arise via a combination of both HGT and vertical transmission. These genetic elements may enhance antimicrobial defense strategies by restricting drug entry via modifications to the cell wall, pumping the drug out of the cell, enzymatic degradation of the drug or deleting or decreasing the affinity of the involved target [87]. Exposure to chlorine can also stimulate the expression of efflux pumps and drug resistance operons, as well as induce mutations in some genes leading to increased antimicrobial resistance [45]. Some antibiotic gene profiles observed in hospital shower hose metagenomes have been reported to be triggered by biocide exposure [45,88,89]. These include commonly used antibiotics such as chloramphenicol, kanamycin, and penicillin. Species such as *Mycobacterium* spp. are commonly found in biofilm communities [45]. This may be because of physiochemical properties such as plumbing pipes being galvanized or made of copper, the disinfectant use and low organic carbon content of the water selectively favoring the growth of some *Mycobacterium* spp. [45]. When exposed to stress conditions, *Mycobacterium* spp. can modify the cell membrane fatty acid composition producing an altered permeability to biocide and antibiotic compounds [45,90,91]. The biofilm-forming capacity of pathogens such as *P. aeruginosa*, *Mycobacterium* spp. and *S. maltophilia* can promote the attachment of other pathogens such as *Salmonella* spp., *Campylobacter* spp. and *S. aureus* that are typically found in the wider hospital environment [92].

3.3. Detection Methods

3.3.1. Outbreak Investigations

Environmental screening typically takes place in response to an outbreak rather than as routine sampling, which leads to inconsistencies between the types of samples taken, isolation methods and antimicrobial resistance reporting. Thirty-five of 88 papers included in this review explored clinical outbreaks and sampled water and/or water related devices as a part of the investigation (Table S1). In contrast, 20/88 papers conducted broad screens of the facilities' environment in a non-outbreak setting. The Australian Guidelines for the Prevention and Control of Infection in Healthcare suggest that environmental testing should be carried out to identify risk factors [1]. However, it is not clear what sampling techniques are to be used and which samples should be taken [1]. Similarly, in the UK, there is guidance available from The National Specifications for Cleanliness in the NHS for monitoring the hospital environment. However, there was no indication of microbiological screening [93,94]. The absence of a standard approach for when environmental sampling should occur and what samples should be taken limits data comparisons that can be made and potentially overlooks reservoirs such as water and water-related devices.

3.3.2. Pathogen Detection from Environmental Sources

International standards have been published for the processing of environmental water samples for organisms such as *Legionella* spp., *P. aeruginosa* and *E. coli*. However, of the publications reviewed in this study, only three referenced a specific ISO standard [31,36,43]. There was significant variation between sampling techniques and selective growth media used in publications that investigated water-related surfaces such as tap faucets and drain holes [32,33,39–41,43,47,48,50,51]. Traditional microbial culturing techniques used for waterborne pathogens such as *Legionella* spp. has presented challenges for some environmental samples as VBNC cells and result in false negative results [83,95]. Furthermore, environmental waterborne pathogens often adapt to environments that are nutrient poor, which may be difficult to culture on nutrient-rich media types. Using nutritionally reduced media types such as R2A agar for longer incubation periods (14–28 days) may enhance the recovery of chlorine damaged and stressed bacteria [76]. Environmental water samples are often passed through membrane filters to concentrate and isolate any bacterial cells present in the sample. The pore diameter in these membrane filters typically ranges from 01 to 0.45 µm depending on the intended use [96]. The size, shape and biovolume of bacteria may influence the filterability of a sample and

potentially lead to inaccurate findings, particularly if multiple species of bacteria are being investigated using the one pore diameter [96]. Alternative molecular techniques for bacterial detection such as qPCR and whole-genome sequencing (WGS) have been employed by 27 studies included in this review [13,14,17,18,20,25,26,34,37,40,43,45,46,51,52,56,57,59,60,63–65,97–101]. Molecular techniques have significant advantages such as rapid turnaround times and detection of non-culturable cells [102]. However, limitations such as environmental inhibitors and potential overestimation of bacterial presence due to the amplification of non-viable cells needs to be considered [103]. For some bacteria, PCR-based techniques have been developed to differentiate viable cells from dead cells. For example, ethidium monoazide bromide viability staining can be used in conjunction with qPCR to enumerate viable cells (such as *L. pneumophila)* [102]. In order to implement effective surveillance programs, detailed and consistent sampling techniques and detection methods are essential.

3.3.3. Characterizing AMR

International standards for antimicrobial susceptibility testing have been jointly published by the Clinical and Laboratory Standards Institute and the European Centre for Disease Prevention and Control and the US CDC [104]. These standards include antibiotics to be tested against species that have commonly been associated with HAIs including *Acinetobacter* spp., *P. aeruginosa*, and *S. aureus* as well as breakpoints to determine an isolate's resistance to each antibiotic. Irrespectively, the reporting of resistant species remains inconsistent. When papers report the resistance profiles of an AMR isolate using differing units such as µg/mL or mg/mL MICs, percentage of isolates resistant or as specific resistance genes, the comparisons that can be made between studies are limited to broad comments rather than quantifiable data trends.

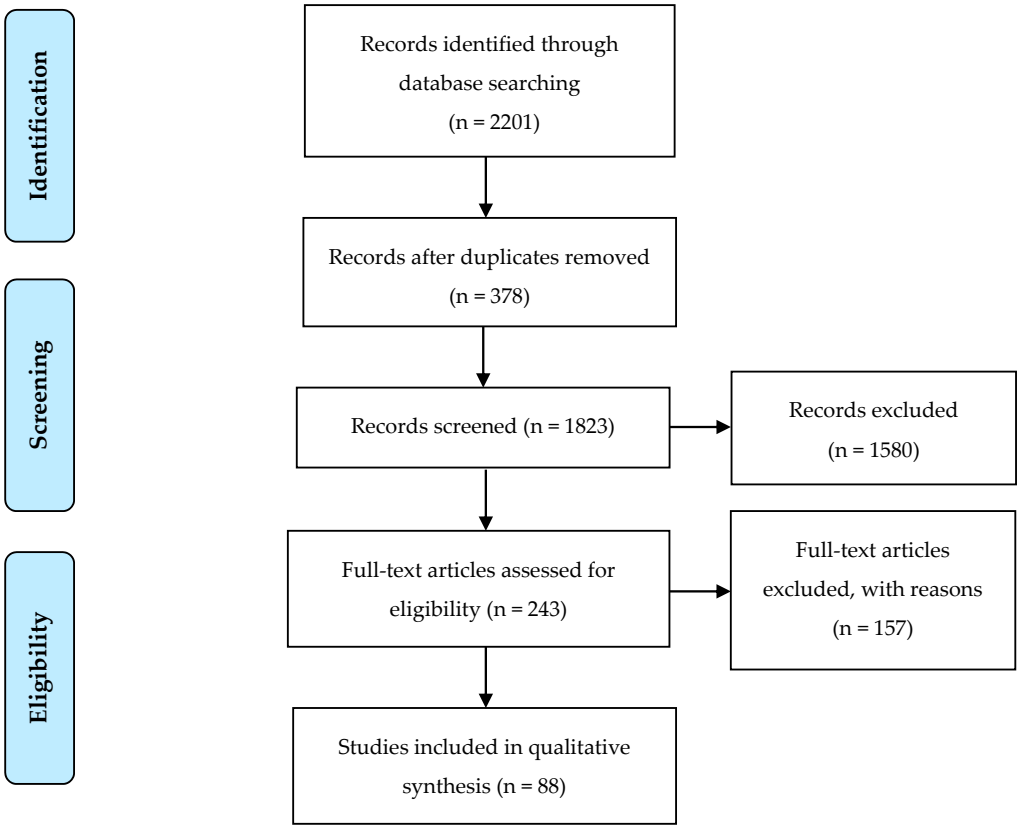

Figure 1. Flow diagram presenting the search strategies used, based on the PRISMA statement reporting guidelines for systematic literature reviews [105].

Figure 1. Flow diagram presenting the search strategies used, based on the PRISMA statement reporting guidelines for systematic literature reviews [105].

A48235836

4. Materials and Methods

This systematic literature review is based on an adapted version of the PRISMA statement [105], presented in Figure 1. This tool is an evidence-based system for evaluating and reporting evidence. A systematic search of the SCOPUS and Web of Science databases was performed, and all literature published prior to 2020 was included. Keywords used in this search are presented in Table 2. A detailed search strategy was established to ensure a comprehensive literature review of all identified antimicrobial resistance bacteria in healthcare water environments was achieved.

Table 2. Complete search strategy and all keywords used to identify relevant literature.

Search Terms Employed to Identify Relevant Literature
"antibiotic resistance *"OR "antimicrobial resistance *" OR disinfectant * OR AMR AND Water OR potable OR drinking OR taps OR faucet OR bath OR shower OR drain OR bathroom OR sink AND Hospital OR healthcare OR "aged care" OR ICU OR "intensive care unit" OR nosocomial OR HCAI OR "healthcare acquired infection" OR HAI OR "hospital acquired infection" OR "hospital associated infection" OR "healthcare associated infection"

'*' Indicates wildcard symbol used to when variations of the search term may be possible.

All titles and abstracts of published literature were manually reviewed to ensure that they reported antimicrobial resistant bacteria to the genus level. The paper must also have reported this presence in a healthcare setting water source or water-related device. Papers were excluded if they were not written in English, reviews, reports of human clinical infection with no mention of a contributing water source, laboratory setting experiments and wastewater investigations. All relevant papers had key points taken and recorded including the study site, water source, country, species of organism, isolation method used, antimicrobial method used, and relevant characteristics.

5. Conclusions

Although environmental reservoirs such as dry surface fomites have been identified as potential sources of HAIs, water and water-related devices are often overlooked. Understanding the role that water and water-related devices play as reservoirs for AMR bacteria is imperative to prevent transmission pathways that may cause HAIs. Water sources contaminated with AMR pathogens provide unique environments for the dissemination of antimicrobial resistance genes that are often unaffected by commonly employed disinfection strategies. Sinks, tap faucets, drains, bathtubs, drinking water fountains, aeration grids, showers and haemodialysis water have all been identified as contaminated with one or more species of AMR bacteria capable of causing HAIs. Broad universal environmental surveillance guidelines must be developed, including sampling locations, methodology and resistance reporting, to monitor resistant pathogens and predict future threats before infection outbreaks occur. By understanding how water and water related devices may harbor AMR species, better environmental controls can be implemented to significantly reduce the rates of waterborne HAIs.

Supplementary Materials: The following are available online at http://www.mdpi.com/2076-0817/9/8/667/s1, Table S1: Summary of reports and studies identifying AMR bacterial species within healthcare water sources and water-related devices during outbreak investigation, environmental screening, and molecular epidemiology.

Author Contributions: C.H., H.W., K.E.R. and M.H.B. designed and participated in review design. C.R.H. drafted and edited the manuscript. H.W., K.E.R. and M.H.B. corrected and contributed to the manusciript. All authors have read and agree to the publishsed version of the manuscript.

Funding: This research receieved no external funding.

Conflicts of Interest: The authors declare no conflict of interest.

Abstract

Objective: Water exposures in healthcare settings and during healthcare delivery can place patients at risk for infection with water-related organisms and can potentially lead to outbreaks. We aimed to describe Centers for Disease Control and Prevention (CDC) consultations involving water-related organisms leading to healthcare-associated infections (HAIs).

Design: Retrospective observational study.

Methods: We reviewed internal CDC records from January 1, 2014, through December 31, 2017, using water-related terms and organisms, excluding *Legionella*, to identify consultations that involved potential or confirmed transmission of water-related organisms in healthcare. We determined plausible exposure pathways and routes of transmission when possible.

Results: Of 620 consultations during the study period, we identified 134 consultations (21.6%), with 1,380 patients, that involved the investigation of potential water-related HAIs or infection control lapses with the potential for water-related HAIs. Nontuberculous mycobacteria were involved in the greatest number of investigations (n = 40, 29.9%). Most frequently, investigations involved medical products (n = 48, 35.8%), and most of these products were medical devices (n = 40, 83.3%). We identified a variety of plausible water-exposure pathways, including medication preparation near water splash zones and water contamination at the manufacturing sites of medications and medical devices.

Conclusions: Water-related investigations represent a substantial proportion of CDC HAI consultations and likely represent only a fraction of all water-related HAI investigations and outbreaks occurring in US healthcare facilities. Water-related HAI investigations should consider all potential pathways of water exposure. Finally, healthcare facilities should develop and implement water management programs to limit the growth and spread of water-related organisms.

Water that is used in health care can harbor pathogenic organisms that can threaten patient safety.[1–3] Patients may be exposed to water sources and so-called “opportunistic pathogens of premise plumbing” through a variety of means.[4] In healthcare facilities, water systems often have complex distribution pathways with areas of stagnation, exposure to a variety of

plumbing materials, and wide variability in temperature, pH, and disinfectant types and levels. These conditions can promote the development of biofilms and the growth of environmental opportunistic pathogens (eg, *Legionella*, nontuberculous mycobacteria (NTM), and *Pseudomonas* species). These organisms can be transmitted to patients, directly or indirectly, through typical water uses involving showers, sinks, and toilets. Moreover, water is widely used in clinical care, often in association with medical devices; it is also a key component in many drug or medication formulations. Patient susceptibility to opportunistic pathogens found in water may be increased by morbidities such as non-intact skin, open wounds, immunocompromising conditions, or the presence of invasive devices. Furthermore, hospital wastewater plumbing, including sink drains, can harbor multidrug-resistant organisms (MDROs), such as carbapenemase-producing *Enterobacteriaceae* (CRE), and may be a source of transmission to patients and a cause of clusters of healthcare-associated infections (HAIs).[5–7]

Outbreaks related to these organisms can be challenging to identify, investigate, and resolve. A high level of suspicion is typically needed to recognize that an infection or cluster of infections might be related to some form of water exposure associated with healthcare delivery. Interruption of transmission may require multidisciplinary interventions, often involving public utilities, health authorities, and consultants with expertise in water and environmental health. *Legionella* is a well-described cause of water-related HAIs, and these outbreaks can be associated with considerable patient harm and costs.[8] However, the occurrence of clusters of other water-related pathogens in healthcare has been less well described. In this report, we present a summary of Centers for Disease Control and Prevention (CDC) consultation experiences that have involved evaluating potential or confirmed transmission of water-related organisms, exclusive of *Legionella*. We describe the distribution of organisms, settings, and potential routes of transmission.

Methods

The Division of Healthcare Quality Promotion (DHQP) at CDC assists health departments and healthcare facilities with investigations of potential outbreaks involving the provision of health care. We reviewed our internal investigation consultation records from January 1, 2014, through December 31, 2017, using a query that involved a predefined set of water-related terms and list of water-related organisms (Table 1).

Investigations were excluded if (1) the consultation was for laboratory referencing testing only; (2) the infections were likely community acquired; (3) the organism in question was not a water-related opportunistic pathogen[3]; (4) an alternate transmission pathway was determined; or (5) the infections occurred outside the United States among non-US patients. Infections or outbreaks occurring abroad among non-US patients residing outside of the United States were excluded, whereas infections or outbreaks related to medical tourism where US patients travel abroad for medical care and acquire infections while abroad were included. Consultations involving *Legionella* infections and outbreaks were excluded because they have been summarized elsewhere.[8,9] Multistate investigations (which may have involved individual consultations with multiple health departments) were analyzed and counted as a single investigation.

A48235836

Author Manuscript Author Manuscript Author Manuscript Author Manuscript

We compiled the following information for each investigation identified: (1) number of patients infected or colonized; (2) organism(s) identified, including multidrug-resistant designation;(3) classification as confirmed or pseudo-outbreak (ie, increase in positive cultures without evidence of disease in patients);(4) whether pediatric patients were involved; (5) type of healthcare facility (ie, inpatient, outpatient, long-term care); (6) whether hemodialysis was an exposure of interest; (7) whether surgery was an exposure of interest; and (8) details regarding medical product exposures. Information regarding the types of infections (eg, disseminated, respiratory) was not available for many consultations and was therefore not reported.

We classified investigations as medical-product related if the use of a medical device or medication was an exposure of interest. Medical devices included central venous catheters, injections, endoscopes, ventilators, and other types of medical devices. We classified investigations that implicated compounded or manufactured medication products as involving either intrinsic contamination (eg, medication supplied in a contaminated state due to a manufacturing error) or extrinsic contamination (eg, medication became contaminated at the point of care). Categories were not mutually exclusive. Although routes of transmission for patient colonization or infection were not always confirmed or documented for each investigation, we determined plausible exposure pathways and routes of transmission based on available epidemiologic and laboratory information. We also identified pathways associated with >1 investigation. Molecular typing methods are increasingly used to help determine potential transmission pathways in HAI investigations, but we did not have consistent or systematic information on molecular typing results for all consultations included in this analysis.

Two authors (K.M.P. and S.C.R.) reviewed a sample of 30% of the investigations to ensure agreement that all investigations met the inclusion criteria and agreement on investigation characteristics and classification. One author (K.M.P.) reviewed the remaining investigations.

Results

We provided consultation support for 620 investigations between 2014 and 2017. Of those, 134 (21.6%) consultations met our criteria (Table 2). These investigations involved 1,380 patients, with an average of 10.3 affected patients per investigation (range, 0–163). Pediatric patients were involved in 21.6% of investigations. More than 20 different organisms were identified as the pathogen of concern (Table 2). Investigations involving NTM accounted for the greatest number of investigations (n = 40, 29.9%) and patients affected (n = 549, 39.8%). *Pseudomonas* spp accounted for the next greatest number of investigations (n = 25, 18.7%; patients: n = 152,11.0%). *Burkholderia* spp accounted for 10.4% of all water-related investigations but represented 26.2% of patients. Some water-related investigations included >1 organism (n = 10, 7.5%). One-third of investigations included pathogens that were multidrug-resistant, excluding NTM (n = 45, 33.6%).

Consultations involved a variety of healthcare settings. Although most occurred in inpatient facilities (n = 94, 70.1%), many also occurred in outpatient (n = 26, 19.4%) and long-term

A48235836

Author Manuscript Author Manuscript Author Manuscript Author Manuscript

care (n = 20, 14.9%) facilities. Surgery was an exposure of interest among 24 investigations (17.9%) and included cardiothoracic (n = 8), cosmetic (n = 5), and orthopedic (n = 3) surgeries among others. Medical products were involved in >35% of investigations, with medical devices representing the majority (n = 40, 83.3%). Medical device investigations involved 654 infected or colonized patients and included heater-cooler devices (n = 8), broncho-scopes (n = 5), other endoscopes (n = 3), and ventilators (n = 3), among others. Contaminated medications represented 9.7% of all investigations, with most involving probable intrinsic medication contamination (n = 10, 76.9%) and the remainder involving probable extrinsic medication contamination (n = 4, 30.8%).

As noted, NTM were involved in more investigations than any other bacterial pathogen. Of investigations involving NTM, most were *Mycobacterium abscessus* only (n = 10, 25.0%) or included multiple species of NTM (n = 11, 27.5%). Other NTM species included *M. fortuitum, M. chelonae, M. avium* complex, *M. goodii*, and *M. mucogenicum*, among others. NTM water-related investigations often involved a medical device (n = 20, 50.0%) or surgery (n = 21, 52.5%).

Table 3 lists examples of exposure pathways and routes of transmission for the investigations included in this study such as medication and nutrition preparation near the splash zones of sinks, contaminated water from operating room and patient care sinks, and poor practices in the reprocessing of reusable medical equipment, among others. Most exposure pathways and routes of transmission were identified in >1 investigation.

Discussion

Water-related opportunistic pathogens appear to contribute in important ways to the US HAI burden. Investigations involving non-*Legionella* water-related organisms or water exposures accounted for more than one-fifth of HAI consultations supported by CDC/DHQP from 2014 to 2017. These involved >1,300 patients, both adult and pediatric. Additionally, these water-related investigations span the spectrum of healthcare settings, including inpatient, outpatient, and long-term care settings. Table 4 provides descriptions of selected examples of water-related investigation consultations that occurred during the study period and represent a variety of healthcare settings and patient populations.

Our review may not represent the full spectrum of non-*Legionella*, water-related HAI investigations because we included only investigations in which CDC/DHQP provided consultation and assistance. The investigations summarized in our review likely represent more complex outbreaks and scenarios than those to which healthcare facilities and health departments might respond without consultation. Although CDC/DHQP tracks its response consultation activities, this does not constitute formal surveillance and final or complete information is lacking for many investigations. Therefore, information such as total number of patients infected or colonized reported in this review are likely underestimates. The number of patients not clinically infected or colonized by water-related organisms but *affected* by water-related outbreaks (eg, by patient notifications of exposed patients) is likely greater.[13] Additionally, as described in the Methods section, multistate outbreaks were counted as a single consultation, thereby underestimating the total number of consultations.

A48235836

Author Manuscript Author Manuscript Author Manuscript Author Manuscript

For example, CDC/DHQP involvement in the multistate outbreak of *Mycobacterium chimaera* infections following cardiac surgery associated with contaminated heater-cooler devices was counted as a single investigation, despite more than a dozen individual consultations with various states across the United States.[14]

In our review, a large proportion of water-related HAI investigations involved surgery (17.9%) or a medical device (29.9%). In the presence of surgical incisions, injections, and invasive devices, normal surface and mucosal host defenses are breached, potentially leading to invasive infections.[18,19] As more invasive medical procedures are transitioned from the inpatient to the outpatient setting, patients at risk for becoming infected with water-related organisms are increasingly being exposed in ambulatory settings. Although more than two-thirds of water-related investigations occurred in the inpatient setting, we found that 20% occurred in outpatient settings. In recent years, increasing attention has focused on adherence to standard infection control practices in the outpatient setting because this setting has been identified as an area with limited to no regulatory oversight.[20] Infection control issues related to water-related HAIs in ambulatory settings pose a special challenge because freestanding outpatient facilities may have little awareness or monitoring of their water quality and of the pathways through which water-related organisms can be transmitted to patients.

Medical products featured prominently in more than one-third of the investigations on which we consulted, with medical devices representing the majority. Transmission pathways from medical devices to patients should always be considered for any device that utilizes water. Water contamination of medical products can occur through local exposures at the facility-level or further upstream at the site of manufacture. Both points of contamination should be considered at the start of an investigation, but when the latter is suspected, CDC and the Food and Drug Administration (FDA) should be alerted early in the investigation because point-source contamination can manifest as sporadic cases across multiple institutions and can be challenging to detect. As the development of new medical devices evolves and the use of established medical devices continues to increase in the delivery of patient care, special attention to the potential introduction of water-related organisms is needed at the point of manufacture.[16,17,15,21–23]

The global outbreak of *Mycobacterium chimaera* infections associated with contaminated heater-cooler devices used during cardiothoracic surgery is a prime example of a medical device that uses water but had not been historically considered to have a water-transmission pathway from device to patient. During this global outbreak, heater-cooler devices were discovered to generate bioaer-osols that were transmitted into the operating room environment, exposing patients to NTM and the risk of infection.[15,23] Prior to the outbreak, heater-cooler devices had been used for years during cardiothoracic surgery without an appreciation of this water-related risk. This example highlights the potential for widespread harm associated with contamination of a medication or device during production and the need for additional safeguards to protect against the introduction of water-related organisms at the site of manufacture. Nonetheless, the introduction of water-related organisms to medical products often occurs proximal to patient care. Examples include the preparation of

Author Manuscript Author Manuscript Author Manuscript Author Manuscript

injections near water sources such as sinks and the use of tap water in reprocessing reusable medical equipment (Table 3).

Nontuberculous mycobacteria featured prominently in our review as the single most common source of water-related organism infections and consultation requests during the study period. Surgery and medical devices were each involved in half of NTM water-related investigations. This finding is consistent with a systematic review of water-related infections of NTM in healthcare facilities, which found that the most common route of NTM infection transmission was through the use of nonsterile water during medical procedures, such as insertion of central venous catheters or with the use of tap water to rinse medical equipment.[24] The presence of NTMs in municipal water systems, their habitation in biofilms, and their relative chlorine resistance makes these organisms especially difficult to control or eradicate.[4,18,19] Given that NTM infections are often marked by long incubation periods, nonspecific symptomatology, and severe clinical impact, standard case reporting and public health surveillance for extrapulmonary NTM have been recommended; these measures could facilitate more timely identification of clusters and outbreaks.[25–27]

More than one-third of our water-related investigation consultations included an MDRO (not including NTM, which are intrinsically resistant to many antibiotics). Many of these MDROs were *Enterobacteriaceae* and other gram-negative organisms, for which routes of transmission other than water, such as person-to-person transmission, may play a significant role. Although incoming healthcare-facility water is often hypothesized as the ultimate source of infections with water-related organisms, MDROs have been identified in healthcare wastewater plumbing, such as sink drains and toilets, and these water reservoirs have been linked to patient transmission events.[5–7] When investigating a cluster of these water-related MDROs, potential transmission from wastewater plumbing should especially be considered.

Water is increasingly recognized as a source of HAIs.[28] A 2016 review of published literature of healthcare outbreaks associated with water reservoirs revealed a wide variety of pathogens and infection types, including bloodstream infections, pneumonia, and disseminated disease.[1] Reservoirs implicated in these outbreaks included potable water, bathing, decorative water fountains, faucets, ice machines, and hospital wastewater systems, among others, and they were consistent with many of the exposure pathways and transmission routes identified in our study (Table 3). CDC and the Centers for Medicare and Medicaid Services (CMS) encourage hospitals and nursing homes to establish water management programs to prevent water-related HAIs.[8,29] CMS recently clarified a memorandum requiring “all hospitals, critical access hospitals and long-term care facilities to develop and adhere to policies and procedures that inhibit microbial growth in building water systems that reduces the risk of growth and spread of *Legionella* and other opportunistic pathogens in water.”[29] However, water management programs should go beyond mitigating the risk of *Legionella* and the traditional routes of spread; they should explore other pathways of transmission, such as those described in this report. CDC’s “Tap Water Quality and Infrastructure Discussion Guide for Investigation of Potential Water-Associated Infections in Healthcare Facilities” is available to assist healthcare facilities identify areas of concern.[3] Water management programs should also maintain awareness of

A48235836

Author Manuscript Author Manuscript Author Manuscript Author Manuscript

the risks and benefits of water conservation efforts, such as those associated with green water systems.[30]

In summary, our review highlights the contribution of water-related organisms to healthcare outbreaks and transmission and helps illustrate some of the challenges surrounding their investigation and prevention. Modern healthcare facilities have large, complex water systems that predispose them to biofilm formation and bacterial growth if not properly maintained.[18] For this reason, it is essential that healthcare facilities devise and implement a water management program that is effective in limiting water-related organisms from growing and spreading in their facility. Patient safety depends on assuring that water entering a healthcare facility meets all applicable quality standards and that the premise plumbing within the healthcare facility is designed and maintained in a way that minimizes growth and spread of water-related pathogens. Additionally, careful consideration should be taken of all potential pathways of water transmission to patients within a facility during patient care to minimize the risk of infection from water exposure.[3] Finally, because the potential exposure pathways for water-related organisms are numerous and extend from points of production to distribution, use, and disposal, primary prevention may never be absolute. Robust systems are needed, bridging healthcare and public health, to actively monitor and identify evidence of patient harms involving water-related organisms and to support timely investigation and effective interventions. This review highlights a wide variety of healthcare exposures and pathways that inform investigation and prevention of water-related healthcare-associated infections.

Acknowledgments.

The authors thank Clifford McDonald, MD and the Division of Healthcare Quality Promotion Water work group for their helpful advice and thoughtful feedback on this manuscript. We thank Steven Franklin for his assistance in database management, and the Prevention and Response Branch, the Clinical and Environmental Microbiology Branch, and other DHQP and CDC staff who assisted with the consultations included in this report. The findings and conclusions in this report are those of the authors and do not necessarily represent the official position of the Centers for Disease Control and Prevention.

Table 4.

Selected Examples of Water-Related Investigations, Division of Healthcare Quality Promotion, CDC, United States, 2014–2017

Year	Healthcare Setting	Description
2015	Outpatient dental clinic	• 24 children with odontogenic infections with *Mycobacterium abscessus* after undergoing pulpotomy procedures • All children required hospitalization and surgical intervention. • Water samples from dental station waterlines were positive for *M. abscessus* with laboratory typing showing matching strains to patient isolates. • Likely mode of transmission was the use of water from dental waterlines during pulpotomy procedures without water quality monitoring or disinfection of the waterlines.[10–11]
2016	Neonatal intensive care unit (NICU)	• 8 infants colonized or infected with *Pseudomonas aeruginosa* • Tap water and surface samples from sinks and expressed breast milk in the NICU were positive for *P. aeruginosa.* • Concern for multiple water transmission routes, including preparation of breast milk and infant formula near sinks, suboptimal cleaning of breast pump equipment, and use of tap water for filling humidifier reservoirs of infant incubators
2016–2017	Skilled nursing facilities	• 163 bloodstream infections of *Burkholderia cepacia* complex among patients from 59 nursing facilities across 5 states • Isolates from manufactured prefilled saline flush syringes were positive for *B. cepacia* complex with laboratory typing showing closely-related strains to patient isolates. • Nationwide recall of the contaminated saline flush syringes issued • Inspection of manufacturing facility identified deficiencies that could have contributed to contamination[16]
2017	Burn unit	• 5 infections of multidrug-resistant *P. aeruginosa* among patients in burn unit • Water samples from hydrotherapy room notable for heterotrophic plate count of >1 million colony-forming units/mL • Samples from family handwashing sinks and counters, hydrotherapy room equipment, and various sink drains were positive for *P. aeruginosa* of multiple different strains on molecular typing. • Likely modes of transmission included insufficient cleaning of hydrotherapy equipment and poor environmental cleaning practices.

Healthcare Outbreaks Associated With a Water Reservoir and Infection Prevention Strategies

Hajime Kanamori,[1,2] David J. Weber,[1,2] and William A. Rutala[1,2]

[1]Division of Infectious Diseases, University of North Carolina School of Medicine, and [2]Hospital Epidemiology, University of North Carolina Health Care, Chapel Hill

Hospital water may serve as a reservoir of healthcare-associated pathogens, and contaminated water can lead to outbreaks and severe infections. The clinical features of waterborne outbreaks and infections as well as prevention strategies and control measures are reviewed. The common waterborne pathogens were bacteria, including *Legionella* and other gram-negative bacteria, and nontuberculous mycobacteria, although fungi and viruses were occasionally described. These pathogens caused a variety of infections, including bacteremia and invasive and disseminated diseases, particularly among immunocompromised hosts and critically ill adults as well as neonates. Waterborne outbreaks occurred in healthcare settings with emergence of new reported reservoirs, including electronic faucets (*Pseudomonas aeruginosa* and *Legionella*), decorative water wall fountains (*Legionella*), and heater-cooler devices used in cardiac surgery (*Mycobacterium chimaera*). Advanced molecular techniques are useful for achieving a better understanding of reservoirs and transmission pathways of waterborne pathogens. Developing prevention strategies based on water reservoirs provides a practical approach for healthcare personnel.

Keywords. waterborne outbreaks; healthcare-associated infections; water; outbreaks.

Hospital water and water-related devices as well as moist environments and aqueous solutions can serve as a reservoir of waterborne pathogens in healthcare settings [1, 2]. The hospital environment may allow contamination by waterborne pathogens, in part because water temperatures are suitable for bacterial growth, and the complex structure of hospital water systems often leads to stagnation, corrosion, and biofilm formation [3]. A variety of water reservoirs have been linked to nosocomial outbreaks including potable water, sinks, faucet aerators, showers, tub immersion, toilets, dialysis water, ice and ice machines, water baths, flower vases, eyewash stations, and dental-unit water stations [4]. Waterborne pathogens have included *Legionella*, other gram-negative bacilli, nontuberculous mycobacteria (NTM), fungi, protozoa, and viruses [3–5]. Transmission of these pathogens from a water reservoir may occur by direct and indirect contact, ingestion and aspiration of contaminated water, or inhalation of aerosols [1, 2]. Waterborne outbreaks caused by these pathogens and reservoirs have occurred among patients in healthcare settings and have been a serious threat to high-risk patients, especially critically ill patients and immunocompromised hosts, leading to substantial morbidity and mortality [3–5].

The aim of this review article was to (1) review healthcare-associated outbreaks and infections associated with a water reservoir from the published literature, and (2) provide infection prevention strategies and control measures by water reservoirs based on the published scientific evidence and available guidelines.

SEARCH AND SELECTION CRITERIA FOR REVIEWING THE LITERATURE

We searched the published literature via PubMed using the following Medical Subject Headings (MeSH) and keywords: (hospital OR hospitals OR hospital units OR nursing homes OR ambulatory care facilities OR ambulatory care OR dental facilities OR assisted living facilities OR healthcare settings OR patient) AND (waterborne pathogens OR *Legionella* OR Legionnaires' disease OR bacterial infections OR *Mycobacterium* infections OR fungal infections OR mycoses OR protozoan infections OR healthcare-acquired infection OR nosocomial OR cross infection OR outbreak) AND (hospital water OR drinking water OR potable water OR ice OR sink OR faucet OR faucet aerator OR shower OR tub or toilet OR water fountain OR water bath OR dialysis water OR decorative fountain OR ice machine OR air conditioning OR heater-cooler unit OR water microbiology OR disease reservoirs).

From January 1967 to July 2015, 2445 publications were identified as a result of our search and were reduced to 1746 by filters of availability in English and abstracts. The 1189 references (January 1997–July 2015) were screened using titles and abstracts, then selected articles were carefully reviewed. For the references published before 1997, we cited a previous review

Received 8 January 2016; accepted 19 February 2016; published online 1 March 2016.

article [4] because of limited numbers of citable references. We excluded articles without abstracts, non-English-language articles, articles that were unavailable in PubMed, reported cases of contaminations or pseudo-outbreaks, and articles that did not include human infections. We identified 179 references by our initial screening process, and then prioritized listed citations to include at least 1 article from each reservoir and organism. Finally, 73 original articles [6–78] were selected and data were retrieved for further analysis. Table 1 provides the features of waterborne healthcare-associated outbreaks and infections by each category, including author, publication year, reservoir, organism, transmission, patient population, infection type, molecular typing, and study type.

HEALTHCARE-ASSOCIATED OUTBREAKS AND INFECTIONS CAUSED BY WATERBORNE PATHOGENS

A review of the literature revealed multiple outbreaks in healthcare facilities due to a variety of pathogens associated with a water reservoir (Table 1). Infections included bloodstream infections, pneumonia, and disseminated diseases (Table 1). Patient populations at risk for waterborne outbreaks and infections included those with hematological and other malignancies or stem cell transplants, immunocompromised patients, location in an intensive care unit (ICU), premature infants in a neonatal intensive care unit (NICU), burn patients, and patients during/after surgery (Table 1).

Causative pathogens included bacteria (*Legionella*, *Pseudomonas*, *Acinetobacter*, *Serratia*, *Stenotrophomonas*, *Enterobacter*, *Klebsiella*, *Alcaligenes*, *Burkholderia*, *Chryseobacterium*, *Elizabethkingia*, *Halomonas*, *Ochrobactrum*, *Sphingomonas*, NTM), fungi (*Aspergillus*, *Mucor*, *Trichosporon*, *Fusarium*, *Exophiala*), and viruses (norovirus) (Table 1). Details of overall waterborne pathogens in healthcare-associated infections [3, 5, 79–82], and specifically *Legionella* [83–86], *Pseudomonas aeruginosa* [87, 88], *Aspergillus* [89], and NTM [90], have been previously reviewed. *Legionella* and NTM can reside in hospital water distribution systems, while other gram-negative bacteria and fungi can form biofilms [3, 79]. We briefly updated key points from recent literature on healthcare-associated pathogens in waterborne outbreaks and infections as described below.

Legionella

Legionella can be detected in most water sources at low levels [91]. The level of contamination of *Legionella* in hospital water systems associated with disease remains unclear. A large healthcare-associated *Legionella* outbreak occurred at a Pennsylvania hospital despite implementing a *Legionella* disinfection program with a copper-silver ionization system of hospital water [40]. In this outbreak, a link between clinical isolates of *Legionella* and hospital environmental samples was confirmed by molecular typing, and *Legionella* was viable and transmissible despite the presence of copper and silver ion concentrations within the manufacturer's recommended range [40].

Multidrug-Resistant Gram-Negative Bacteria

As antimicrobial resistance in bacteria has become a global concern, multidrug-resistant gram-negative bacteria (*Klebsiella*, *Enterobacter*, *Pseudomonas*, *Acinetobacter*), including bacteria producing extended-spectrum β-lactamases or carbapenemases (eg, *Klebsiella pneumoniae* carbapenemase [KPC] and New Delhi metallo-β-lactamase), were described as waterborne pathogens causing healthcare-associated infections [19, 21, 22, 48, 50, 52, 54, 55, 57–59, 70, 71]. Multidrug-resistant organisms were most commonly linked to contaminated sinks as a reservoir (Table 1). Notably, an outbreak of 6 infections due to KPC-2–producing *Klebsiella oxytoca* in patients with hematological malignancies was linked to contaminated handwashing sinks [57].

Nontuberculous Mycobacteria

Our review found that a variety of NTM, including both rapid-growing and slow-growing species, has led to waterborne healthcare-associated outbreaks and infections as follows: *Mycobacterium abscessus* with tap water, *Mycobacterium avium* with potable water, *Mycobacterium chelonae* with ice and ice machines, *Mycobacterium chimaera* with heater-cooler units, *Mycobacterium fortuitum* with hospital water systems and showers, *Mycobacterium genavense* with tap water, *Mycobacterium mucogenicum* with bathing and tub immersion, electronic faucets, sinks, showers, and hospital water systems, *Mycobacterium neoaurum* with hospital water systems, *Mycobacterium phocaicum* with showers, *Mycobacterium porcinum* with ice and ice machines and tap water, and *Mycobacterium simiae* with tap water [7, 13, 20, 27, 28, 31, 34, 35, 37, 41, 45, 51, 60, 62, 66]. NTM can be present in municipal water systems and is relatively resistant to chlorination as well as being difficult to eradicate from contaminated water systems [3].

Fungi

Waterborne fungal outbreaks and infections occurred among patients with hematological malignancies or stem cell transplantation. *Aspergillus* can be detected from hospital water samples and has been reported to cause invasive aspergillosis [25, 43, 68, 89]. However, there are no criteria for contamination levels of hospital water associated with fungal infections. Furthermore, whether *Aspergillus* can cause waterborne healthcare-associated infections via aerosols generated from contaminated hospital water remains controversial [92]. Other fungal outbreaks associated with water reservoirs included *Mucor* with water-damaged plaster, *Trichosporon asahii* with wash basins, *Fusarium* with showers and sinks in a hospital water distribution system, and *Exophiala jeanselmei* with deionized water from the hospital pharmacy [11, 24, 74, 78].

A48235836

Table 1. Characteristics of Waterborne Outbreaks and Infections in Healthcare Settings, 1997 January–2015 June

Reservoir	Organism(s)	Transmission	Patient Population	Type of Infection	Molecular Typing	Study Type	First Author, Year
Bathing and tub immersion (bathing tub drain)	*Pseudomonas aeruginosa*	Tub immersion water contaminated from drain when whirlpool bathtub filled	Patients with hematological malignancies (leukemia)	Bloodstream infection, pneumonia, UTI	PFGE	Outbreak – strong causation	Berrouane, 2000 [6]
Bathing and tub immersion (showering)	*Mycobacterium mucogenicum*	Water contamination of CVCs during bathing or showering	BMT and oncology patients	Bacteremia	RAPD	Outbreak – strong causation	Kline, 2004 [7]
Bathing and tub immersion	*Legionella pneumophila*	24 h bath water contaminated	An elderly patient with dementia admitted to a nursing home	Pneumonia	PFGE	Case report (single) – strong causation	Mineshita, 2005 [8]
Bathing and tub immersion (bathing mattress)	*Alcaligenes xylosoxidans*	Bathing procedures and hydrotherapy in burn unit	Burn patients	Cholecystitis, meningitis	PFGE	Case report (single) – strong causation	Fujioka, 2008 [9]
Decorative water fountain	*Legionella pneumophila*	Exposure to contaminated water from decorative fountain	Allogeneic stem cell transplant patients	Pneumonia	PFGE	Outbreak – strong causation	Palmore, 2009 [10]
Deionized water from the hospital pharmacy	*Exophiala jeanselmei*	Contaminated deionized water solution that was used to prepare antiseptic solutions	Hematological malignancies	Fungemia	RAPD	Outbreak – strong causation	Nucci, 2002 [11]
Dialysis water supply	*Burkholderia cepacia*	Inadequate cleaning and a leak in the reverse osmosis tubing connection	Hemodialysis patients	Bacteremia	RAPD	Outbreak – strong causation	Souza, 2004 [12]
Electronic faucet	*Mycobacterium mucogenicum*	Exposure of CVC sites to contaminated water during bathing	Cancer patients (leukemia, rhabdomyosarcoma, neuroblastoma)	Catheter-associated BSI	RAPD	Outbreak – strong causation	Livni, 2008 [13]
Electronic faucet	*Pseudomonas aeruginosa*	Contamination of outlet, magnetic valve, and mixing device of the electric faucets	Patients in NICU	Bloodstream infection, ventilator-associated pneumonia	PFGE	Outbreak – strong causation	Yapicioglu, 2012 [14]
Faucet (aerator)	*Stenotrophomonas maltophilia*	Contaminated water after aeration	Patients in surgical ICU	Pneumonia, peritonitis, bacteremia, UTI	PFGE	Outbreak – strong causation	Weber, 1999 [15]
Faucet	*Pseudomonas aeruginosa*	Contaminated faucets	Patients in ICU	*P. aeruginosa* infection	PFGE	Case series (multiple) – strong causation	Blanc, 2004 [16]
Faucet	Nonfermentative gram-negative bacilli (eg, *Chryseobacterium meningosepticum*)	Unknown	Patients in ICU	Nosocomial infections	PFGE	Case series (multiple) – strong causation	Wang, 2009 [17]
Faucet (outlet)	*Pseudomonas aeruginosa*	Potential transmission from contaminated flow straighteners in the water outlets	Neonates in NICU	Bacteremia	VNTR	Case series (multiple) – strong causation	Walker, 2014 [18]
Faucet (water-saving device)	MDR-*Pseudomonas aeruginosa*	Water-saving device (aerator) in a staff hand basin and biofilm in the basin's plumbing contaminated	Patients in high dependency units	Nosocomial infection	PFGE	Case series (multiple) – strong causation	Inglis, 2010 [19]
Heater-cooler unit for cardiac surgery	*Mycobacterium chimaera*	Airborne transmission from contaminated heater-cooler unit water tanks	Patients who received open-chest heart surgery	Endocarditis, bloodstream infection, vascular graft infection	RAPD	Outbreak – strong causation	Sax, 2015 [20]

Reservoir	Organism(s)	Transmission	Patient Population	Type of Infection	Molecular Typing	Study Type	First Author, Year
Hospital waste water system	MDR *Pseudomonas aeruginosa*	Contaminated hospital waste water systems (sink, shower, and toilet)	Patients in ICU and hematology units	Bacteremia	PFGE, VNTR	Outbreak – strong causation	Breathnach, 2012 [21]
Hospital waste water system	IMP-type metallo-β-lactamase-producing *Klebsiella oxytoca*	Contaminated water	Patients in medical and surgical ICU	Bacteremia, ventilator-associated pneumonia, UTI, peritonitis	PFGE	Outbreak – strong causation	Vergara-Lopez, 2013 [22]
Hospital water system	*Legionella pneumophila*	Contaminated water supply	Immunocompromised patients	Pneumonia	PFGE	Case series (multiple) – strong causation	Rangel-Frausto, 1999 [23]
Hospital water system	*Fusarium*	Aerosols from showers and sinks	Patients with leukemia, neutropenia, BMT or stem cell transplant	Invasive fusariosis	RAPD, RFLP, IR-PCR	Case series (multiple) – strong causation	Anaissie, 2001 [24]
Hospital water system	*Aspergillus fumigatus*	Unknown	BMT patients	Invasive pulmonary aspergillosis	AFLP	Case series (multiple) – strong causation	Warris, 2003 [25]
Hospital water system	Amoeba-associated bacteria (mainly *Legionella anisa, Bosea massiliensis*)	Unknown	Patients receiving mechanical ventilation in ICU	Ventilator-associated pneumonia	Seroconversion	Case series (multiple)	La Scola, 2003 [26]
Hospital water system	*Mycobacterium avium* complex	Contaminated hospital hot water system	Hospitalized patients	NTM pulmonary disease	PFGE	Case series (multiple) – strong causation	Tobin-D'Angelo, 2004 [27]
Hospital water system	NTM (*Mycobacterium mucogenicum, Mycobacterium neoaurum*)	Exposure of CVC sites to contaminated water during showering	Patients with hematological malignancies	Bacteremia	NA	Outbreak	Baird, 2011 [28]
Hospital water system	Rapidly growing mycobacteria (eg, *Mycobacterium chelonae*)	Contaminated water and ice machines	Hematopoietic cell transplant patients	Mycobacterial infection	NA	Outbreak	Iroh Tam, 2014 [29]
Hospital water system	*Pseudomonas aeruginosa*	Contaminated water outlet and shower hydrotherapy	Burn patients	Nosocomial infection	Whole-genome sequencing	Case series (multiple) – strong causation	Quick, 2014 [30]
Hospital water system	*Mycobacterium fortuitum*	Contaminated shower water	A postoperative patient with breast cancer	Breast infection	Repetitive extragenic palindromic PCR	Case report (single) – strong causation	Jaubert, 2015 [31]
Ice and ice machine	*Legionella pneumophila*	Microaspiration of ice or ice water	A patient with interstitial pneumonia and mechanical ventilation treated with steroids	Respiratory tract infection	NA	Case report (single)	Graman, 1997 [32]
Ice and ice machine	*Enterobacter cloacae*	Contaminated ice used for cardioplegia in cardiac surgery	Patients who received coronary artery bypass grafting	Postoperative wound infection	PFGE	Outbreak – strong causation	Breathnach, 2006 [33]
Ice and ice machine/ tap water	*Mycobacterium chelonae*	Application of contaminated nonsterile ice to the skin	Patients after cosmetic dermal filter injections at a plastic surgery clinic	Cutaneous infection	PFGE	Case series (multiple) – strong causation	Rodriguez, 2013 [34]
Ice and ice machine/ tap water	*Mycobacterium porcinum*	Contaminated water	Patients with pulmonary disease or extrapulmonary disease	Pulmonary infection, localized abscess, infected port, peritonitis	PFGE	Case series (multiple) – strong causation	Brown-Elliott, 2011 [35]
Ice bath	*Pseudomonas fluorescens*	Contaminated ice bath used for cardiac output infusion	Patients with cardiac diseases in a CCU	Bacteremia	PFGE	Outbreak – strong causation	Benito, 2012 [36]
Potable water	*Mycobacterium avium*	Contaminated water	Patients with AIDS and non-AIDS	Disseminated infection	PFGE	Outbreak – strong causation	Aronson, 1999 [37]

Table 1 continued.

Reservoir	Organism(s)	Transmission	Patient Population	Type of Infection	Molecular Typing	Study Type	First Author, Year
Sink	GIM-producing *Pseudomonas aeruginosa*	Inappropriate use of surface areas around washbasins as placement of clean items	Patients in a tertiary care hospital	*P. aeruginosa* infection	PFGE, MLST	Outbreak – strong causation	Wendel, 2015 [55]
Sink	*Pseudomonas aeruginosa*	Contaminated water from sink	Infants in NICU	Pneumonia	Whole-genome sequencing, ERIC-PCR typing	Outbreak – strong causation	Davis, 2015 [56]
Sink	KPC-producing *Klebsiella oxytoca*	Contaminated handwashing sink	Patients with hematological malignancies	Pneumonia, abdominal wall abscess	Repetitive-sequence-based PCR, MLST	Outbreak – strong causation	Leitner, 2015 [57]
Sink / Shower	NDM-producing *Klebsiella pneumoniae*	Interhospital transfer of patients and contaminated sink trap	Older or chronically ill patients	*K. pneumoniae* infection	PFGE, MLST	Outbreak – strong causation	Seara, 2015 [58]
Sink / Tap water	MDR *Pseudomonas aeruginosa*	Contaminated water or patient-to-patient transmission	Patients in a neurosurgery ICU	Multiple (urinary infection, pneumonia, sinusitis)	PFGE	Outbreak – strong causation	Bert, 1998 [59]
Tap water	*Mycobacterium abscessus*	Inadequate sterilization of surgical instruments	Postsurgical patients	Wound infection	NA	Outbreak	Chadha, 1998 [60]
Tap water	Small round structured viruses	Transient contamination of the taps	Patients in a reeducation ward	Gastroenteritis	Sequencing	Outbreak – strong causation	Schvoerer, 1999 [61]
Tap water	*Mycobacterium genavense*	Ingestion of contaminated water	HIV-infected patients treated with HAART	Disseminated mycobacteriosis	NA	Case series (multiple)	Hillebrand-Haverkort, 1999 [62]
Tap water	*Ochrobactrum anthropi*	Unknown	Immunocompromised patients (leukemia) in hematology unit	Bacteremia	PFGE (unrelated)	Case series (multiple)	Deliere, 2000 [63]
Tap water	*Chryseobacterium* (*Flavobacterium*) *meningosepticum*	Contaminated sink drain and biofilm inside the sink tap	Neonates in NICU	Pneumonia, meningitis with septicemia	PFGE	Outbreak – strong causation	Hoque, 2001 [64]
Tap water	*Sphingomonas paucimobilis*	Contaminated taps and showers used in a hematology ward	A neutropenic patient with leukemia	Bacteremia	RAPD	Case report (single) – strong causation	Perola, 2002 [65]
Tap water	*Mycobacterium simiae*	Potential transmission via showering	Pulmonary cancer, chronic pulmonary disease	Pulmonary infection	PFGE	Outbreak – strong causation	Conger, 2004 [66]
Tap water	*Burkholderia cepacia*	Alcohol skin antiseptic diluted by contaminated tap water that was applied to intravenous catheter site	Patients with cardiovascular disease or cancer	Bacteremia	RFLP	Outbreak – strong causation	Nasser, 2004 [67]
Tap water	*Aspergillus flavus*	Contamination of hospital environment (air, tap water, surface)	Patients in BMTU, ICU, and NICU	Invasive aspergillosis	RAPD	Case report (single) – strong causation	Ao, 2014 [68]
Tap water	*Pseudomonas aeruginosa*	Contaminated tap water	Patients in ICU	Nosocomial infection	NA	Case series (multiple)	Venier, 2014 [69]
Tap water / Wash basin	MDR *Pseudomonas aeruginosa*	Contaminated water taps and wash basins	Patients receiving mechanical ventilation in ICU	Lower respiratory infection and bloodstream infection	AFLP	Outbreak – strong causation	Bukholm, 2002 [70]
Toilet	MDR *Pseudomonas aeruginosa*	Potential cross transmission via toilet brush	Hospitalized patients	Nosocomial infection	PFGE	Case series (multiple) – strong causation	Kouda, 2011 [71]
Toilet / Shower	Norovirus	Possible transmission via hand contact and contaminated items within toilets and the bedside environment	Hospitalized patients with symptoms of gastroenteritis	Gastroenteritis	RT-PCR	Case series (multiple)	Morter, 2011 [72]

Table 1 continued.

Reservoir	Organism(s)	Transmission	Patient Population	Type of Infection	Molecular Typing	Study Type	First Author, Year
Wash basin / Potable water	*Legionella pneumophila*	Contaminated water in wash basins	A patient with leukemia	Pneumonia	PFGE	Case report (single) – strong causation	Brulet, 2008 [73]
Wash basin / Sink	*Trichosporon asahii*	Contaminated wash basins	Patients with malignancies, burns, and surgery in ICU	Disseminated infection	Sequencing	Case series (multiple) – strong causation	Fanfair, 2013 [74]
Water bath	*Pseudomonas aeruginosa*	Transfusion of contaminated fresh frozen plasma or human albumin	Infants in NICU	Bloodstream infection	RAPD	Outbreak – strong causation	Muyldermans, 1998 [75]
Water bath	*Halomonas phocaeensis* sp nov	Administration of fresh frozen plasma warmed by contaminated water baths	Neonates in NICU	Bacteremia	16S rRNA gene sequencing	Outbreak	Berger, 2007 [76]
Water birthing	*Legionella pneumophila*	Aspiration of pool water contaminated	A neonate	Pneumonia	NA	Case report (single)	Franzin, 2001 [77]
Water-damaged plaster	*Rhizomucor pusillius*	Water damage in a linen room and parents' shower room	Patients with leukemia	Rhinocerebral mucormycosis	NA	Outbreak	Garner, 2008 [78]

In study type, each article's definition of "case series (multiple)" or "outbreak" was used. "Case series (multiple)" or "case report (single)" was determined based on the number of human infections linked to a water reservoir. "Strong causation" was added when at least 1 molecular typing method indicated relatedness to a water reservoir.

Abbreviations: AFLP, amplified fragment length polymorphism; AP-PCR, arbitrarily primed polymerase chain reaction; BMT, bone marrow transplant; BMTU, bone marrow transplant unit; BSI, bloodstream infection; CCU, coronary care unit; CVC, central venous catheter; ERIC-PCR, enterobacterial repetitive intergenic consensus polymerase chain reaction; ESBL, extended-spectrum β-lactamase; GIM, German imipenemase; HAART, highly active antiretroviral therapy; HIV, human immunodeficiency virus; ICU, intensive care unit; IMP, imipenem; IR-PCR, interrepeat polymerase chain reaction; KPC, *Klebsiella pneumoniae* carbapenemase; MDR, multidrug resistant; MLST, multilocus sequence typing; NA, not applicable; NDM, New Delhi metallo-β-lactamase; NICU, neonatal intensive care unit; NTM, nontuberculous mycobacteria; PCR, polymerase chain reaction; PFGE, pulsed-field gel electrophoresis; RAPD, random amplification of polymorphic DNA; RFLP, restriction fragment length polymorphism; rRNA, ribosomal RNA; RT-PCR, reverse transcription polymerase chain reaction; UTI, urinary tract infection; VNTR, variable number tandem repeat.

RESERVOIRS AND TRANSMISSION ROUTES OF WATERBORNE PATHOGENS AND INFECTION PREVENTION STRATEGIES AGAINST WATERBORNE OUTBREAKS IN HEALTHCARE SETTINGS

All water with the exception of sterile water and filtered water is contaminated with microbes (eg, potable water, tap water, showers, and ice). In healthy persons, contact or ingestion of such water rarely leads to infection. However, contact or ingestion of such water may cause infection in immunocompromised persons or when applied to nonintact skin. Water-related reservoirs in healthcare settings during 1997–2015 were as follows: bathing and tub immersion, decorative water fountains, deionized water, dialysis water, electronic faucets, faucets, heater-cooler units, hospital wastewater systems, hospital water systems, ice and ice machines, ice baths, potable water, showers, sinks, tap water, toilets, wash basins, water baths, water birth, water-damaged plaster, and water-saving devices (Table 1). Transmission routes were primarily direct contact with contaminated water and water-related devices/activities or inhalation via aerosols generated from the contaminated water (Table 1). Waterborne healthcare-associated outbreaks and infections continue to occur and were mostly associated with well-recognized water reservoirs as previously described [4]. Moreover, recent studies document electronic faucets (*P. aeruginosa*, *Legionella*, *M. mucogenicum*) [13, 14, 93–95], decorative water wall fountains (*Legionella*) [10, 91], and heater-cooler devices used for cardiac surgery (*M. chimaera*) [20, 96] as water reservoirs. Infection prevention and control measures by each reservoir category are summarized in Table 2. The Centers for Disease Control and Prevention (CDC) has published recommendations of infection prevention and management for hospital water [1, 2].

Potable Water, Tap Water, and Hospital Water Systems

Various healthcare-associated infections were linked to contaminated potable/tap water and hospital water systems, especially among immunocompromised and severely ill patients [21–26, 28, 29, 37–39, 62–65, 68–70]. The common pathogens included gram-negative bacilli (eg, *Pseudomonas*, *Stenotrophomonas*) [21, 30, 38, 39, 69, 70], *Legionella* [23, 40], and NTM [27–29, 31, 37, 60, 62, 66]. Waterborne organisms may exist in potable water at acceptable levels of coliform bacteria (<1 coliform bacterium/100 mL) [4]. Standards for potable water should adhere to public health guidelines, and hot water temperature at the outlet should be maintained at the highest temperature allowable [1, 2].

Sinks

Some studies demonstrated a transmission link between sinks colonized with a pathogen and patients using molecular typing methods [47–52, 54–59]. The most frequent pathogens associated with sinks were gram-negative bacilli (eg, *Pseudomonas*, *Acinetobacter*, *Serratia*), as gram-negative bacilli can survive in wet

A48235836

Table 2. Summary of Key Issues and Infection Prevention Strategies Against Waterborne Outbreaks by Major Water Reservoir in Healthcare Settings

Reservoir	Key Issues	Infection Prevention Strategies
Potable water, tap water, and hospital water systems	Potable water is not sterile, and pathogenic waterborne organisms may exist in potable water at acceptable levels of coliform bacteria (<1 coliform bacterium/100 mL). Healthcare-associated outbreaks have been linked to contaminated potable water. Semicritical devices are often rinsed with potable water, which may lead to contamination of the equipment and subsequent healthcare-associated infections. Common pathogens include nonenteric gram-negative bacilli (eg, *Pseudomonas aeruginosa*), *Legionella*, NTM.	Follow public health guidelines. Hot water temperature at the outlet at the highest temperature allowable, preferably >51°C. Water disruptions: post signs and do not drink tap water. Maintain standards for potable water (<1 coliform bacterium/100 mL). Rinse semicritical equipment with sterile water, filtered water, or tap water followed by alcohol rinse. Some experts have recommended periodic monitoring of water samples for growth of *Legionella*. *Legionella* eradication can be technically difficult, temporary, and expensive. Potential methods of eradication include filtration, ultraviolet, ozonization, heat inactivation (>60°C), hyperchlorination, and copper-silver ionization (>0.4 ppm and >0.04 ppm, respectively).
Sinks	Colonization of sinks with gram-negative bacilli has been reported. Some studies demonstrate a transmission link between a colonized sink and infected patients. Some studies describe that multidrug-resistant gram-negative bacilli are associated with contaminated sinks. Gram-negative bacilli can survive wet environments, including sinks, for a long time (>250 d) Transmission can be caused by splashing of water droplet from contaminated sinks to hands of healthcare personnel, followed by transient colonization of hands. Common pathogens include gram-negative bacilli (eg, *Pseudomonas*, *Acinetobacter*, *Serratia*).	Use separate sinks for handwashing and disposal of contaminated fluids. Decontaminate or eliminate sinks as a reservoir if epidemic spread of gram-negative bacteria via sinks is suspected.
Faucet aerators	Faucet aerators may serve as a platform for accumulation of waterborne pathogens. Potential pathogens include *Pseudomonas*, *Stenotrophomonas*, and *Legionella*.	Routine screening and disinfection or permanent removal of all aerators are not warranted at present. No precautions necessary at present. For *Legionella* outbreaks, clean and disinfect faucet aerators in high-risk patient areas periodically, or consider removing them in the case of additional infections.
Showers	Some outbreaks are linked to contaminated shower heads or inhalation of aerosols. Potential pathogens include *Legionella*, *Pseudomonas*, NTM, group A *Streptococcus*, and *Aspergillus*.	Prohibit use of showers in neutropenic patients. Control *Legionella* colonization of potable water.
Ice and ice machines	Patients can acquire pathogens by sucking on ice, ingesting iced drinks, or use of contaminated ices for cooling medical procedure and patients' skin. Large outbreaks occurred when ice machines have become contaminated and ice used for cooling drinking water. Common pathogens include *Pseudomonas*, *Enterobacter*, *Legionella*, NTM, and *Cryptosporidium*.	Do not handle ice by hand. Do not store pharmaceuticals or medical solutions on ice for consumption. Use automatic dispenser rather than open chest storage compartments in patient areas. Clean and disinfect ice-storage chests regularly. Meaningful microbial standards for ice and ice machines do not exist. Routine culturing of ice machines are not recommended. A regular disinfection program for ice machines is recommended.
Eyewash stations	Stationary and portable eyewash stations may not be used for months or years. The water source may stand in the incoming pipes at room temperature for a long period. Pathogens, including *Pseudomonas*, *Legionella*, amoebae, and fungi, could be transmitted.	Use sterile water for eye flush or regularly (eg, monthly) flush eyewash stations.
Dental-unit water systems	Potable water usually supplies dental units. Water delivered to dental devices (eg, dental handpieces and air/water syringes) as well as dental unit water lines may be contaminated. Immunocompromised patients may be at risk for infection. Pathogens, including *Sphingomonas*, *Pseudomonas*, *Acinetobacter*, *Legionella*, and NTM, have been recovered from water supplies in dental units.	Clean dental water systems. Flush with water and disinfectant solution, or use of clean-water systems that put sterile water into the dental unit. Flush dental instruments with water and air for 20–30 sec from any dental device connected to the dental water system that enters the patient's mouth (eg, handpieces). Ensure that water in dental unit meets standards (<500 CFU/mL).
Dialysis water	Excessive levels of gram-negative bacilli in the dialysate were responsible for pyrogenic reactions in patients or bacteremia, which was caused by bacteria or endotoxin entry into the blood from the contaminated dialysate.	Follow AAMI standards for quality assurance performance of dialysis devices. Disinfect water distribution system on a regular basis. Perform microbiological testing and endotoxin testing for water in dialysis settings regularly. Maintain dialysis water (input) <200 CFU/mL and dialysate (output) <200 CFU/mL per CMS.
Water and ice baths	Contaminated water baths were used to thaw or warm blood products (fresh plasma, cryoprecipitate) or peritoneal dialysate bottles, followed by contamination of the infusates occurred during preparation. Contaminated ice baths were used to cool syringes or bottles of saline in measuring cardiac output. Potential pathogens include *Pseudomonas*, *Acinetobacter*, *Burkholderia*, *Staphylococcus*, and *Ewingella*.	Consider routine cleaning, disinfection, and changing of water in water baths. Add germicide to water bath or use plastic overwrap of blood products and keep the surfaces dry. Use sterile water in ice baths (or at room temperature) used for thermodilution catheters.

A48235836

Table 2 continued.

Reservoir	Key Issues	Infection Prevention Strategies
Bathing, tub immersion, and hydrotherapy	Tub immersion used in hospitals for physical hydrotherapy and for cleaning of burn wounds can cause cross-transmission, transmission from environmental reservoirs, or autotransmission. Skin infections such as folliculitis and cellulitis occurred related to water immersion. Water contamination of central venous catheters during bathing was related to bloodstream infection. Potential pathogens include *Pseudomonas*, *Enterobacter*, *Citrobacter*, *Acinetobacter*, *Legionella*, *Alcaligenes*, and NTM.	Adhere strictly to proper disinfection of tub between patients. Drain and clean tanks and tubs after use of each patient, and disinfect surfaces and components according to the manufacturer's instructions. Add disinfectant to the water: 15 ppm in small hydrotherapy tanks and 2–5 ppm in whirlpools per CDC. Disinfect after using tub liners. Cover catheter sites with transparent occlusive dressing.
Toilets	Transmission can be caused by aerosolization of fecal bacteria via flushing or surface contamination by fecal bacteria. Transmission could happen in healthcare facilities caring for mentally or neurologically impaired patients, or children. Potential pathogens include enteric bacteria, *Pseudomonas*, *Clostridium difficile*, and norovirus.	Facilitate good handwashing practices. Maintain clean surfaces with disinfectants. Clean bowl with a scouring powder and a brush. No reason to pour disinfectant into bowl. Separate toilet bowl from clean hospital surfaces.
Flowers and vases	Flower vases and potted plants are heavily colonized with potential pathogens, including *Acinetobacter*, *Klebsiella*, *Enterobacter*, *Pseudomonas*, *Serratia*, *Burkholderia cepacia*, *Aeromonas hydrophila*, and *Flavobacterium*. No healthcare-associated outbreaks directly linked to flower vases or potted plants have been reported.	Prohibit fresh flowers and potted plants in the rooms of immunocompromised and ICU patients. Or add antimicrobial agent to vase water and disinfect vases after use.
Electronic faucets	Electronic faucets were likely to be contaminated by several waterborne pathogens than handle-operated faucets. Issues associated with electronic faucets include a longer distance between the valve and the tap, resulting in a longer column of stagnant, warm water, which favors production of biofilms; reduced water flow; reduced flushing effect (growth favored); valves and pipes made of plastic (enhances adhesion of *P. aeruginosa*).	Electronic faucets need to be designed so that they do not promote the growth of microorganisms. No guideline (but some authors have recommended) to remove electronic faucets from high-risk patient care areas [eg, BMTU]). Some have recommended periodic monitoring of water samples for growth of *Legionella*.
Decorative water wall fountains	*Legionella* pneumonia cases associated with decorative water fountain were reported. There is an unacceptable risk in hospitals serving immunocompromised patients (even with standard maintenance and sanitizing methods).	Avoid installation, especially in healthcare facilities serving immunocompromised patients or in areas caring for high-risk patients. Perform maintenance regularly and monitor water safety strictly unless removed.
Heater-cooler units	Healthcare-associated *Mycobacterium chimaera* outbreak due to heater-cooler units during cardiac surgeries as a water source has been recently reported. Airborne transmission from contaminated heater-cooler unit water tanks.	Ensure that heater-cooler units are safe and properly maintained according to the manufacturer's instructions. Enhance vigilance for NTM infections in patients after cardiac surgeries using heater-cooler devices. If NTM infections are suspected, review microbiology database (NTM-positive cultures) and medical records of surgical procedures within several years after cardiac surgeries.
Miscellaneous	Potential reservoirs include distilled water or containers (outbreaks with *Enterobacter cloacae* and *B. cepacia*), wash basins (*Salmonella urbana* infection, *Trichosporon asahii* infection, *Legionella* pneumonia), intraaortic balloon pump (*B. cepacia* bacteremia), humidifier water in ventilator systems (*Acremonium kiliense* postoperative endophthalmitis), water cooler (gastrointestinal illness), holy water (*Acinetobacter baumannii* infection), deionized water (*Exophiala jeanselmei* fungemia), water-damaged plaster (mucormycosis), water birth (*Legionella* pneumonia), water-saving device (*P. aeruginosa* infection), rinse water during endoscope reprocessing (gram-negative bacteria).	Consider control measures based on risk assessment by each reservoir when available.

The information used in this table is based on references in this review. The infection prevention and control section was updated from our previous review [4] and recommendations from CDC and the Healthcare Infection Control Practices Advisory Committee [1, 2].

Abbreviations: AAMI, Association for the Advancement of Medical Instrumentation; BMTU, bone marrow transplant unit; CDC, Centers for Disease Control and Prevention; CFU, colony-forming unit; CMS, Centers for Medicare and Medicaid Services; ICU, intensive care unit; NTM, nontuberculous mycobacteria; ppm, parts per million.

environments, including sinks, for a long time [4]. Sinks should be decontaminated if epidemic spread of gram-negative bacteria via sinks is suspected [4]. Further, multidrug-resistant gram-negative bacilli have been linked to contaminated sinks and healthcare-associated infections as stated above [48, 50, 52, 54, 55, 57–59]. Although hand hygiene is an essential precaution against healthcare-associated infections in healthcare personnel, transmission from contaminated sinks to their hands during hand washing can occur [3]. Separate sinks should be used for handwashing and disposal of contaminated fluids [1, 4].

Showers

Healthcare-associated infections have been linked to use of contaminated showers or inhalation of aerosols by immunocompromised patients [41–43, 45]. Potential pathogens related to showers were *Legionella*, *Pseudomonas*, NTM, and *Aspergillus* [41–45]. The use of showers in immunocompromised patients (eg, neutropenic patients) should be avoided [4].

Bathing and Tub Immersion

Tub immersion used in hospitals for physical hydrotherapy and for cleaning of burn wounds can cause cross-transmission and

A48235836

transmission from environmental reservoirs [4]. Water contamination of central venous catheters during bathing was linked to bloodstream infection [7]; therefore, catheter sites should be covered with transparent occlusive dressing. Pathogens associated with bathing and tub immersion were *Pseudomonas*, *Legionella*, *Alcaligenes*, and NTM [6–9]. Tubs should be drained and cleaned after use of each patient, and strict adherence to proper disinfection of tubs between patients is essential [1, 4].

Electronic Faucets

Electronic faucets have been introduced in healthcare facilities, mainly to save water consumption and costs and avoid healthcare personnel's hands from being contaminated by touching the handle [93]. However, several studies have revealed that water samples from electronic faucets were heavily or frequently contaminated by *P. aeruginosa* and/or *Legionella*, compared with handle-operated faucets [93–95], and a *P. aeruginosa* outbreak due to electronic faucets among immunocompromised patients in a NICU has been reported [14]. Electronic faucets are more likely to be colonized because of low amounts of water flow, more favorable conditions for growth of waterborne pathogens (temperature of about 35°C in the column; materials made of rubber, plastic, and polyvinylchloride), and less flushing. Although the degree of risk posed by electronic faucets has not been quantified and there is no guideline for the water quality of electronic faucets, some authors have recommended monitoring water samples periodically from electronic faucets as well as removing electronic faucets from high-risk patient areas (eg, stem cell transplant units), given the difficulty of decontamination even with hyperchlorination [14, 93–95].

Decorative Water Wall Fountains

Two immunocompromised patients were exposed to a decorative water fountain in radiation oncology, which was heavily contaminated despite standard maintenance and disinfection (ozone generator, filter, and weekly cleaning), and developed *Legionella* pneumonia [10]. Another study described laboratory-confirmed Legionnaires' disease (pneumonia) in 8 patients, 6 of whom had exposure to a decorative fountain near the main hospital entrance; high counts of *Legionella* were detected from foam materials on the fountain despite routine maintenance [91]. A fountain's water has a closed recirculating system that can stagnate, and the spraying function may generate aerosols [91]. The results from both studies suggested that decorative water fountains can pose a risk for transmission of waterborne pathogens and should not be installed in healthcare facilities serving immunocompromised patients, even with standard cleaning, disinfection, and maintenance; at a minimum, water safety should be strictly monitored [10, 91].

Heater-Cooler Units

Heater-cooler devices are frequently used in cardiopulmonary bypass during cardiac surgeries to warm and cool patients' blood [97]. A *M. chimaera* outbreak associated with heater-cooler units during cardiac surgeries as a water source has been recently documented [20, 96]. Patient infections included prosthetic valve endocarditis, bloodstream infection, and vascular graft infection. The transmission was potentially caused by aerosols generated from stirred water in contaminated heater-cooler unit water tanks. In a report of surgical site infections due to *Mycobacterium wolinskyi*, a cold-air blaster and a self-contained water system in a heater-cooler unit was identified as a potential reservoir [98]. The CDC's recommendations for healthcare facilities are as follows: (1) ensure that heater-cooler units are safe and properly maintained according to the manufacturer's instructions; (2) enhance vigilance for NTM infections in patients after cardiac surgeries using heater-cooler devices; and (3) if NTM infections are suspected, review microbiology data (NTM-positive cultures) and medical records of surgical procedures within 4 years after cardiac surgeries [97]. The US Food and Drug Administration recommended the following maintenance of heater-cooler units: (1) use sterile water or filtered water (≤0.22 μm) to rinse or fill water tanks or when making ice for cooling patients during a surgical procedure (avoid using tap water); (2) monitor cleaning, disinfection, and maintenance for heater-cooler units regularly with written documentations of the quality control program; and (3) avoid using heater-cooler units with cloudiness or discoloration in the fluid lines or circuits (http://www.fda.gov/MedicalDevices/Safety/AlertsandNotices/ucm466963.htm).

WATER SAMPLING AND MOLECULAR STRAIN TYPING IN OUTBREAK INVESTIGATION OF WATERBORNE HEALTHCARE-ASSOCIATED INFECTIONS

Infectious disease physicians and infection preventionists should recognize the emergence of waterborne healthcare-associated pathogens and the unusual change of these rates, and begin an initial investigation if waterborne healthcare-associated cases are suspected [3]. Microbiologic sampling can be considered to enhance epidemiological investigations and to develop infection prevention and control measures. Microbiologic water sampling is not routinely recommended, but can be performed in the following situations: support of outbreak investigations, research purposes, evaluation of a potentially hazardous environmental situation, and quality assurance (eg, biological monitoring of dialysis water or assessment of infection control measures) [1, 2]. Established water sampling methods (eg, volume, media, and incubation temperature) should be utilized to ensure recovery of waterborne pathogens; water samples should be filtered before culturing when low counts are expected and large volumes are needed (>100 mL) [1].

Molecular typing has been increasingly applied to outbreak investigations in healthcare settings, and the advantages as well as disadvantages of molecular methods have been described by other authors [99–101]. In our review, molecular

A48235836

typing methods used for waterborne healthcare-associated pathogens when applicable were mostly pulsed-field gel electrophoresis, followed by random amplification of polymorphic DNA (Table 1). Recent studies using whole-genome sequencing demonstrated more powerful evidence of water reservoirs in transmission dynamics of waterborne pathogens, including an outbreak of *P. aeruginosa* (1 pneumonia/17 colonizations) from contaminated water via sinks among infants in a NICU; transmission of *P. aeruginosa* from contaminated water outlets and a thermostatic mixer valve among burn patients receiving hydrotherapy even in plumbing of a new hospital; and 2 healthcare-associated cases of pneumonia caused by *Legionella pneumophila* serogroup 1 from a contaminated hospital water distribution system [30, 56, 102]. Thus, whole-genome sequencing is now promising for genomic comparative analysis in investigations of waterborne healthcare-associated outbreaks and can provide more accurate and informative strain typing to assess the relatedness of pathogens isolated from clinical and environmental water sources.

CONCLUSIONS

We reviewed waterborne healthcare-associated outbreaks and infections and summarized current infection prevention and control. With emergence of reservoirs and pathogens that have been unrecognized so far, waterborne healthcare-associated outbreaks and infections continue to occur and affect patients' health and safety, underscoring the significant role of water as a reservoir for healthcare-associated infections. Water contamination can cause pseudo-outbreaks [3, 80] as well as outbreaks/infections, both of which require substantial efforts and resources for investigation and control. Waterborne healthcare-associated infections are preventable for some pathogens and reservoirs, but eliminating contamination of waterborne pathogens as natural inhabitants of water systems may be difficult in healthcare settings. It is essential for healthcare personnel to understand reservoirs and transmission pathways of waterborne pathogens for developing prevention strategies and control measures of healthcare-associated infections. Multiple approaches of engineering and hygiene measures as well as surveillance and clinical management for hospital water can reduce the risk for contracting waterborne healthcare-associated infections [3]. Advancement of pathogen identification and molecular typing methods has enhanced outbreak investigations as well as provided better understanding of reservoirs and transmission routes of waterborne pathogens. The safe level of microbial water contamination, which would preclude healthcare-associated infections for any waterborne pathogen in susceptible patients, remains to be determined. Further scientific and practical evidence on hospital water reservoirs, pathogens, and healthcare-associated infections is needed to address unresolved issues on infection prevention and control.

Notes

Acknowledgments. We are very grateful to Karen Crowell, a clinical information specialist at Health Sciences Library, University of North Carolina, for her assistance with literature search.

Potential conflicts of interest. H. K. received financial support from the JSPS Postdoctoral Fellowship for Research Abroad. All other authors report no potential conflicts. All authors have submitted the ICMJE Form for Disclosure of Potential Conflicts of Interest. Conflicts that the editors consider relevant to the content of the manuscript have been disclosed.

International Water Association (IWA)

The International Water Association (IWA), a global network of water professionals, is a Non-Government Organization (NGO) in Official Relations with WHO. WHO's network of NGOs in Official Relations contributes to promote the policies, strategies and programmes derived from the decisions of the Organization's governing bodies. IWA's role as an NGO in Official Relations with WHO focuses on supporting countries to implement intersectoral policies and interventions for protecting health from immediate and longer-term environmental threats. A long history of cooperation exists, built on previous joint activities between WHO and IWA's predecessors, the International Water Supply Association and the International Water Quality Association. A key area of cooperation is on drinking-water safety.

IWA's Bonn Charter for Safe Drinking Water promotes the application of Water Safety Plans (WSPs) as expressed in the WHO Guidelines for Drinking-water Quality. (Revisions to the WHO Guidelines will be taken as revisions to the Bonn Charter in as much as the Bonn Charter refers to the Guidelines). IWA promotes WSPs with WHO through a formal project collaboration agreement and associated programme of work lasting through 2015, and through its membership of water utilities, research institutes, industry, and individual professionals. IWA's work spans the continuum between research and practice, covering all facets of the water cycle. IWA is a registered charity in England (Company registered in England No. 3597005 Registered Charity (England) No. 1076690).

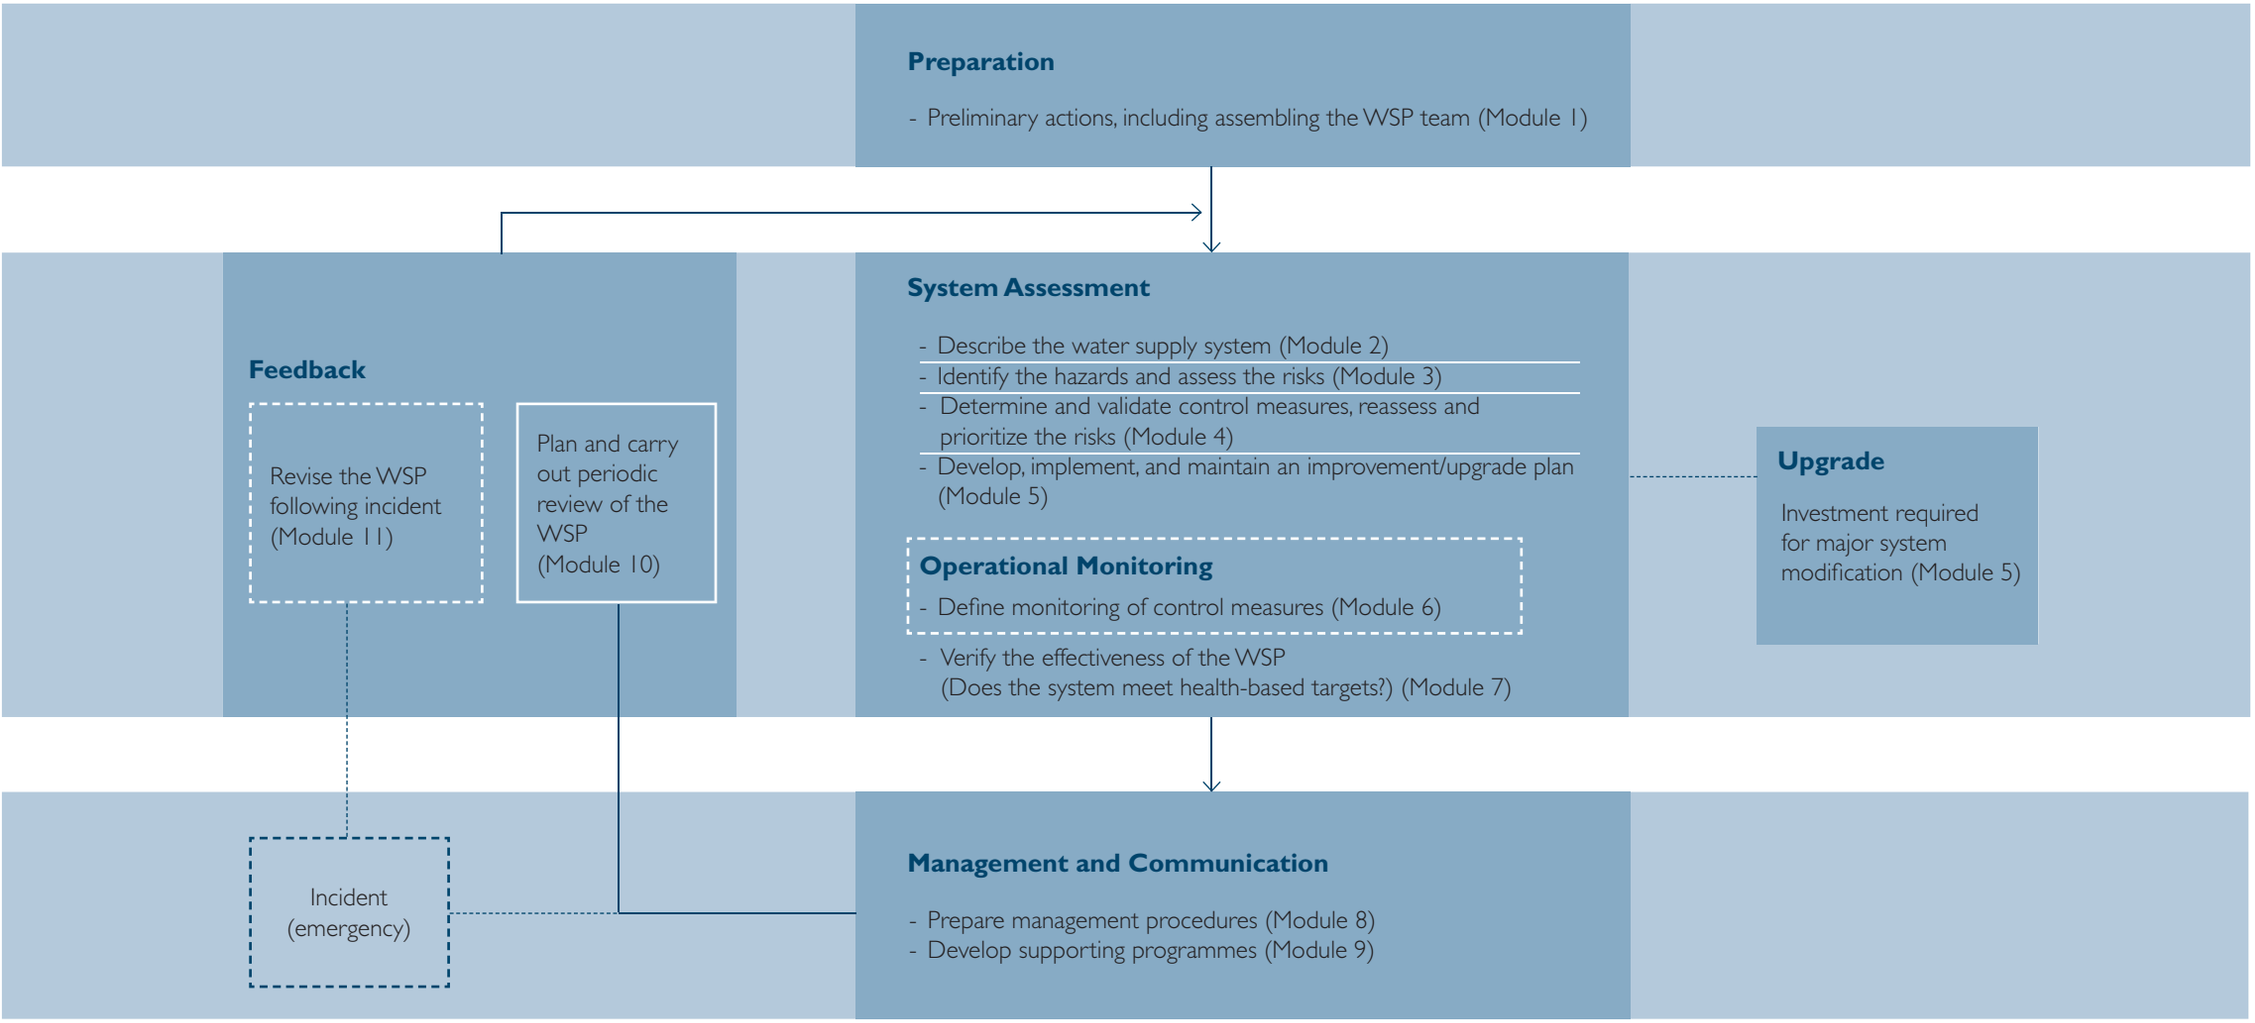
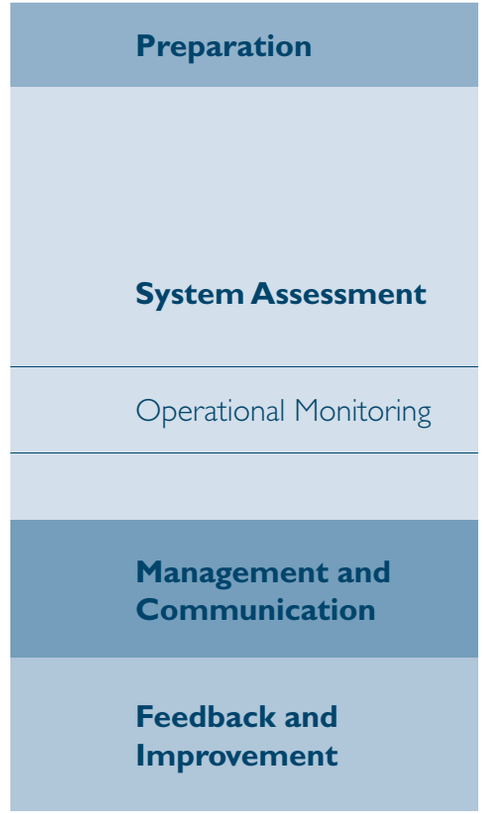
How to develop and implement a Water Safety Plan

A step-by-step approach using 11 learning modules





Contents

Introduction

"The most effective means of consistently ensuring the safety of a drinking-water supply is through the use of a comprehensive risk assessment and risk management approach that encompasses all steps in water supply from catchment to consumer. In these Guidelines, such approaches are called water safety plans (WSPs)".

Purpose of the Manual

The words above open Chapter 4 of the Third Edition of the WHO Guidelines for Drinking-water Quality (2004) and capture the philosophy of the WSP approach. The chapter describes the principles of the WSP approach rather than being a guide to their practical application. The aim of this Manual is to provide that practical guidance to facilitate WSP development focusing particularly on organized water supplies managed by a water utility or similar entity.

Points to consider when developing and implementing a WSP

The aim of a WSP is very straightforward:
To consistently ensure the safety and acceptability of a drinking-water supply.

The development and implementation of the WSP approach for each drinking-water supply is as follows:

- Set up a team and decide a methodology by which a WSP will be developed;
- Identify all the hazards and hazardous events that can affect the safety of a water supply from the catchment, through treatment and distribution to the consumers' point of use;
- Assess the risk presented by each hazard and hazardous event;
- Consider if controls or barriers are in place for each significant risk and if these are effective;
- Validate the effectiveness of controls and barriers;
- Implement an improvement plan where necessary;
- Demonstrate that the system is consistently safe;
- Regularly review the hazards, risks and controls;
- Keep accurate records for transparency and justification of outcomes.

This systematic nature of the WSP strategy should never be lost or forgotten during implementation. The great advantage of the WSP strategy is that it is applicable to ensuring the safety of water in all types and sizes of water supply systems no matter how simple or complex.

The WSP approach should be considered as a risk management strategy or umbrella which will influence a water utility's whole way of working towards the continuing supply of safe water. Significant risks that are not currently controlled need to be mitigated. This may involve short-, medium- or long-term steps for improvement. **The WSP approach should be dynamic and practical and not merely another operating procedure.** It should not be viewed as a vehicle for generating bureaucracy and paperwork. If it just ends up as a rarely-used folder labelled 'WSP' on a shelf, it is almost certainly not an effective approach.

There is no one way to undertake the WSP approach. The text in this Manual shows how the strategy can be implemented, with examples showing what has been effective for some water utilities. What is important is that the WSP approach fits in with the way a utility is organized and operates, otherwise it will not be accepted within the organization. Developing the WSP approach may show that certain ways of working introduce, or do not properly control risks, in which case the utility should alter its way of working. It should not alter its way of working just to comply with a recommendation from a manual or to reflect another utility's methodology.

Implementation of the WSP approach requires both financial support and encouragement from senior management within a utility. There will be financial and resource requirements and these need to be addressed at the outset but there should also

be the understanding that proper implementation of the **WSP approach can save money** and better target resources in the longer term.

It is important that the WSP team has adequate experience and expertise to understand water abstraction, treatment and distribution and the hazards that can affect safety through the supply system. For small utilities, additional external expertise may be helpful. The team is vital to getting the WSP approach understood and accepted by everyone connected with water safety in the utility and those outside.

A WSP cannot be done solely as a desk study. It must involve site visits to confirm the knowledge, information and schematics available to the utility. Site visits need to include input from those who work at the sites or within catchments and have detailed local knowledge that may not have been captured within the utility's records. Assessment, updating, compiling or rewriting standard operating procedures is an integral part of the WSP strategy. Ideally, all procedures should be labelled as part of the WSP strategy or way of working which helps to gain recognition and acceptance across the utility.

The water utility will take the lead in the WSP approach but it should not do this in isolation. It is a prime purpose of the WSP approach to identify that others have responsibilities towards ensuring the safety of water and for them to work with the water utility on risk reduction. Examples are agriculture and forestry workers, landowners, industry, transport, other utilities, local government and consumers. It is probably not necessary for representatives of all organizations to be included in the WSP team but they should be part of a communication network and aware of the impact of their contributions to the WSP effort. It is important that the WSP is subject to regular external independent audit. This will retain the confidence of all stakeholders.

There can be a tendency for the identification of hazards to be limited to thinking about those direct inputs to the water supply system impacting microbial and chemical parameters, as these are important in terms of compliance with water quality standards. However, the approach to ensure safe water must go much wider, with consideration of aspects such as potential for flood damage, sufficiency of source water and alternative supplies, availability and reliability of power supplies, the quality of treatment chemicals and materials, training programmes, the availability of trained staff, service reservoir cleaning, knowledge of the distribution system, security, emergency procedures, reliability of communication systems and availability of laboratory facilities all requiring risk assessment. This list is by no means exhaustive. **If a water utility considers that some of these areas fall outside of its WSP approach, then it does not have a comprehensive WSP strategy and has not fully understood the concept.**

The obvious controls for identified risks are physical barriers or processes within water treatment plants such as filtration and disinfection, but consideration and assessment of controls needs to be much wider. Agreements with farmers and industry on chemical usage, livestock controls, use only of trained staff, pumping regimes, visual inspection, auto-shutdown or turnout, audit of, or quality agreements with, chemical suppliers and plant manufacturers, could all be considered controls as long as they can be validated as effective and monitored to demonstrate that they continue to provide protection. Again, this list is by no means exhaustive. **Starting out on the implementation of the WSP approach does not mean that every existing control has to be re-validated but it does require the robustness of existing data and reports to be evaluated.**

It is important to assess risk before and after its control (or mitigation) where this exists because this will demonstrate that each hazard has been recognized and its control assessed for

effectiveness. The risk assessment is likely to highlight a great many risks that are not considered significant to the safety of the water supply system. It is important, though, that all risks are clearly documented and understood by the utility. Even **more important is the need to prioritize and quickly put in place an improvement programme** where significant risks are identified.

Not all risks can be easily assessed using a methodology (e.g. a 'semi-quantitative' risk matrix), where a risk is estimated in terms of likelihood of the hazard occurring, and severity of the consequence should the hazard occur. Some risks do not lend themselves to be assessed via narrow definitions of likelihood (e.g. estimated occurrence is 'monthly') or consequence (e.g. estimated severity is 'moderate' public health impact). For example, potential negative feedback from consumers regarding issues that may not have a significant impact on health may be viewed as a significant risk to a utility's reputation and therefore should be addressed for the WSP. Sometimes, it may be more appropriate to assess risk in a simplified format (e.g. 'significant', 'non-significant' or 'uncertain') based on a group decision. **Whatever method is used, it is imperative that the risk assessment methodology is sufficiently clear and detailed to allow consistency.** This is a particular concern for a large utility, where the risk assessment is likely to be undertaken by many different people.

The complexity of the risk assessment depends on the complexity of the water supply system. Sophisticated water treatment equipment and processes viewed as controls for safe water production introduce their own potential hazards to a water supply system which will require detailed risk assessment. For example, an ozone and granular activated carbon system introduced as a control for organic contamination could generate hazards such as ozone emissions, bromate formation, biofilm growth, taste problems and contamination after regeneration. **The WSP approach needs to be included from the planning stage of any improvements or new arrangements for a water supply system.**

Compliance monitoring is an important part of the verification process to show that the WSP is working. It will show whether water at the point of compliance, which is often the consumers' tap, is meeting water quality standards; it does not make the water safe because by the time the results of compliance monitoring are available the water will have been drunk and used for other domestic purposes. Validation, to show that controls are capable of mitigating risks, and operational monitoring, to demonstrate that they continue to work effectively, are much more important tools in ensuring the safety of water because they focus on the processes that make water safe. **Operational monitoring is an integral part of the WSP approach.**

Overcoming complacency

Many elements of the WSP approach are already incorporated in existing water utility good operating practice. However, fully implementing the WSP will require all utilities to take a fresh look at everything that can affect the safety of water. **Nothing should be taken for granted.** If barriers are in place and producing water of acceptable quality, is this because they are robust or through luck? The water utility that has no incidents or near misses and consumers that are happy with their safe water supplies is fortunate indeed, or maybe it is lacking the procedures and assessment it needs to identify problems. Open and transparent implementation of the WSP approach will increase the confidence of consumers and all other stakeholders in the safety of water supplies. Developing a WSP is not an end in itself, but a means to an end. A WSP is only useful if it is implemented and revised.

A48235836

Overview of the modules

Points to consider when using the Manual

The Manual is divided into 11 Modules, each representing a key step in the WSP development and implementation process. Every Module is divided into three sections: 'Overview', 'Examples and Tools', and 'Case Studies', as described below.

Overview

The overview section provides a brief introduction to the Module, including why it is important and how it fits into the overall WSP development and implementation process. It outlines key activities that should be carried out, lists typical challenges that may be encountered, and summarizes the essential outputs to be produced.

Examples and Tools

The examples and tools section provides resources which could be adapted to support the development and implementation of WSPs. These resources include example tables and checklists, template forms, diagrams, or practical tips to help a WSP team address specific challenges. These are often example outputs and methodologies adapted from recent WSP experiences.

Case Studies

Case studies present lessons-learned from real-life experiences. They are intended to make WSP concepts more concrete and to help readers anticipate issues and challenges that may arise. The descriptions were drawn from WSP initiatives in Australia, the Latin American and the Caribbean region (LAC), and the United Kingdom. These experiences are presented as three distinct case studies. The insights gained through the development of these 'composite' WSPs are likely to apply to other water systems that share a similar profile. A general description of the water supplier and the context within which the WSP was developed and implemented is provided in the following pages.

CASE STUDY 1: AUSTRALIA

Profile
Organized urban piped water supply systems in Australia.

Introduction
These WSPs were undertaken almost entirely by the urban water utilities themselves without significant external agency support. Most water utility employees were familiar with the use of systematic risk assessment and management systems, and of management systems generally, due to previous requirements to implement occupational health and safety and environmental management systems. In addition to this, most utilities had some kind of generic management system in place, such as ISO 9001. The WSPs drew to varying degrees on these management systems in place, and on food safety management systems, such as HACCP and ISO 22000. The WSPs were driven initially by a desire by utilities to adopt good practice, and more recently by a desire to conform to the Australian version of the WHO WSP, being the Framework for Management of Drinking Water Quality (Australian Drinking Water Guidelines 2004).

Population served
The populations served ranged from around 50,000 to over 4 million.

Water sources
Water was supplied from a combination of surface and groundwater sources. In most cases, there was considerable unregulated low intensity agricultural activity within the catchment, such as cattle grazing; there was also rural residential habitation. Sewage systems existed in some catchments and others included on-site sanitation with varying degrees of oversight.

Treatment processes
Treatment processes typically consisted either of chlorine disinfection only, or of direct or conventional filtration and chlorination. Surface water sources from protected catchments were typically treated by chlorination only and those from impacted catchments by conventional coagulation/flocculation/sedimentation, filtration and chlorination. Chloramination was commonly applied to maintain residual in many systems. Groundwater sources were typically treated by aeration and chlorination. Treatment processes were well-operated.

Delivery point
Households received water directly to their homes through internal plumbing systems. The cities were predominantly connected to the municipal water system with reliable continuous pressurization so that storage in household tanks was virtually absent.

Water quality standards
Water quality standards were set out in the Australian Drinking Water Guidelines, which are very similar to the WHO Guidelines for Drinking-water Quality. Testing and reporting against guidelines was well established, particularly for *E. coli* or thermotolerant coliforms.

Quality of service
Water service to taps was continuous and water quality standards were met almost continually. There were no recorded waterborne disease incidents during the period of WSP development and implementation. Point-of-use treatment was not required, although this was sometimes used by consumers for aesthetic reasons to remove chlorinous tastes and odours.

Resource constraints
Systems were operating on full cost recovery with government dividends being paid. The utility recovered all costs associated with maintaining water quality and quantity.

Condition of infrastructure
The systems described were well maintained with low leakage rates reflecting the focus on water savings in these relatively dry Australian settings. Systematic asset management systems were in place to repair and replace assets to keep failure rates under control.

CASE STUDY 2: LATIN AMERICA AND THE CARIBBEAN (LAC)

Profile
Organized piped water supplies operating under significant resource constraints in Latin America and the Caribbean.

Introduction
These WSPs were initiated as part of a multi-agency effort for which external technical advice and seed funding were provided to promote WSP demonstration projects in the LAC region. Project site selections were made by drinking-water utility managers and senior government officials, primarily within the Ministry of Health. Although some water utility employees were familiar with the WSP approach, they did not have a formal process of preventive risk management and believed that they did not have the expertise or resources to carry out the process.

Population served
The populations served by the utilities ranged from 30,000 to 120,000.

Water sources
Water was supplied from a combination of surface and groundwater sources. In all cases, there was considerable unregulated industrial activity within the watershed, such as mining, forestry, or road construction. Municipal sewerage systems did not exist; hence excreta was treated in poorly maintained septic systems or deposited directly into source waters.

Treatment processes
Between one and five treatment plants served each community. Surface water sources were treated by conventional treatment techniques: coagulation/flocculation/sedimentation, filtration and chlorination. Groundwater sources were treated by aeration, filtration and chlorination, or in some cases, chlorination alone. In all cases, treatment processes were not operated optimally due to poorly trained operators and financial constraints.

Delivery point
Most households received water directly to their homes. Others had yard taps, and some used shared community taps or storage sites. In each case, there were parts of the city that were not connected to the municipal water system, or had unauthorized and clandestine connections. Storage in household storage tanks was common due to inconsistent service.

Water quality standards
Water quality standards were often poorly defined, or were inconsistent, with some agencies using environmentally-based targets and others using health-based targets for the same system. In some cases, WHO's health-based guidelines were adopted without adaptation to local conditions and constraints, making standards unrealistic and therefore of little value. In all cases, there were no active enforcement programmes.

Quality of service
Water service to taps was intermittent. In some areas, households routinely experienced eight hours or more per day without service and periods of low pressure were the norm in a majority of homes. Water quality was consistently out of compliance with regulatory standards; secondary treatment within the home was common.

Resource constraints
Systems were not operating at cost recovery even with government subsidies. The utilities could therefore not afford to maintain a sufficient supply of chemicals, adequate equipment maintenance, or the high energy cost of pumping 24 hours a day.

Condition of infrastructure
The systems described were characterized by aging treatment infrastructure, leaking distribution system pipes with as much as 70% loss, and decrepit storage tanks in the distribution system that had been taken off-line, affecting pressure and ability to meet demand. In all cases, capital improvements were needed in order to achieve desired water quality and consistency of service.

CASE STUDY 3: UNITED KINGDOM (ENGLAND AND WALES)

Profile
Privately-operated organized piped water supplies in England and Wales.

Introduction
This case study, written by a regulator of drinking-water quality, describes some of the benefits and challenges faced by private water suppliers introducing WSPs in England and Wales. The regulator encouraged water companies to implement WSPs following the publication of the third edition of the WHO Guidelines for Drinking-water Quality in 2004, with its advocacy of the WSP approach. Impetus for WSP implementation was given by the regulator stating that drinking-water improvement schemes for the next five year investment programme would only receive regulator support if they were identified through WSP methodology.

The case study focuses on areas where the regulator viewed WSP methodology as weak or incomplete, in order to be most helpful to suppliers starting out on WSP implementation. Experiences should not be taken to reflect the experiences of all suppliers, as some companies developed good WSP methodologies from the outset.

For the first three years of WSP implementation the regulator gave guidance and advice on development. The regulator made a point of not specifying detailed WSP methodology, in order to ensure that companies developed their WSPs in a way that fitted in with how each company operated, an important consideration given the diversity in water companies under the regulations.

Compliance monitoring was initially viewed as the main WSP verification stage. However, additionally from the beginning of 2008, the hazard identification and risk assessment elements of the WSP framework were made regulatory requirements and WSPs began to feature in the regulator's audit programme.

Population served
The populations served by individual utilities ranged from 2,500 to 8.5 million consumers.

Water sources
Approximately 70% of supplies originated from surface water sources, 30% from groundwater sources. Twenty-six water companies supplied 15,750 million litres a day of mains water to a population of 53.6 million people through a distribution network of 338,500 km. There were 4,520 service reservoirs and 1,690 water supply zones.

Treatment processes
The case study covered 1,220 water treatment works, with a range of processes, encompassing conventional coagulation/flocculation/sedimentation, filtration and chlorination, and increasingly, technologies such as GAC (granular activated carbon), membranes, ozonation and UV light, to deal with emerging risks. Many groundwater sources were still treated by disinfection only.

Delivery point
Households received water directly to their homes through internal plumbing systems, connected to the companies' water system with reliable continuous pressurization. Despite this, plumbed-in water storage within premises was common in England and Wales.

Water quality standards
Water quality regulations were set out for England and Wales, in line with the European Union's Drinking Water Directive, which in turn reflect the WHO Guidelines for Drinking-water Quality. Water suppliers were subject to firm regulation from financial, drinking-water quality, and environmental regulators.

Quality of service
Treated water quality as a whole was very good, generally 99.9% in compliance with European and national standards for drinking-water quality.

Resource constraints
The water industry in England and Wales was privatized in 1989, which has resulted in improved investment by the water suppliers. It is a technically sophisticated and advanced industry.

Condition of infrastructure
The systems described were well maintained, but leakage rates from the network are still a problem in some areas with aging mains.

Module 1

Assemble the WSP team

A48235836

Introduction

Establishment of a qualified, dedicated team is a prerequisite to securing the technical expertise needed to develop a Water Safety Plan (WSP). This step involves assembling a team of individuals from the utility, and also in some cases, from a wider group of stakeholders, with the collective responsibility for understanding the water supply system and identifying hazards that can affect water quality and safety throughout the water supply chain. The team will be responsible for developing, implementing and maintaining the WSP as a core part of their day-to-day roles. It is essential that all involved play an active role in the development of the WSP and support the WSP approach. It is important that the WSP team has adequate experience and expertise to understand water abstraction, treatment and distribution and the hazards that can affect safety through the supply system from the catchment to the point of consumption. For small utilities, additional external expertise may be helpful. The team is vital to getting the WSP approach understood and accepted by everyone connected with water safety within and outside the utility. Therefore, an inclusive team that works with everyone within a utility and outside is likely to be far more effective than an exclusive team who impose their WSP approach on the utility. A vital early task of the team is to set out how the WSP approach is to be implemented and the methodology that will be used, particularly in assessing risk.

Key actions

Engage senior management, and secure fi nancial and resource support

For successful implementation of the WSP, it is important that senior management support the process. This support is crucial to obtain support for changes in working practices, to ensure sufficient fi nancial resources are available and to actively promote water safety as a goal of the organization. A clear case is needed to show that the adoption of a WSP is important and advantageous to the organization.

Identify the required expertise and appropriate size of the team

Involving operational staff on the team will contribute to the success of the plan through facilitating its ownership and implementation. However, depending on the size of the utility, most members of the team will not be 100% committed to WSP duties, but will also continue with their normal duties. Team members need to collectively possess the skills required to identify hazards as well as to understand how the associated risks may be controlled. The team needs to have the authority to enable implementation of the recommendations stemming from the WSP.

Appoint a team leader

A team leader should be appointed to drive the project and ensure focus. This person should have the authority and organizational and interpersonal skills to ensure the project can be implemented. In situations where required skills are unavailable locally, the team leader should explore opportunities for external support.

This can include use of benchmarking or partnering arrangements with other organizations, national or international assistance programmes and resources, such as the internet.

Define and record the roles and responsibilities of the individuals on the team

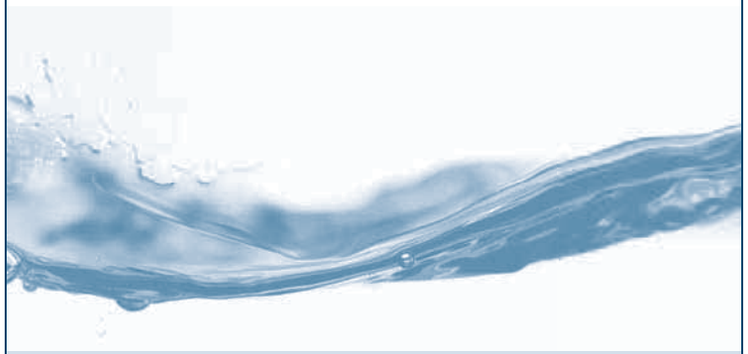
It is important to divide responsibilities among the team members at the start of the process and clearly defi ne and record their roles. For large teams it is often helpful to put together a table outlining WSP-related activities along with who will be responsible for carrying these out.

Define the time frame to develop the WSP

The initial development of a WSP requires considerable time input. WSPs will increase the amount of time staff spend in the fi eld inspecting the system yet reduce the reliance on the results of routine laboratory tests. The WSP approach enables the operators to get to know their system more effectively as they spend more time identifying and controlling risks instead of just analyzing risks. Once the WSP is established and the organization becomes familiar with the system the time input will decrease.

Typical challenges

- Finding skilled personnel;
- Organizing the workload of the WSP team to fit in with the existing organizational structure and roles;
- Identifying and engaging external stakeholders;
- Keeping the team together;
- Getting the team to communicate effectively with the rest of the utility and other stakeholders.



Outputs

Establishment of an experienced, multidisciplinary team that understands the components of the system, and is well-placed to assess the risks that may be associated with each component of the system. The team needs to understand the health and other targets which have to be achieved; and have the expertise to confi rm, following an assessment, whether the system can meet the relevant water quality standards.

Example/tool 1.1: Checklist of skills to be considered when identifying the required expertise for a large WSP team

- ☑ Technical expertise and operational system-specific experience;
- ☑ Capacity and availability to undertake the WSP development, implementation and maintenance;
- ☑ Organizational authority to report through to the relevant controlling authorities, such as the executive of an organization, or leaders of a community;
- ☑ Understanding of the management systems including emergency procedures;
- ☑ Understanding of the processes used to obtain and communicate the results of monitoring and reporting;
- ☑ Understanding the water quality targets to be met;
- ☑ Appreciation of the water quality needs of the users;
- ☑ Understanding of the practical aspects of implementing WSPs in the appropriate operational context;
- ☑ Understanding the impact of proposed water quality controls on the environment;
- ☑ Familiarity with training and awareness programmes.

Example/tool 1.2: WSP team composition (from Melbourne Water, a large utility supplying water to 3.5 million people through separate retail companies)

Job title	Work team	Expertise
Team Leader / Senior Engineer	Water Quality Planning	Water quality engineering
Water Supply Operator	Water Harvesting Team	Operations – Upper Yarra
Process Support – Service Delivery	Operations – North Area	Water treatment specialist
Water Supply Operator	Westernport Area Team	Operations – distribution/treatment
Section Leader Water Treatment	Treatment Systems	Treatment plant asset management
Operations Contractor	Operations – South Area	Water supply engineering
Water Supply Operator	Thomson Reservoir Team	Operations – Thomson Reservoir
Process Engineer	Operations – North Area	Water supply engineering
Water Supply Operator	Silvan Reservoir Team	Treatment plant operations
Water Supply Operator	Maroondah-Winneke Reservoir Team	Sugarloaf Reservoir, Winneke Treatment Plant and Maroondah Reservoir area
Principal Scientist	Water Quality Planning	Microbiology
Section Leader Headworks	Operations	Catchment operations
Scientist from retail water company	Retail Water Company	Water quality specialist/chemist
Engineer from retail water company	Retail Water Company	Water quality engineering (distribution)
Engineering Manager from retail water company	Retail Water Company	Water quality planning

Example/tool 1.3: Different WSP team building approaches for larger and smaller systems

Depending on the size of the water supply organization, and where organizations are responsible for multiple systems, it may be necessary to have more than one WSP working group, which report to a central team. The usefulness of this arrangement needs to be assessed at the commencement of the process, but may include: a core team; subordinate working groups that undertake particular aspects of the WSP (e.g. on 'catchment', 'source water', 'treatment' and 'distribution system'); and external team members and reviewers, which may comprise government agencies and independent experts. It is essential that each team uses the same methodology, particularly for assessing risks and is aware of what the other teams are doing.

Small utilities may often not have in-house water quality experts. However, such utilities should at least have the operators and management on the team and bring in health and water quality expertise from external sources. External sources could include agencies (e.g. the department of health, engineering and sanitation or natural resources) or consultants.

Examples of forms that can be used to record essential information when assembling the WSP team and starting the initial stages of the WSP are listed in Example/tool 1.4, 1.5 and 1.6.

Example/tool 1.4: WSP team details form

The details of the WSP team and any subordinate teams should be documented as part of a utility's WSP methodology. This needs to be kept up to date as personnel and contact details change.

Name	Affiliation	Title	Role in team	Contact Information
Sam Kariuke	Blue Water Supply	Water Supply Operator	Catchment Liaison Officer	234-5678 kariuke@bluewater.com
Etc. ↴				

A48235836

Example/tool 1.5: WSP resourcing plan form (example for a large utility)

While outsourcing work may be necessary when there is limited in-house expertise or capacity, it should be minimized as much as possible as in-house knowledge development will be impeded.

Activity	Activity budget	Aspects sourced within the utility	Aspects sourced from outside the utility	Staff budget
Establishment of WSP team	US $5,000	Project management and delivery	Facilitation and review	1.5 Full-time equivalents (FTE) during development and implementation 0.5 FTE for ongoing maintenance
WSP working group(s)	US $30,000 each	Project management Stakeholder liaison Integration with existing systems	Technical support Data assembly Data analysis and presentation	3 FTE during development and implementation 1 FTE for ongoing maintenance
Etc. ↴				

Example/tool 1.6: WSP stakeholder identification form

Stakeholder name	Relationship to drinking-water supply issues	Key point	Point of contact in WSP team	Stakeholder point of contact	Interaction mechanism	Reference to contact details and record of interaction
Environment Protection Authority (EPA)	Regulate large polluting facilities	Affects catchment protection	Regulatory Liaison Officer	Regional Manager	Annual meeting	EPA file
Farming organization with land adjacent to catchment	Livestock raising and agricultural chemical use	Minimizes the introduction of microbial and chemical hazards to catchment	Catchment Protection Liaison Officer	Manager of Operations	Informal and scheduled meetings	Catchment stakeholder file
Chemical manufacturing plant	Point-source discharges to catchment	Adheres to industrial effluent standards	Regulatory Liaison Officer	Plant Manager	Annual meeting	Catchment stakeholder file
Etc.						

Example/tool 1.7: Understanding the WSP commitment

A WSP represents a significant responsibility that is shared by all relevant employees within a water supply organization. Development and implementation is time consuming and requires significant resources. Implementation requires commitment at all levels within the organization. Maintenance of the WSP requires ongoing management attention to reinforce a culture of compliance with the requirements of a WSP. It may take several years to see all the benefits of WSP implementation, but experience has shown that the input and commitment is rewarded as the WSP leads to efficiencies and better understanding of the water supply system, including producing water of a quality that consistently meets the health-based targets.

A48235836

Case study 1: Australia

Field Experience 1.1 – roles of the WSP team

The WSP team was typically set up and led by a dedicated utility coordinating person. This person was usually a graduate engineer or scientist with several years or more experience working in water quality management. The coordinating person typically had titles such as 'Water Quality Manager', or 'Water Quality Coordinator', or more recently, the title 'Product Quality Coordinator' has been used to reflect an extension of their role to cover recycled water. Typically the WSP coordinating team was small, made up of just the coordinator, or the coordinator and one or a few support staff, being almost solely dedicated to creating and maintaining the WSP. The coverage of the full team extended to a dozen or more staff which typically included staff from operations, field maintenance and water supply planning who contributed to the work of the WSP team as a small part of their overall role.

Field Experience 1.2 – external parties

One or more stakeholders usually contributed to the WSP efforts. In most cases, the health authority that regulated the utility was involved in risk assessment workshops and in reviewing the plan. Often local government and catchment management agencies were involved in the plan. Bulk water suppliers, or retail utilities, were often involved in WSP development, represented by their retail customers or wholesale suppliers, respectively. Contractors, such as treatment or operations and maintenance contractors, were also typically involved in the utility's WSP development. However, the involvement of these external stakeholders and contractors was usually limited to review and workshop participation. Sometimes professional facilitators were contracted to help support the development of the plans, acting as coaches or mentors and providing technical support to the WSP coordinator, and general support to run workshops and help complete documentation.

Case study 2: Latin America and the Caribbean (LAC)

Field Experience 1.1 – roles of the WSP team

A small 'initiating' group comprising external experts and a senior utility manager discussed the objectives and composition of the WSP team and agreed that it should serve two key functions. The first was to bring together people with expertise in water supply (e.g. abstraction, treatment and distribution), health, and environmental issues, to develop the WSP. Thus, a multidisciplinary Task Force was formed to provide this on-the-ground role. The second purpose of the team was to provide the political support and authority necessary to enable implementation of the recommendations that followed from the WSP. To this end, a Steering Committee comprising senior officials of the water utility, the Ministry of Health, and the regional Environmental Protection Agencies was formed to oversee and support the activities of the Task Force. Engaging senior officials from the start of the project proved essential for generating support to carry out tasks that required managerial or political authority, such as establishing water quality standards, introducing regulatory requirements, and dedicating financial or personnel resources.

Field Experience 1.2 – designating a WSP writer/coordinator

While the role of the WSP coordinator is ideally filled by water utility personnel, the utility was unable to commit full-time personnel to this time-intensive task due to resource constraints. Therefore the WSP team decided to engage a consultant to assume the role of the WSP coordinator, which involved planning and facilitating Task Force meetings, liaising with Task Force and Steering Committee members, identifying information gaps, providing technical expertise in water quality assessment, and writing the WSP document. A number of problems soon presented themselves, including the utility's hesitation to share potentially sensitive information about their operations; concerns about conflicts of interests in a small country where considerable overlap in professional spheres exists; and a reduced sense of utility investment and engagement in the WSP.

Personality conflicts also contributed to an ineffective team dynamic and progress was significantly hindered. A second consultant was ultimately engaged to replace the first and a senior utility manager assumed additional responsibility for WSP development. The increased role of the utility manager required relieving her of some other duties for the duration of the WSP development process, but it proved essential to increasing interagency collaboration and project momentum. The second arrangement was successful and underscored the importance of giving careful consideration to the designation of a WSP coordinator to avoid conflicts of interest and to ensure team cohesion.

Case study 3: United Kingdom (England and Wales)

Field Experience 1.1 – gaining commitment to adopt the WSP approach

Enthusiasm for the WSP approach was initially not universal within the industry and in some companies there was scepticism of its additional value to an advanced, well performing industry. However, other companies immediately viewed the approach as developing what they were already doing in risk assessment and risk management.

Some companies were uncomfortable using the term 'safety' in Water Safety Plan, because they felt consumers might perceive that the water may be unsafe. Therefore, these companies preferred to label their WSPs as 'Risk Management Plans' or similar, terms which the regulator viewed as appropriate alternatives, provided that the content was consistent with a WSP.

A short document explaining WSP methodology, how they were going to be implemented and what was expected to be achieved was seen as a necessary starting point to obtain board and senior management approval which was essential for the success of the project. A common experience among almost all water companies was that the time required for WSP implementation was significantly underestimated.

Paper-based WSPs restricted access within the company and therefore did not encourage staff ownership. For large water companies computer-based systems available to all staff through an intranet was much more successful. Such systems usually had the basic elements of the WSP for each water supply system laid out in a conventional manner and included links to all the associated procedures and other material. The best plans identified everything as part of the WSP. Issues with sensitive and security related matters were overcome by having restricted levels of access.

Field Experience 1.2 – expanding the WSP team

In most companies, teams expanded from an initial small core group as appreciation of how wide the WSP approach covered was fully understood. In very large companies that covered a wide geographical area, sub-teams were set up that liaised with a central team. This worked well in getting company wide involvement.

External stakeholders have not yet been generally included as members of the WSP team. This probably results from understandable reticence about making sensitive information too readily available.

Field Experience 1.3 – valuing WSP team members with fresh perspectives

Early in the implementation process, in some companies, responsibility for WSP development was given solely to the water quality manager or similar post. This meant that the water supply system was considered only by someone who thought they were already fully familiar with it and aware of all the hazards, risks and weaknesses so the fresh WSP approach was lost. Such individuals also tended to limit their thinking to hazards relating to compliance parameters (although this was not a problem confined to individuals) as this was their main area of experience. This meant that the wide umbrella WSP approach was missing from the beginning.

A48235836

Module 2

Describe the water supply system

A48235836

Introduction

The first task of the WSP team is to fully describe the water supply. Where utilities do not already have documentation of the water system, it is essential that field investigations are conducted. The objective is to ensure that subsequent documentation of the nature of the raw, interim, and finished water quality, and of the system used to produce water of that quality is accurate to allow risks to be adequately assessed and managed. While it is accepted that there may be some room for a generic approach to be taken where works are very similar, or where liaison with outside bodies remains the same for a number of water supplies, each supply must be assessed in detail on its own. Data should be gathered specifically for that supply, and all other steps taken leading to a WSP should be exclusive to that particular supply. Many utilities will already have extensive experience of their water system and hold relevant documentation. In this case, the WSP will simply require this to be systematically reviewed to ensure it is up to date and complete and checked for accuracy by a site visit.

Key actions

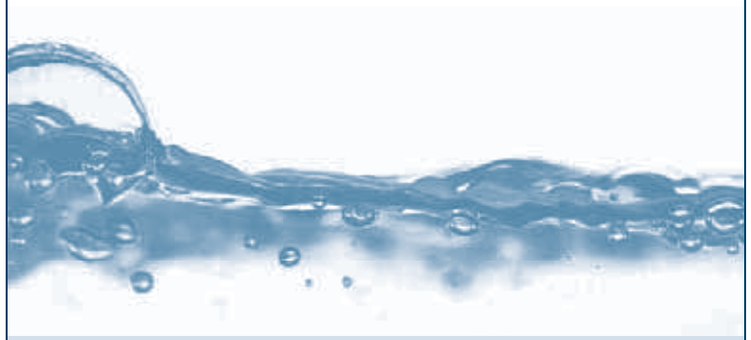
A detailed description of the water supply system is required to support the subsequent risk assessment process. It should provide suffi cient information to identify where the system is vulnerable to hazardous events, relevant types of hazards, and control measures. The following should be included in the description but it is not an exhaustive list, nor is every point relevant for each water supply system:

- Relevant water quality standards;
- The source(s) of water including the runoff and/or recharge processes, and if applicable, alternative sources in case of incident;
- Known or suspected changes in source water quality relating to weather or other conditions;
- Any interconnectivity of sources and conditions;
- Details of the land use in the catchment;
- The abstraction point;
- Information relating to the storage of water;
- Information relating to the treatment of the water, including the processes and chemicals or materials that are added to the water;
- Details of how the water is distributed including network, storage and tankers;
- Description of the materials in contact with water;
- Identification of the users and uses of the water;
- Availability of trained staff;
- How well existing procedures are documented.

A fl ow diagram should be developed which captures all the elements of the water supply system in suffi cient detail. The fl ow diagram should be validated through on-site field checking and then used in the risk assessment process. Cross reference should be made to other documentation showing details such as maps with property boundaries, sewage treatment plants, septic tanks, industry and other potential sources of risk. A map of the supply areas should be checked. Referenced and dated copies of the validated flow diagram should be retained as part of the WSP. Not all process steps are the responsibility of the water supply organization. However, it is important to record who has primary responsibility as this information will impact on the choice and effi cacy of control measures. For simple systems, showing the order of each step is suffi cient to indicate the direction of water fl ow through the system. However, for more complex systems it may be necessary to indicate the water direction with the use of arrows.

Typical challenges

- Lack of accurate maps showing distribution systems;
- Lack of knowledge of land use / management in catchments;
- Lack of knowledge of industry and risks;
- Finding all government and local agencies with potential information or a role to play;
- Time required by staff to undertake fieldwork;
- Out-of-date procedures and documentation.



Outputs

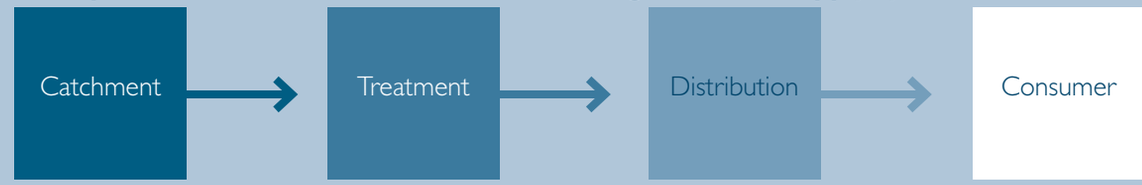
1. A detailed up-to-date description of the water supply system, including a fl ow diagram.
2. An understanding of water quality currently being provided by the utility.
3. Identifi cation of the users and uses of the water.

A48235836

Example/tool 2.1: Consider the basic arrangements of the water supply system to be assessed

The description should cover the whole system from the source to the end point of supply. Staff should be prepared to spend considerable time on this step. For example, undertaking the field assessment of a large water distribution system of more than 800 km of pipeline in Kampala, Uganda took 40 person days, while the assessment of a smaller network of 600 km took 15 days.

Example/tool 2.2: Basic elements for describing the water supply system



Several other formats for a supply system are possible, for example, more than one source catchment feeding a treatment works; a distribution area receiving water from more than one treatment works; further dividing distribution into trunk main, service reservoir and network elements; and separately considering consumers as industrial and domestic users. The basic system must document all inputs and outputs even if they do not operate all the time.

Example/tool 2.3: A good water system flow diagram

An accurate flow diagram of the water supply system from catchment to point-of-use greatly helps the identification of hazards, risks and current controls. It will help identify how risks can be transferred to consumers and where they are or can be controlled. It is vital to take the flow diagram out on site to check its accuracy and local knowledge is an important input. For simplicity and consistency, standard engineering flow diagram symbols can be used (see Example/tool 2.5). For large systems it may be helpful to divide the flow diagram for each or some of the basic elements (catchment, treatment, distribution, and consumer) into discrete sections. Discrete flow diagrams could be produced, for example for more than one source in the catchment, for different treatment streams and service reservoirs, and trunk mains and network mains in distribution.

Example/tool 2.4: Intended uses and users of the water

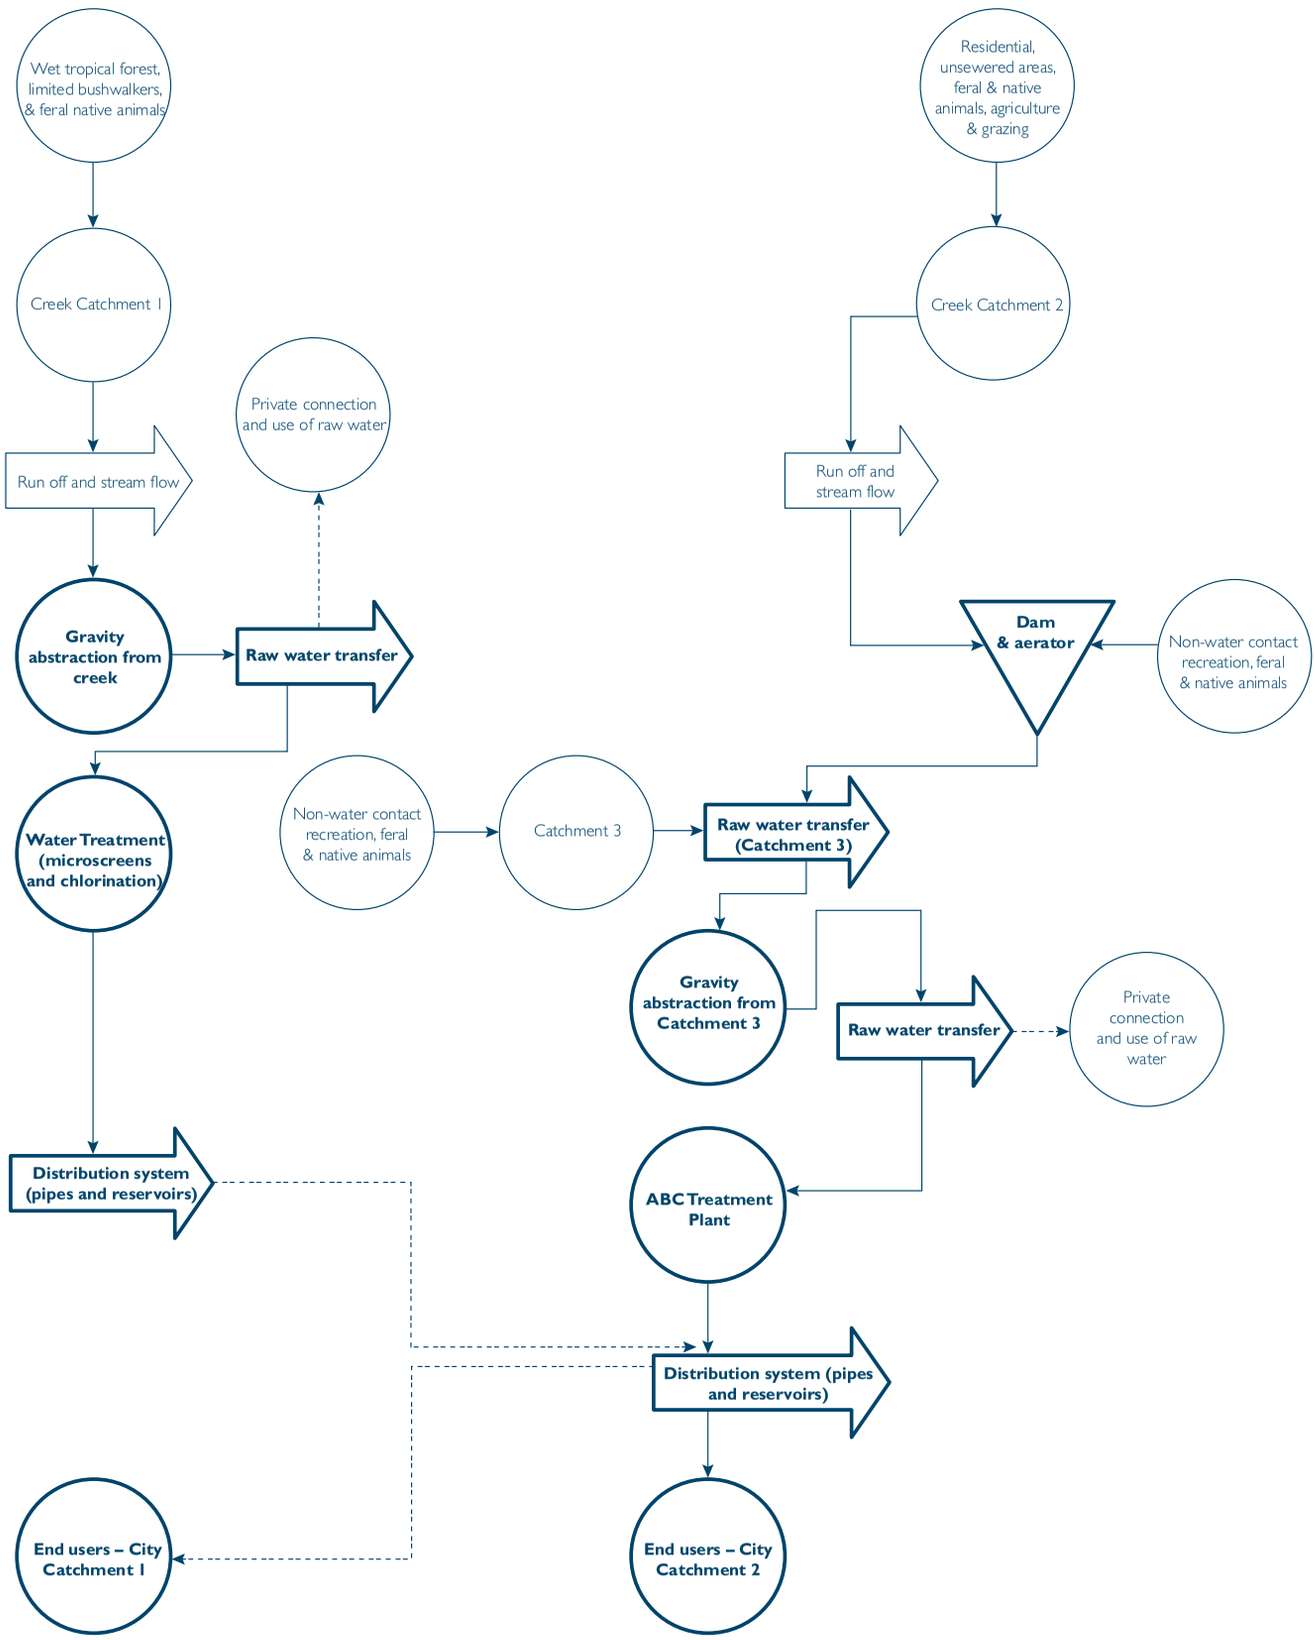
Suitable uses may be specified in regulations. For example, the European Drinking Water Directive covers water intended for human consumption which is defined as water intended for drinking, cooking, food preparation and food production.

Intended use	Intended users
The water supplied is intended for general consumption, personal hygiene and clothes washing. Foodstuffs may be prepared from the water.	Water is provided to the general population. The intended consumers do not include those who are significantly immunocompromised or industries with special water quality needs. These groups are advised to provide additional points-of-use treatment.

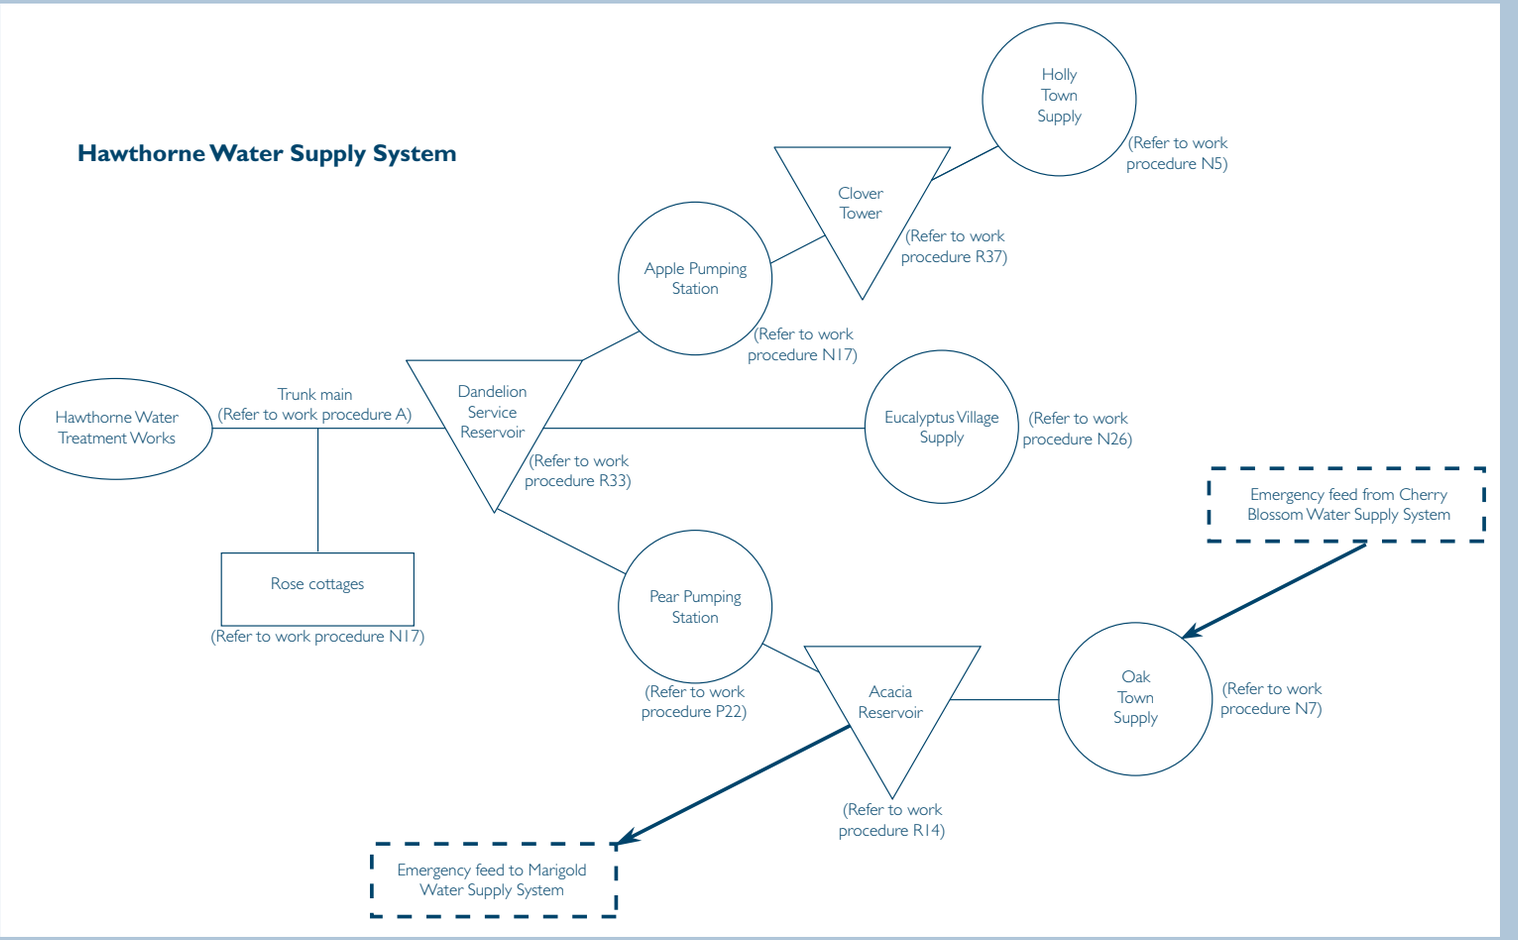
A48235836

A48235836

Example/tool 2.5: Checked system process flow diagram. Note that a separate flow diagram would be produced for the water treatment plant to show the steps involved in treatment (e.g. coagulation, flocculation, sedimentation, filtration, clearwell storage, and chemical addition points such as alum and pH adjusters, any upfront oxidants, chlorine for primary disinfection, and if necessary, additional chlorine for desired residual, finished water pH adjustment, etc.).



Example/tool 2.6: Basic distribution system diagram, referencing more detailed procedures and diagrams as necessary



Case study 1: Australia

Field Experience 2.1 – the flow diagram

Most utilities already had extensive system diagrams including geographic information system (GIS) data for their catchments, asset locations and distribution network. Most utilities also had process flow and hydraulic system diagrams for their assets. However, few had the type of theoretical flow diagram typically used for WSPs. Therefore, most utilities developed one or more additional flow diagrams to support their WSPs. Most utilities developed one overarching flow diagram and many then developed specific flow diagrams for each treatment plant and for each distinct water supply system. The flow diagrams were generally developed using common generic software, but many also used specialized flow diagram software.

Field Experience 2.2 – describing current water quality

Most utilities undertook water quality data analysis as part of the risk assessment phase of their WSP development. Water quality was typically plotted showing time series graphs of results against date, usually illustrating guideline values on the plots. Tables were usually prepared to summarize water quality statistics and compared with guideline values. This data was used to help inform the utility of what hazards might be present at levels of concern. Additional, or special water quality testing was usually not required to complete the WSP, although investigative sampling was often flagged as an action for improvement in the future.

Field Experience 2.3 – describing the system

System descriptions were typically brief and summary in nature. Detailed system descriptions, such as reports used for design and operation, were referenced for full details, with the WSP just providing summary details. As a result, the WSP system descriptions were usually quite brief and were aimed at the key audience: the WSP team.

Case study 2: Latin America and the Caribbean (LAC)

Field Experience 2.1 – the flow diagram

The WSP team found the flow diagram to be a useful tool for describing the system and referred to it frequently throughout the WSP development process. Rather than using the standard engineering flow diagram symbols, the team opted for an alternative schematic to represent the water supply system in an intuitive way because these were seen to be more easily interpreted and user friendly. The schematic showed all surface and groundwater sources and a detailed description of treatment processes, including coagulation/flocculation/sedimentation, filtration, clearwell storage and all chemical addition points, and directional arrows with pipe diameters to indicate flow through the distribution system. This level of detail made the diagram a useful tool to facilitate understanding and discussion of the system being assessed. Additional maps of the watershed and distribution network were also useful visual guides.

Field Experience 2.2 – describing current water quality

A key component of the system description is an assessment of the current quality of treated and delivered water. Water quality testing and a review of monitoring records collected by the water utility and the health department showed that finished water was consistently not meeting water quality standards, revealing discrepancies between perceived and actual water quality. These discrepancies were particularly important to consider when evaluating the effectiveness of existing control measures and in assessing the risk presented by the identified hazards (Module 4). For example, if the belief that chlorination at the water treatment plant was sufficient to maintain water quality throughout the distribution network had not been disproven through a current water quality assessment, increased chlorine dosing would not have been identified as a critical corrective action to prevent microbial contamination. Because subsequent steps of the WSP rely and build upon information gathered in the system description, it was important that the system description accurately reflected current conditions.

A48235836

Field Experience 2.3 – conducting a household survey

Problems with inconsistent service and uncertainty about water quality led many community residents to store or treat water in the home. To better understand the impact of point-of-use practices, a Household Water Use and Health Survey was conducted that included questions about household water sources, household storage and treatment practices, consumer perceptions, satisfaction and health concerns. Water from household taps was tested for chlorine residual and some samples were also tested for microbial contaminants. The household survey found that storing water in household tanks and drinking-water containers was associated with increased contamination; identified areas with inconsistent or no service; found that most water reaching the taps was not chlorinated; and revealed that water-associated health impacts and costs were major community concerns. Such information served to inform the water utility about consumers' experiences and priorities and informed the Ministry of Health of health concerns and the need for public education.

Field Experience 2.4 – selecting appropriate regulatory standards

In order to determine whether regulatory standards for chemicals and disinfection were being met, it was first necessary that all agencies involved in monitoring agree upon which standards should be targeted. At the start of the WSP process, target levels for some chemicals were set so low that they could not be expected to be reached even within an optimized system. Agencies differed on whether they used the environmentally-based EPA, European Union or national standards, or WHO health-based standards. The agencies represented on the WSP team agreed to adopt a consistent set of criteria that ensured drinking-water safety and was also achievable given system capabilities. In the case of turbidity, the team determined that the system could not be expected to consistently reach the indicated target until considerable system improvements were made. Rather than remain in continual non-compliance, a step-wise approach was taken, in which intermediate targets were set with the understanding that standards would be modified in subsequent WSP revisions as improvements were made. This incremental approach to reaching target turbidity levels represented a realistic and proactive way of dealing with certain limitations within the system and provided a long-term plan for reaching compliance for this parameter.

Case study 3: United Kingdom (England and Wales)

Field Experience 2.1 – field checking system descriptions

The water treatment works and distribution systems were already reasonably well documented using flow and engineering diagrams. A lot of information was already available on catchments, from companies' own investigations and regulatory requirements in respect of pesticides, nitrate and *Cryptosporidium*. The main challenge was the time and workload required to take existing and desk reviewed system diagrams out on site to check their accuracy and obtain input from catchment and site technicians and operators. This exercise paid dividends in that the review often revealed small errors or provided information previously not available centrally.

Field Experience 2.2 – incorporating existing water supply data into the WSP

Generally companies had very good information on their distribution systems and maintained sophisticated GIS systems and records of large industrial users and sensitive users such as hospitals and schools. Such systems and records, being already in place were not always immediately included in WSP development.

Module 3

Identify hazards and hazardous events and assess the risks

A48235836

Introduction

In practice this Module, together with Module 4 (determine and validate control measures, reassess and prioritize the risks), and Module 5 (develop, implement and maintain an improvement/upgrade plan), are usually carried out concurrently. For clarity, each of these is being presented as a separate step as they involve a number of activities. In essence these steps constitute the system assessment which identifies the potential hazards and hazardous events in each part of the water supply chain, the level of risk presented by each hazard and hazardous event, the appropriate measures to control the identified risks, and confirmation that standards and targets are met.

Module 3, the first step in this process, should:

- Identify all potential biological, physical and chemical hazards associated with each step in the drinking-water supply that can affect the safety of the water;
- Identify all hazards and hazardous events that could result in the water supply being, or becoming, contaminated, compromised or interrupted;
- Evaluate the risks identified at each point in the flow diagram previously prepared.

Key actions

Identify the hazards and hazardous events

For each step of the validated process flow diagram, the WSP team is required to assess what could go wrong at what point in the water supply system in terms of hazards and hazardous events. Hazard identification involves site visits as well as desk studies. Visual inspection of aspects such as the area surrounding abstraction points and elements of treatment may reveal hazards that would not have been identified through desk studies alone. Hazard identification also requires assessment of historic information and events, as well as predictive information based on utility data and knowledge of particular aspects of the treatment and supply systems. The team should consider factors that could introduce risks that are not readily obvious, for example the siting of a water treatment works in a flood plain (where there was no record of flooding) or the age of pipes in a distribution system (old pipes could be more susceptible to pressure fluctuations than new ones). Identification of 'influencing' factors like these will require the WSP team to think laterally and widely. A number of hazards and hazardous events may occur at any step in the water supply system.

Assessment of risk

The risk associated with each hazard may be described by identifying the likelihood of occurrence (e.g. 'certain', 'possible', 'rare') and evaluating the severity of consequences if the hazard occurred (e.g. 'insignificant', 'major', 'catastrophic'). The potential impact on public health is the most important consideration, but other factors such as aesthetic effects, continuity and adequacy of supplies, and utility reputation should also be considered.

The aim should be to distinguish between significant and less significant risks. The best way of carrying this out is to draw up a simple table in order to systematically record all potential hazardous events and associated hazards, together with an estimation of the magnitude of risk (see Example/tool 3.8). When starting the risk assessment process, utilities should draw up detailed definitions of what they mean by 'possible', 'rare', 'insignificant', 'major' etc. These definitions should enable the risk assessment to avoid being too subjective. Of crucial importance is the need to define in advance the definition or risk matrix score that identifies 'significant' risk. The information that will inform the risk assessment will come from the experience, knowledge and judgment of the utility and the individual team members, industry good practice and technical literature. When data is insufficient to determine whether a risk is high or low, risks should be considered significant until further investigations clarify the assessment.
The risk assessment should be specific for each drinking-water system because each system is unique.

Hazards and hazardous events
Hazards are defined as: Physical, biological, chemical or radiological agents that can cause harm to public health. Hazardous events are defined as: An event that introduces hazards to, or fails to remove them from, the water supply. For example, heavy rainfall (hazardous event) may promote the introduction of microbial pathogens (hazards) into source water.

Typical challenges

- The possibility of missing new hazards and hazardous events. Since a risk assessment provides a 'point in time' picture of the system, the risk assessment should be reviewed on a regular basis in order not to miss new hazards and hazardous events.
- Uncertainty in assessment of risks due to unavailability of data, poor knowledge of activities within the water supply chain and their relative contribution to the risk generated by the hazard or hazardous event.
- Properly defining likelihood and consequence with sufficient detail to avoid subjective assessments and to enable consistency.

Outputs

1. Description of what could go wrong and where in terms of hazards and hazardous events.
2. Assessment of risks expressed in an interpretable and comparable manner, such that more significant risks are clearly distinguished from less significant risks.

A48235836

Example/tool 3.1: Typical hazards affecting a catchment

Hazardous event (source of hazard)	Associated hazards (and issues to consider)
Meteorology and weather patterns	Flooding, rapid changes in source water quality
Seasonal variations	Changes in source water quality
Geology	Arsenic, fluoride, lead, uranium, radon Swallow holes (surface water ingress)
Agriculture	Microbial contamination, pesticides, nitrate Slurry and dung spreading Disposal of dead animals
Forestry	Pesticides, PAHs - polyaromatic hydrocarbons (fires)
Industry (including abandoned and former industrial sites)	Chemical and microbial contamination Potential loss of source water due to contamination
Mining (including abandoned mines)	Chemical contamination
Transport – roads	Pesticides, chemicals (road traffic accidents)
Transport – railways	Pesticides
Transport – airports (including abandoned airfields)	Organic chemicals
Development	Run-off
Housing – septic tanks	Microbial contamination
Abattoirs	Organic and microbial contamination
Wildlife	Microbial contamination
Recreational use	Microbial contamination
Competing water uses	Sufficiency
Raw water storage	Algal blooms and toxins Stratification
Unconfined aquifer	Water quality subject to unexpected change
Well / borehole headworks not watertight	Surface water intrusion
Borehole casing corroded or incomplete	Surface water intrusion
Flooding	Quality and sufficiency of raw water

Example/tool 3.2: Typical hazards associated with treatment

Hazardous event (source of hazard)	Associated hazards (and issues to consider)
Any hazard not controlled / mitigated within the catchment	As identified in catchment
Power supplies	Interrupted treatment / loss of disinfection
Capacity of treatment works	Overloading treatment
Disinfection	Reliability Disinfection by-products
By-pass facility	Inadequate treatment
Treatment failure	Untreated water
Unapproved treatment chemicals and materials	Contamination of water supply
Contaminated treatment chemicals	Contamination of water supply
Blocked filters	Inadequate particle removal
Inadequate filter media depth	Inadequate particle removal
Security / vandalism	Contamination / loss of supply
Instrumentation failure	Loss of control
Telemetry	Communication failure
Flooding	Loss or restriction of treatment works
Fire / explosion	Loss or restriction of treatment works

A48235836

Example/tool 3.3: Typical hazards within a distribution network

Hazardous event (source of hazard)	Associated hazards (and issues to consider)
Any hazard not controlled / mitigated within treatment	As identified in treatment
Mains burst	Ingress of contamination
Pressure fluctuations	Ingress of contamination
Intermittent supply	Ingress of contamination
Opening / closing valves	Reversed or changed flow disturbing deposits Introduction of stale water
Use of unapproved materials	Contamination of water supply
Third party access to hydrants	Contamination by backflow Increased flow disturbing deposits
Unauthorized connections	Contamination by backflow
Open service reservoir	Contamination by wildlife
Leaking service reservoir	Ingress of contamination
Unprotected service reservoir access	Contamination
Security / vandalism	Contamination
Contaminated land	Contamination of water supply through wrong pipe type

Example/tool 3.4: Typical hazards affecting consumer premises

Hazardous event (source of hazard)	Associated hazards (and issues to consider)
Any hazard not controlled / mitigated within distribution	As identified in distribution
Unauthorized connections	Contamination by backflow
Lead pipes	Lead contamination
Plastic service pipes	Contamination from oil or solvent spillage

Example/tool 3.5: Deciding which method of risk assessment is most appropriate

The risk assessment process can involve a quantitative or semi-quantitative approach, comprising estimation of likelihood/frequency and severity/consequence (see Example/tool 3.6, 3.7 and 3.8), or a simplified qualitative approach based on expert judgment of the WSP team (see Example/tool 3.9 and 3.10). A small water supply system may only require a team decision, whereas a more complex system may benefit from a semi-quantitative risk prioritization approach. In any case, it is beneficial to record the basis of the decision to act as a reminder to the team and/or auditor or reviewer as to why the decision was taken.

Example/tool 3.6: Semi-quantitative risk matrix approach (from Deere et al., 2001)

		Severity or consequence				
		Insignificant or no impact - Rating: 1	**Minor compliance impact - Rating: 2**	**Moderate aesthetic impact - Rating: 3**	**Major regulatory impact - Rating: 4**	**Catastrophic public health impact - Rating: 5**
Likelihood or frequency	**Almost certain / Once a day - Rating: 5**	5	10	15	20	25
	Likely / Once a week - Rating: 4	4	8	12	16	20
	Moderate / Once a month - Rating: 3	3	6	9	12	15
	Unlikely / Once a year - Rating: 2	2	4	6	8	10
	Rare / Once every 5 years - Rating: 1	1	2	3	4	5
Risk score		<6	6-9	10-15	>15	
Risk rating		Low	Medium	High	Very high	

All risks should be documented in the WSP and be subject to regular review even when the likelihood is rare and the risk rating is low. This avoids risks being forgotten or overlooked and provides the water utility with a record of due diligence should incidents occur.

A48235836

Example/tool 3.7: How to calculate the risk using the matrix

Event	Loss of network integrity through illegal connections results in the ingress of pathogens.
Severity of event and basis for score	5 – Public health impact including disease and potentially death.
Likelihood of event and basis of score	2 – Plumbing controls are in place, but are ineffective - at least two outbreaks have occurred from illegal connections in the past 5 years.
Score	5 x 2 = 10 high risk
Outcome	Risk requires prioritizing for action, including reviewing the current controls and whether new control(s) could be implemented (see Module 5).

Example/tool 3.8: Output of hazard assessment and risk assessment using semi-quantitative approach

Process step	Hazardous event (source of hazard)	Hazard type	Likeli-hood	Severity	Score	Risk rating (before consideration of controls)	Basis
Source (groundwater)	Cattle defecation in vicinity of unfenced wellhead causing source of potential pathogen ingress in wet weather	Microbial	3	5	15	High	Potential illness from pathogens from cattle, such as *Cryptosporidium*
Source	Cocktail of pesticides from agricultural uses	Chemical	2	4	8	Medium	Potential introduction of toxic chemicals which could lead to concentrations in finished water above national standards and WHO Guideline values
Source	Potential for informal solid waste disposal	Microbial and chemical	1	1	1	Low	Potential for hazardous waste plus rainfall event causing contamination to water supply is low
Storage tank	Unroofed reservoir allows birds to congregate and defecate in treated water	Microbial	2	5	10	High	Potential illness from pathogens such as *Salmonella* and *Campylobacter*
Treatment	No back-up power supply	Microbial and chemical	2	5	10	High	Potential loss of treatment and pumps/pressure
Distribution	Leaks on trunk main and distribution system	Microbial	5	3	15	High	Leaks are a potential source of microbial pathogens and contribute to high % of unaccounted for water

Example/tool 3.9: Simplified risk assessment based on expert judgment of the WSP team

An alternative to scoring risks based on the likelihood and severity of consequences model, is to undertake a simplified risk assessment process, drawing on the team's judgment. Risks may be ranked as 'significant', 'uncertain', or 'insignificant', based on an assessment of the hazards/hazardous events at each step in the process. Following this, and as explained in Module 4 and 5, it will be necessary to determine whether risks are under control, through which control measures, and when necessary, identify and put in place an improvement programme, which may require short-, medium- and long-term mitigation measures. It is critical to document which events need urgent attention. The NZ MoH (2005) defines 'urgent attention' as those things that can happen frequently and/or could cause significant illness. The descriptors below can be used to capture this information.

Example/tool 3.10: Definition of descriptors for use in simple risk prioritization

Descriptor	Meaning	Notes
Significant	Clearly a priority	The risk should be considered further to determine whether additional control measures are required and whether a particular process step should be elevated to a key control point in the system. It is necessary to validate existing control measures before defining whether additional control measures are required.
Uncertain	Unsure if the event is or is not a significant risk	The risk may require further studies to understand if the event is really a significant risk or not.
Insignificant	Clearly not a priority	Note that the risk will be described and documented and will be revisited in future years as part of the WSP rolling review.

Example/tool 3.11: Prioritizing and documenting risks for urgent action or regular review

Any hazard scored for risk as 'high' or 'very high' or 'significant', should have in place, or requires urgently, validated controls (or mitigation measures). Where controls are not in place, an improvement programme should be drawn up. Any hazard classified as 'moderate' or 'low risk' should be documented and kept under regular review. Controls for 'high' or 'very high' risks may also mitigate other risks.

Example/tool 3.12: The necessity of working with stakeholders

Identification of a hazard does not mean the water company is responsible for the cause. Many hazards are naturally occurring or the result of agricultural or industrial activity. The WSP approach requires water utilities to work with other stakeholders to make them aware of their responsibilities and the impact that their actions have on the utility's ability to supply safe drinking-water. The WSP approach promotes dialogue, education and collaborative action to remove or minimize risks.

A48235836

Case study 1: Australia

Field Experience 3.1 – identifying threats to water quality

Usually two-day workshops were convened for each major water supply system and involved the full WSP team with one or more external experts, stakeholders and facilitators. The process of hazard identification and risk assessment was usually carried out on day one. Control point determination and specification was usually carried out on day two. Hazardous events were typically listed for each process step identified in the flow diagram. For each hazardous event, the hazards arising were considered and risks were scored against two factors: likelihood and consequence. Likelihood was usually expressed as a frequency of anticipated occurrence. Consequence was usually expressed in terms of population size (small-large) and severity of effect (operational-aesthetic-health). The workshops typically involved brainstorming exercises, review of water quality data and consideration of a range of what-if scenarios. Most utilities assessed risks assuming that the current control measures were in place and working normally. Some utilities assessed each risk twice: both with and without considering the effect of the current controls in place. Most utilities used a risk assessment ranking matrix that was based on their corporate risk assessment system which was often used for environmental, occupational health and safety and other types of risk assessment, too.

Field Experience 3.2 – limitations of the semi-quantitative approach to risk assessment

The semi-quantitative approach was relatively easy to apply in Australia because it formed the basis of the Australian and New Zealand Risk Management Standard (1995, 1999, 2004) and was very familiar to most industry professionals. However, there was always difficulty forming agreement on risks. In particular, it was common for the same stated risk to have more than one connotation: a low likelihood of a severe consequence and a high likelihood of a minor consequence. For instance, the risk of dirty water contamination was both likely but minor (sporadic dirty water complaints with no health implications are quite common) and rare but severe (major dirty water events that compromise disinfection are serious but not common). Therefore, it was necessary to set out very clearly what each risk was. Another limitation of the scoring system was that health consequences were typically not differentiated between short-term acute and established effects, such as pathogen infections, and long-term theoretical effects, such as disinfection by-product effects. Therefore, the risk ranking tended to overstate the importance of some chemical related health risks of relatively low or even questionable significance as compared with microbial risks.

Case study 2: Latin America and the Caribbean (LAC)

Field Experience 3.1 – identifying threats to water quality

A two-day workshop was convened to carry out the process of hazard identification and risk assessment. Hazards in the watershed, treatment process, distribution system, and household were identified by Task Force members through brainstorming exercises and through a review of water quality monitoring site visits and household survey reports. The most critical threats identified were institutional, including a lack of operator training, a lack of system accountability to ensure routine monitoring and a lack of standard operating procedures. Physical hazards identified through brainstorming, such as the introduction of sewage and gasoline, while important, were found to be largely hypothetical. The more critical physical threats, such as a lack of chlorine and the presence of thermotolerant coliforms in delivered water,

A48235836

were identified through a review of the monitoring and survey reports of existing conditions and practices.

Because of the range of possible hazards at each step of the water supply chain, the multiple factors considered in assigning risk, and the relative and subjective nature of the scoring process, the input of stakeholders with varied expertise and experience was important for minimizing bias by any single agency perspective. It also improved the accountability of those agencies and facilitated the appropriate assignment of responsibility for corrective actions identified to address the risks.

Field Experience 3.2 – limitations of the semi-quantitative approach to risk assessment

Initially a semi-quantitative approach following WHO's WSP risk scoring matrix (chapter 4 of the Guidelines) was employed. Considerable confusion and disagreement arose, however, over some hazards that did not always lend themselves to quantitative ranking and led to time-consuming discussions of hypothetical situations. In many cases, assignment of severity and likelihood was inconsistent. The severity of sewage effluent from cesspool emptying, for example, was ranked high, while the severity of sewage effluent from on-site absorption pits was ranked low, resulting in vastly different priority assignments, even though likelihood was ranked the same. Participants also found it difficult to exclude consideration of existing control measures when assessing risk, further contributing to frustration in the preliminary ranking process. WSP team members found that the resulting rankings did not reflect priorities and therefore decided to switch to a more intuitive approach and to delay priority ranking of risks until after control measures had been considered (see LAC Field Experience 4.1).

Case study 3: United Kingdom (England and Wales)

Field Experience 3.1 – broadening the application of risk assessment

The initial process for many companies was to restrict hazard identification and risk analysis to those that related directly to compliance parameters. Issues such as flooding, power supplies, security, emergency responses, telemetry, communications and IT systems, although well documented within company procedures, were not considered as part of the WSP, often because they were not under the direct control of the WSP team lead or members (usually from the operations or scientific divisions of a company). Gradual development of the WSP approach demonstrated the need for wider application but this area remains a problem.

Many companies had applied risk assessment techniques to their operations, assets and financial systems for many years and had risk registers. Sometimes ownership of the risk register was not covered by the WSP team so that, for example, a waterborne outbreak of illness did not feature in the WSP because it already featured in the company's risk register. Widening WSP application is still a challenge in some companies.

Field Experience 3.2 – tailoring the risk scoring matrix to fit the supplier

Most companies found the 5x5 risk matrix from Chapter 4 of the third edition of the Guidelines useful for scoring and prioritizing risks. Some changed the scoring ratio because they considered it was easier to separate high, medium and low risks. The use of a basic non-scoring 3x3 risk matrix (high, medium and low) was not found to be very helpful because most risks ended up in the medium category and then had to be reprioritized. Many companies found it useful to supplement the basic definitions in the Guidelines with further explanations to help with consistent

A48235836

assessment, particularly where more than one team was carrying out assessments. An example is shown below but it is important that each company works out its own methodology rather than copy other examples.

High risk ≥20 Medium risk 10-19 Low risk <10				Consequence				
				Wholesome water Insignificant 1	Short term or localised, not health related non compliance or aesthetic Minor 2	Widespread aesthetic issues or long term non compliance not heath related Moderate 4	Potential long term heath effects Major 8	Potential illness Catastrophic 16
Likelihood	Has not happened in the past and it is highly improbable that it will happen in the future	Most unlikely	1	1	2	4	8	16
	Is possible and cannot be ruled out completely	Unlikely	2	2	4	8	16	32
	Is possible and under certain circumstances could happen	Forseeable	3	3	6	12	24	48
	Has occurred in the past and has the potential to happen again	Very likely	4	4	8	16	32	64
	Has occurred in the past and could happen again	Almost certain	5	5	10	20	40	80

Field Experience 3.3 – addressing risks within consumer premises

It was noticeable that many WSPs did not identify consumers or consumer organizations as WSP stakeholders. Hazard identification and risk assessment of consumer premises was a weak area in most WSPs and it is true that there is a limit to what water companies can achieve although they do have powers of inspection. Water storage within premises is common in England and Wales and is a source of hazards but is an area where water companies have little control. A good example of co-operation within the water industry was an education package for consumers setting out what they can do to protect the safety of their water supplies in areas such as hygiene, plumbing and preventing back syphonage. Companies were aware that this is an area that requires handling carefully as there is a danger of scaring consumers away from drinking tap water.

A48235836

Module 4

Determine and validate control measures, reassess and prioritize the risks

Introduction

Concurrently with identifying the hazards and evaluating the risks, the WSP team should document existing and potential control measures. In this regard, the team should consider whether the existing controls are effective. Depending on the type of control, this could be done by site inspection, manufacturer's specification, or monitoring data. The risks should then be recalculated in terms of likelihood and consequence, taking into account all existing control measures. The reduction in risk achieved by each control measure will be an indication of its effectiveness. If the effectiveness of the control is not known at the time of the initial risk assessment, the risk should be calculated as though the control was not working. Any remaining risks after all the control measures have been taken into account, and which the WSP team consider unacceptable, should be investigated in terms of additional corrective actions.

Control measures (also referred to as 'barriers' or 'mitigation measures') are steps in the drinking-water supply that directly affect drinking-water quality and ensure the water consistently meets water quality targets. They are activities and processes applied to reduce or mitigate risks.

Key actions

Identify the controls

Existing control measures should be determined for each of the identified hazards and hazardous events. Missing controls (i.e. those that are needed, but are not in place to mitigate hazards) need to be clearly documented and addressed, as explained below.

Validate the effectiveness of the controls

Validation is the process of obtaining evidence on the performance of control measures. For many controls validation will require an intensive programme of monitoring to demonstrate the performance of a control under normal and exceptional circumstances. This should not be confused with operational monitoring, which shows that the validated control continues to work effectively. The efficacy of each control measure should be determined at its point in the water supply system rather than in isolation as the performance of one control can influence the performance of subsequent controls. If a control has been in place for some time, a utility may have sufficient operating data to give it confidence that further validation monitoring is not required.

Technical data from scientific literature or data from studies at pilot drinking-water treatment plants may be helpful in the validation process, but care must be taken to check that the circumstances described or piloted are the same or very similar to the risks that have been identified as requiring controls. Validation may also be carried out by seeding challenge organisms or chemicals and determining the effectiveness of removal or inactivation, although this is not a procedure that should be used when water is going into supply. Validation of controls will involve a variety of methodologies. For example, validating buffer distances and fencing in a catchment may be carried out through catchment sanitary surveys to ensure minimal risk of microbial pathogens entering a water intake; and an alternative power source, supplied through an on-site emergency generator, may be validated by demonstrating that it switches on when power is lost, and that it has sufficient power output to run the required process.

A48235836

During operations, it is critical to monitor the effectiveness of validated controls against pre-determined targets or 'critical limits' (see Module 6 on operational monitoring). These targets may be expressed as upper and/or lower limits. For example, if a control measure is 'maintenance of continuous chlorine residual', a critical limit might be expressed as water meeting a 0.2-0.5 mg/l residual chlorine level, pH 6.5-7 and turbidity <1 NTU.

Reassess risks, taking into account the effectiveness of controls

The risks should be recalculated in terms of likelihood and consequences taking into account the effectiveness of each control. Control measures must be considered not only for their longer-term average performance, but also in light of their potential to fail or be ineffective over a short space of time. It is important that significant risks that do not have controls are highlighted as remaining significant risks in that water supply system. The determination of the appropriate missing controls is critical and is discussed in Module 5.

Prioritize all the identified risks

Risks should be prioritized in terms of their likely impact on the capacity of the system to deliver safe water. High priority risks may require system modification or upgrade to achieve the water quality targets. Lower priority risks can often be minimized as part of routine good practice activities.

As per Module 5, an upgrade or improvement plan should be developed to address all uncontrolled and prioritized risks. Upgrade plans should identify who is responsible for the improvements, together with an appropriate time frame for implementation of these controls.

Examples of controls include short-term mitigation measures (e.g. advice notices and restricting output or not using a particular source); and medium- and long-term mitigation measures (e.g. improving community consultation activities; catchment measures, such as covering of water storages; treatment improvements, such as enhanced coagulation and filtration; and other capital investment projects).

Typical challenges

- Identifying staff responsibilities in terms of who will undertake the field work to identify the hazards and determine the control measures;
- Ensuring appropriate controls are identified that are cost-effective and sustainable;
- Uncertainty in prioritizing the risks due to unavailability of data; poor knowledge of activities within the water supply chain and their relative contribution to the hazard type generated by the hazardous event as well as the risk score of the event.

Outputs

1. Identification of the controls.
2. Validation of the effectiveness of the controls.
3. Identification and prioritization of insufficiently controlled risks.

A48235836

Example/tool 4.1: Typical control measures associated with hazards at a catchment

Restricted access to catchments
Water utility ownership and control of catchment land
Stock fencing
Moving stock away from river access at calving / lambing times
Codes of practice on agricultural chemical use and slurry spreading
Moving farm operations away from sensitive locations
Planning controls
Agreements and communication with transport organizations
Communication and education of catchment stakeholders
Industrial effluent standards and volume controls
Raw water storage
Ability to close intakes (time of travel information)
River biology – indicator of diffuse or point source contamination
Covering and protecting springs
Ability to use good alternative water sources when hazards affect one source
Continuous monitoring of intake and river
Site inspections
Regular internal inspections of wells and boreholes

Example/tool 4.2: Typical control measures associated with hazards at treatment

Validated treatment processes
Alarmed operating limits
Stand-by generator
Automatic shut-down
Continuous monitoring with alarms
Trained staff (operator competency)
Purchasing policy and procedure
Fencing, locked premises, intruder alarms
Communications back-up

Example/tool 4.3: Typical control measures associated with hazards at a distribution network

Regular reservoir inspections (external and internal)
Cover open service reservoirs
Up-to-date network maps
Known valve status
Purchasing policy and procedure
Mains repair procedures
Trained staff (operator competency)
Hygiene procedures
Hydrant security
Non-return valves
Pressure monitoring and recording
Protected pipes
Fencing, locked hatches, intruder alarms for service reservoirs and towers

Example/tool 4.4: Typical control measures associated with hazards at consumer premises

Property inspections
Consumer education
Plumbosolvency control
Non-return valves
Advice to boil / not use the water

Example/tool 4.5: Critical limits and actions relating to microbial hazards

Hazards and hazardous events	Examples of control measures	Critical limit target	Critical limit trigger for action
Microbial hazards from contamination of a service reservoir	Ensure inspection covers remain in place Ensure ventilators and cable ducts are secured against vermin entry	Inspection covers locked in place and vermin-proofing intact	Inspection covers not in place or unlocked or damage to vermin-proofing
Microbial hazards from contamination of a source water reservoir	Protection of catchments from stock and human habitation Fencing stock from catchment streams and watercourses	Only permitted development or activity in catchment and stock fencing intact	Any non-permitted development or activity in catchment and any damage to stock fencing
Chemical, microbial and physical hazards overwhelming treatment capability	Cessation of source water abstraction during high contamination periods, e.g. after storms	Rain event, flow rate and turbidity monitoring within normal range	Rain event, flow rate and turbidity monitoring outside of specified range
Chemical cyanotoxin hazards from algal bloom in source water reservoir	Mixing of storages to reduce cyanobacteria	Mixing system operating when required	Failure of mixing system and stratification forming

Example/tool 4.6: Validation information capture format

Item validated	Validation	Reference
Chlorine residual critical limit values	Australian Drinking Water Guidelines state that a Ct of 15 is required to control bacterial pathogens which require the minimum specific chlorine concentrations at the specified measurement points in peak day demand flows.	*Australian Drinking Water Guidelines* (1996 and 2004). National Health and Medical Research Council.
Filtered effluent critical limit values	Systems that filter must ensure that the turbidity goes no higher than 1 NTU and 0.3 NTU for conventional or direct filtration in at least 95% of the daily samples in any month.	US EPA National Primary Drinking Water Regulations (2002)
Critical limits for underground travel time in riverbank filtration	Site and depth of wells should ensure minimal travel times of the water in the ground of 30 days (as shown from a two year observation programme run with a sequence of observation wells) to ensure elimination to < 1 µg/L of toxins even during prolonged cyanobacterial blooms with > 1000 µg/L of toxins in the river.	Internal report documenting analysis of two years' worth of data in observation and production wells.
Critical limit for turbidity at outlet of each single rapid filtration unit	Research programme run by five utilities over a two year period showed *Cryptosporidia* oocysts to remain below detection limit if the filters are operated to meet this critical limit for turbidity.	Project report of joint research programme. Analytical method had to meet performance target for result to be accepted.

A48235836

Example/tool 4.7: Validate controls before prioritizing risks for mitigation

Risks can only be reassessed and prioritized following validation of control measures. Initial validation of controls can be carried out through intensive monitoring, unless controls have proved their effectiveness over time. If it is clear that the system needs to be improved to achieve the relevant water quality objectives, an upgrade/improvement plan should be developed and implemented.

Example/tool 4.8: Maintaining consistency in reassessing and prioritizing risks

- ☑ Decide on a consistent risk assessment methodology upfront, as done in Module 3;
- ☑ Be specific about what the hazard is in terms of:
  - Likelihood of the hazard occurring, taking into account effectiveness of controls;
  - Consequence of the hazard occurring;
  - Probability that it will affect the safety of the water supply; and
  - Where and when it can occur.

Example/tool 4.9: Establishing cut-off points to prioritize risks

The WSP team needs to establish a cut-off point, above which the reassessed risks will require further action and below which they will be kept under review. In Example/tool 3.6, a score of 6 is taken as the cut-off point, but in addition, any risk that includes a catastrophic consequence rating should be documented and kept under review even if the likelihood is rare. Classifying the risk from low to very high can be rather subjective but should help to prioritize where the most urgent action is required.

Example/tool 4.10: Output of hazard assessment and determination and validation of control measures

Hazardous event	Hazard type	Likelihood	Severity	Risk	Control measure	Efficacy of control measure	Basis
Cattle defecation followed by rainfall	Microbial (pathogens)	3	5	15	Filtration of water Boil water advisory if filtration fails (corrective action)	Protozoa controlled by filtration validated by manufacturer's data on pore size and testing for oocysts	Waterborne disease outbreaks seen in similar situations
Etc. ↴							

A48235836

Example/tool 4.11: Dealing with uncertainty in scoring of risks

The uncertainty of risk scoring for each of the hazards and hazardous events can be addressed by further investigations which can be added to the WSP.

Step	Catchment
Event	Leaching from sites such as disused cattle, landfill or contaminated sites and run-off of water soluble compounds (e.g. pesticides) into the source water.
Basis	While the dilution factors are significant, there is no monitoring data available and no barriers in place for this hazard. If pesticides are present in high concentrations, there could be potential health risk.
Possible investigations to reduce uncertainty	1. Undertake a sanitary survey with special focus on pesticide usage and dip site locations, particularly those in the proximity of spray from pesticides. 2. Undertake pesticide monitoring at the source intake during normal and event conditions.
Practicality of investigation	1. High practicality but low cost and could be combined with other studies being undertaken by other stakeholders. 2. High practicality but high cost.
Output	The WSP team recommends which of the above options to undertake, by whom, at what time, and at what cost.

A48235836

Example/tool 4.12: Risk prioritization and reassessment

Hazard	Hazardous event (source of hazard)	Likelihood	Severity	Score	Risk rating (see table 3.6)	Example control measure	Validation of control measure	Reassessment of risk post-control
Microbial	Inadequate disinfection method	3	4	12	High	Improve disinfection method (longer-term). Minimizing ingress of contamination to system and lengthening reservoir detention times (short-term). Fitting alarms triggered by low disinfectant level.	Alarms effective and demonstration of consistent removal of indicator organisms under range of operating conditions.	Low with appropriate operational monitoring.
Chemical	Formation of disinfection by-products at levels that exceed Guideline values	3	3	9	Medium	Reducing water age through tanks downstream where possible in periods of low water demand.	Consistent reduction in disinfection by-products under range of operating conditions.	Low with appropriate operational monitoring.
Microbial	Less effective disinfection due to elevated turbidity	4	4	16	Very high	Improve clarification and filtration processes (longer-term). Fitting alarms triggered by low disinfectant level.	Alarms effective and demonstration of consistent removal of indicator organisms under range of operating conditions.	Low with appropriate operational monitoring.
Microbial	Major malfunction/ failure of disinfection plant	2	5	10	High	Chlorination plants refitted for equipment and process reliability of 99.5%. Fitting alarms triggered by low disinfectant level.	Alarms effective and demonstration of consistent removal of indicator organisms under range of operating conditions.	Low with appropriate operational monitoring.
Microbial	Reliability of disinfection plant less than target level of 99.5%	3	4	12	High	Defined band widths for chlorine dosing linked to alarms.	Alarms effective and demonstration of consistent removal of indicator organisms under range of operating conditions.	Low with appropriate operational monitoring.
Microbial	Failure of UV disinfection plants	3	4	12	High	Alarms in place for power outages.	Alarms triggered under a range of operating conditions.	Low with appropriate operational monitoring.

A48235836

Hazard	Hazardous event (source of hazard)	Likelihood	Severity	Score	Risk rating (see table 3.6)	Example control measure	Validation of control measure	Reassessment of risk post-control
Microbial	Low chlorine residual in distribution and reticulation systems	4	4	16	Very high	Set point designed to achieve established target chlorine residual to achieve microbial standards at consumer premises linked to alarms.	Alarms effective and demonstration of consistent removal of indicator organisms under range of operating conditions.	Low with appropriate operational monitoring.
Microbial	Power failure to disinfection plant	2	5	10	High	Dual power source.	Supplies confirmed to come from different generating sources. Automatic switching shown to be triggered under a range of operating conditions.	Low with appropriate operational monitoring.
Physical, chemical, microbial	Contamination of dosing chemicals or wrong chemical supplied and dosed	2	4	8	Medium	On-line monitoring controls. Laboratory analysis certificate from supplier.	Intensive audit of suppliers. Alarms triggered under a range of operating conditions.	Low with appropriate operational monitoring.
Chemical	Over or under dosing from fluoridation plants	3	3	9	Medium	Plants have alarms on high and low levels with dosing cut-offs on high levels.	Alarms triggered under a range of operating conditions.	Low with appropriate operational monitoring.
Chemical, physical	Over or under dosing of lime for pH correction	3	3	9	Medium	Plants have alarms on high and low pH with dosing cut-offs on high pH.	Alarms triggered under a range of operating conditions.	Low with appropriate operational monitoring.
Physical	Failure of pumps	4	3	12	High	Pressure measurement triggering back-up pumps. (Not in place.)	No controls in place.	High - priority for mitigation.
Chemical	Nitrate exceeds compliance standards	3	2	6	Medium	Blending with low-nitrate source from another water supply. (Alternative source itself has rising levels of nitrate and is subject to other demands.)	Unreliable long-term control.	Medium - keep trend under regular review and propose alternative mitigation scheme.

Case study 1: Australia

Field Experience 4.1 – using a qualitative approach to assessing controls

In most cases, actual performance of controls in the removal of contaminants, and actual source water concentrations of hazards, were not defined. Rather, a qualitative, 'gut feel' approach was used to rate the adequacy of controls based on operator experience. Reliable, telemetered, automated engineered controls, such as treatment plants, were often classified as critical control points. Less directly controlled control measures, such as backflow prevention strategies and catchment management actions, were sometimes classified as critical control points but were more usually classified as supporting programmes or just control points. There was often great difficulty in coming to agreement as to what should constitute a critical control point rather than a control point and some utilities did not use the term critical control point at all (consistent with WHO WSP and NZ MoH guidance). In general, however, there was good agreement as to which controls were important and needed to be actively managed.

Field Experience 4.2 – areas of uncertainty

There were significant uncertainties in estimating the effectiveness and value of some catchment and distribution system controls. There was often a reluctance to rely on catchment controls due to difficulties with measuring and enforcing controls in practice. There was also difficulty in having confidence as to the effectiveness of catchment controls, other than total exclusion of people, agriculture, industry and development, which was practiced in some catchments. In general, if activities were allowed in the catchments, it was assumed that treatment was required regardless of the way that the activities were managed. A good example of this was that many source waters that feed disinfection-only treatment systems prohibit recreational activity in catchments and dams because there is not confidence that these activities can be managed to low enough levels to avoid excessive contamination. Another area of concern was disinfectant residual maintenance in distribution systems. Most utilities targeted residual maintenance to water tanks, which are obvious points of possible ingress, but most did not target residual disinfection to all taps, relying instead on low leakage rates and reliable pressurization combined with sanitary repair procedures.

Case study 2: Latin America and the Caribbean (LAC)

Field Experience 4.1 – using qualitative operator knowledge and experience to inform risk assessment

Through discussion of the hazards, existing control measures, the effectiveness of the control measures, and 'gut feelings' about the relative importance of the hazards, the team came to consensus on the prioritization of risks. Because the water supply system was recognized as 'risky' a comprehensive pre-control risk assessment was not done. Postponing assessment of risk until after consideration of existing control measures and their effectiveness reduced the time spent on evaluating the risk of hazards for which good control measures were in place and allowed for the inclusion of additional variables, such as the feasibility of preventing the hazard. For example, theft of chlorine tanks resulting in no chlorination, which had occurred in the past, was ranked low in the semi-quantitative approach, while contamination due to residential and industrial activities along the 13-mile intake canal was ranked high. The qualitative approach considered the ease with which the problem of stolen tanks could be corrected (lock boxes), and thus ranked it higher than addressing the multitude of threats that existed along the expanse of the intake canal. This showed that prioritization of risks can be easily influenced by how readily they are mitigated. In this example, although locking the boxes was

A48235836

obviously an improvement, the much higher risk of the quality of the source water should have still remained a top priority.

Field Experience 4.2 – considering the effectiveness of control measures

In preparing the system description, the WSP team found that there were standards and protocols that were not always carried out as indicated. For example, chlorination was described as part of the standard operations for the water treatment plant; but at the time of the WSP development, a chlorinator had not yet been connected. Routine water quality monitoring was carried out as indicated, but there was no system of review or communication of results. Thus, even though control measures were indicated, they were shown to be minimally or not effective. The evaluation of current system operations as described in LAC Field Experience 2.2 proved helpful for understanding the effectiveness of the control measures and instances in which revising existing control measures or establishing new control measures were needed.

Case study 3: United Kingdom (England and Wales)

Field Experience 4.1 – assessing risk before and after controls

An area that the regulator has encouraged, which had been included in some but not all methodology, is the assessment of risks before and after controls. The reason for this is that it is important to know how many risks can affect the water supply system if no controls were in place. This in turn leads to the clear consideration of the effectiveness of each control under normal and abnormal conditions. Having to prove the reasons for the reduction in risk pre- and post-control is a powerful tool for confirming the validity of risk assessment criteria, scoring and effectiveness of controls.

Field Experience 4.2 – validating control measures

For a mature industry, identification and validation of controls was sometimes seen as a less important step because companies considered that they had so much data and information that the effectiveness of controls was self evident. However the WSP approach does encourage re-evaluation of the use of such data.

Validation of catchment initiatives such as animal management and pesticides and fertilizer usage is a challenge because it is not always a clear measurement and they require the involvement of catchment stakeholders as well as the water company.

The effectiveness of the WSP approach is now seen to be in the interest of the industry and regulator. For example, the WSP approach was effective in validating UV disinfection units, which have recently been allowed for use as a treatment measure for *Cryptosporidium*.

There was confusion about the meaning of the terms validation and verification and these sometimes appeared interchangeable although understanding has improved as the WSP approach has become more widely implemented.

A48235836

Module 5

Develop, implement and maintain an improvement/upgrade plan

A48235836

Introduction

If the previous step identifies significant risks to the safety of water and demonstrates that existing controls are not effective or are absent, then an improvement/upgrade plan should be drawn up. Each identified improvement needs an 'owner' to take responsibility for implementation and a target implementation date. The assessment may not automatically result in the need for new capital investment. In some instances, all that may be needed is to review, document and formalize the practices that are not working and address any areas where improvements are needed. In other cases, new or improved controls or a major infrastructure change may be needed.

Improvement/upgrade plans can include short-, medium- or long-term programmes. Significant resources may be needed and therefore a detailed analysis and careful prioritization should be made in accordance with the system assessment. It may be that improvements need to be prioritized and phased in.

Implementation of improvement/upgrade plans should be monitored to confi rm improvements have been made and are effective and that the WSP has been updated accordingly. It should be taken into consideration that the introduction of new controls could introduce new risks to the system.

A48235836

Key actions

Draw up an improvement/upgrade plan

Identify in the improvement/upgrade plan short-, medium- or long-term mitigation or controls for each significant risk, recognizing that other less significant risks can also be controlled by these measures.

Implement the improvement/upgrade plan

Update the WSP, including recalculating risks taking into account the new control(s).

Typical challenges

- Ensuring the WSP is kept up to date;
- Securing financial resources;
- Lack of human resources, including technical expertise, to plan and implement needed upgrades;
- Ensuring new risks are not introduced by the improvement programme.

Outputs

1. Development of a prioritized improvement/upgrade plan for each significant uncontrolled risk.
2. Implementation of the improvement plan according to the planned schedule of short-, medium- or long-term activities.
3. Monitoring the implementation of the improvement/upgrade plan.

A48235836

Example/tool 5.1: A checklist of issues to be considered when developing an improvement/upgrade plan

- ☑ Options for mitigating risks
- ☑ Responsibility for improvement programme (process owner)
- ☑ Financing
- ☑ Capital works
- ☑ Training
- ☑ Enhanced operational procedures
- ☑ Community consultation programmes
- ☑ Research and development
- ☑ Developing incident protocols
- ☑ Communication and reporting

Example/tool 5.2: Drinking-water quality improvement/upgrade plan actions and accountabilities

Action	Arising from	Identified specific improvement plan	Accountabilities	Due	Status
Implement measures to control *Cryptosporidium*-related risks.	*Cryptosporidium* has been identified as an uncontrolled risk. Cattle defecation in vicinity of unfenced wellhead is a potential source of pathogen ingress, including *Cryptosporidium*, in wet weather. Currently there is no confidence that these risks are adequately controlled.	Install and validate ultraviolet light treatment. Validation includes comparing theoretical treatment performance against that required to inactivate *Cryptosporidium* infectivity.	e.g. Engineer	e.g. Date the action should be completed by.	e.g. Ongoing, not started, etc.
Implement measures to control risks arising from agricultural pesticides introduced into the water supply.	Risk assessment process has identified a cocktail of pesticides from agricultural uses. Currently there is no confidence that these risks are adequately controlled.	Install ozone and granular activated carbon filtration within the water treatment plant. These controls should be validated through intensive monitoring and shown to continue to work through operational monitoring.	e.g. Engineer	e.g. Date the action should be completed by.	e.g. Ongoing, not started, etc.
Review the need for, and if required, the options for, reducing the risks from viral and protozoan water quality contamination from sewage systems to reduce risks to acceptable levels.	Risk assessment process for pathogens risks arising from sewage systems. Currently there is no confidence that these risks are adequately maintained to acceptable levels by the control measures in place.	Develop additional sewage disinfection and downstream water treatment, including avoidance strategies as warranted.	e.g. Water quality officer	e.g. Date the action should be completed by.	e.g. Ongoing, not started, etc.
Etc. ↴					

A48235836

Case study 1: Australia

Field Experience 5.1 – corrective actions to address inadequate chlorine dosing

In general, corrective actions in the event of critical limits being exceeded involved shutting down supplies until problems were fixed. Most systems had enough treated water in storage or alternative supply options, that it was possible to do this. However, some systems that would have difficulty shutting off supply had installed multiple duty and standby systems with automatic changeover to reduce the risk of untreated water being supplied. In general, treatment failure followed by an inability to provide an alternative supply or rely on stored treated water resulted in the issue of precautionary boil water advisories.

Field Experience 5.2 – revising the capital improvement plan

Most WSPs identified the need for capital works to improve the reliability of systems and address vulnerabilities. Generally the Australian water supplies were able, under normal circumstances, to provide safe water, so most capital upgrades were aimed at reducing risks of process failures and improving overall system reliability. One of the major benefits of a WSP was the identified capital improvements, using the evidence obtained through the WSP as the driver, had a very high probability of being funded and given a priority. Prior to the use of WSPs there was often less clarity as to the real priority needs of the water quality investments. Furthermore, the WSP provided a justification for capital improvements to improve theoretical reliability and reduce risk. In the past there was more reliance on reacting only to the adverse events that actually occurred. Therefore, the WSP has helped to drive more proactive, preventive water quality planning.

Case study 2: Latin America and the Caribbean (LAC)

Field Experience 5.1 – corrective actions to address inadequate chlorine dosing

Several of the hazards identified through the household survey and the monitoring records led to a lack of chlorine residual in the distribution system. The risk associated with this was high and therefore corrective actions to optimize chlorine dosing were ranked among the highest priorities. The insufficient chlorine was associated with a lack of operator knowledge about appropriate dosing, a lack of routine monitoring of chlorine in the distribution system, a lack of communication of monitoring results to operators, and the perception that one source was clean and therefore required only minimal treatment. Corrective actions were proposed to address each of these contributing factors: a training programme for plant operators was developed (see LAC Field Experience 9.1); a schedule was developed and sites were selected for routine monitoring along the distribution system (LAC Field Experience 7.1); a protocol for communicating monitoring results to plant operators was developed (LAC Field Experience 7.1); and water quality test results were presented to address misperceptions about the safety of water sources (LAC Field Experience 2.2). Corrective actions were highly detailed, and included responsible parties (process owners), specific tasks and target completion dates.

Field Experience 5.2 – developing a consumer education programme

The household survey revealed that a perception existed in the community that springs and a creek supplied water of high quality and could therefore be consumed directly, while water quality testing found the sources to be microbially contaminated. It also showed a lack of knowledge about effective point-of-use treatment and household storage methods to prevent

contamination in the home. Corrective actions to address these hazards focused on designing and carrying out a consumer education programme. Appropriate medias for communicating different messages, including radio and television public service announcements and posters, were developed jointly by the water utility and the Ministry of Health. Again, detailed action plans identified responsible parties, specific tasks and target completion dates.

Field Experience 5.3 – revising the capital improvement plan

Some capital improvement needs were identified through the system and hazard review. At the time of the WSP development, a plan for capital improvements, developed by the utility and sponsored by an outside donor, had already been proposed. The WSP team found that the improvements proposed by the plan did not necessarily reflect the priorities identified through the WSP process and were not based on a thorough needs assessment and risk analysis; thus, the plan had some important deficiencies. Identifying priority needs through the WSP allowed the team to provide input to the plan, to which the donor was responsive due to the team's ability to justify the proposed changes. The existing capital improvement plan was modified to address the priorities identified by the team, increasing its potential impact by making it an informed and recipient-driven process.

Case study 3: United Kingdom (England and Wales)

Field Experience 5.1 – targeting investment programmes

The financial regulatory regime in place requires five-year investment programmes, with potential support from the regulator provided that investments were identified through WSP methodology. Implementation of WSPs provides the opportunity for a comprehensive risk based prioritized investment programme. Some companies were reluctant at first to share the outputs of risk analysis with the regulator even on an informal basis but this tendency has reduced with the need for the water quality regulator to approve improvement programmes to be put forward for funding. Risk assessment also highlights the need for good maintenance of assets, an area that has previously been difficult to justify for proper funding. There were a few examples of companies already being aware of investment requirements and trying to work these backwards into the risk assessment process. External audit of the improvement programmes should be able to identify flawed risk assessments.

Field Experience 5.2 – prioritizing catchment initiatives

Over the years water treatment has become more sophisticated and complex to deal with contaminated water sources. With little control over many catchments, water companies had little alternative. However, the WSP approach is now starting to give more priority to catchment initiatives with collaboration between water companies and catchment stakeholders. Such initiatives also require a more flexible approach from regulators because benefits are likely to take longer to achieve than through installing water treatment but they are likely to be more sustainable and have a lower carbon footprint.

Many companies had done a lot of liaison work in this area and some companies had very good links and communications with the environmental regulator which had a lot of information on catchments; in other cases these links were weaker but as a result of the WSP approach, were improving. Many companies had also undertaken initiatives with other catchment stakeholders, particularly with agriculture in respect to pesticides and fertilizer usage and animal grazing and breeding. In some cases these

A48235836

initiatives had lost impetus and the WSP approach was a way of re-invigorating them. For example, re-organization of the rail network had meant that some previous understandings on pesticides usage near water sources needed reinforcing. The WSP approach is helping involvement from other catchment stakeholders such as industry, forestry, road, rail and airport authorities but this is an area that water companies have found often requires a lot of work to raise stakeholder awareness and interest.

Module 6

Define monitoring of the control measures

A48235836

Introduction

Operational monitoring includes defi ning and validating the monitoring of control measures and establishing procedures to demonstrate that the controls continue to work. These actions should be documented in the management procedures.

Defining the monitoring of the control measures also requires inclusion of the corrective actions necessary when operational targets are not met.

Key actions

The number and type of control measures will vary for each system and will be determined by the type and frequency of hazards and hazardous events associated with the system. Monitoring of control points is essential for supporting risk management by demonstrating that the control measure is effective and that, if a deviation is detected, actions can be taken in a timely manner to prevent water quality targets from being compromised.

Effective monitoring relies on establishing:

- What will be monitored
- How it will be monitored
- The timing or frequency of monitoring
- Where it will be monitored
- Who will do the monitoring
- Who will do the analysis
- Who receives the results for action?

Examples of operational monitoring parameters

Measurable: Chlorine residuals; pH; turbidity.

Observable: Integrity of fences or vermin-proofing screens; stock density on farms in catchments.

Routine monitoring is usually based on simple observations and tests, such as turbidity or structural integrity, rather than complex microbial or chemical tests. For some control measures, it may be necessary to define 'critical limits' outside of which confidence in water safety would diminish. Deviations from these critical limits usually require urgent action and may involve immediate notifi cation of the local health authority and/or the application of a contingency plan for an alternative supply of water. Monitoring and corrective actions form the control loop to ensure that unsafe drinking-water is not consumed. Corrective actions should be specifi c and predetermined where possible to enable their rapid

implementation. Monitoring data provide important feedback on how the water supply system is working and should be frequently assessed.

Regularly assessed monitoring records are a necessary element of the WSP as they can be reviewed, through external and internal audit, to identify whether the controls are adequate and also to demonstrate adherence of the water system to the water quality targets.

Typical challenges

- Lack of sufficient human resources to carry out monitoring and analysis;
- Financial implications of increased monitoring, particularly on-line monitoring;
- Inadequate or absent evaluation of data;
- Changing the attitude of staff members who are used to monitoring in a certain way;
- Ensuring that resources are available to the operations department to carry out corrective actions.

Outputs

1. An assessment of the performance of control measures at appropriate time intervals.
2. Establishment of corrective actions for deviations that may occur.

Example/tool 6.1: Checklist of factors to be considered when establishing a monitoring programme for the control measures

- ☑ Who will do the monitoring?
- ☑ How frequently will the monitoring be done?
- ☑ Who will analyse the samples?
- ☑ Who will interpret the results?
- ☑ Can the results be easily interpreted at the time of monitoring or observation?
- ☑ Can corrective actions be implemented in response to the detected deviations?
- ☑ Has the list of hazardous events and hazards been checked against monitoring or other appropriate criteria to ensure that all significant risks can be controlled?

* Note: often verification monitoring (see Module 7) will be the compliance monitoring required by regulatory or government bodies in which case parameters and monitoring frequencies will be specified as part of compliance.

Example/tool 6.2: Corrective actions

A corrective action(s) should be identified for each control that will prevent contaminated water being supplied if monitoring shows that the critical limit has been exceeded. Such events may be: non-compliance with operational monitoring criteria, inadequate performance of a sewage treatment plant discharging to source water, extreme rainfall in a catchment, or spillage of a hazardous substance. Examples of corrective actions include the use of alarms and auto-shutdown mechanisms, or switching to an alternative water source during a period of non-compliance (allowing the operator time to bring the supply back into compliance). Risks associated with use of the alternative source should be identified and addressed within the overall WSP framework.

Example/tool 6.3: Checklist of issues to consider for devising corrective actions

- ☑ Have corrective actions been documented properly, including assigning responsibilities for carrying out the actions?
- ☑ Are people correctly trained and appropriately authorised to carry out corrective actions?
- ☑ How effective are the corrective actions?
- ☑ Is there a review process in place for analysing actions to prevent recurrence of the need for a corrective action?

A48235836

Example/tool 6.4: Long- and short-term monitoring requirements and corrective actions

Process step/Control measure	Critical limit	What	Where	When	How	Who	Corrective action
Source: Control of development in catchment (example of long-term monitoring)	<1 septic tank per 40 ha and none within 30 m of watercourse	Council planning approvals	Council offices Site inspection	Annually	On site at council	Catchment/ Watershed Liaison Officer	Seek removal of septic system through planning tribunal
	Fencing out of all juvenile cattle from riparian or unfenced paddocks	Farm management practice audits	Dept of Agriculture Site Inspection	Annually	On site at Dept of Agriculture	Catchment/ Watershed Liaison Officer	Meet with landholder in breach and discuss incentive programme
Treatment: Chlorination at water treatment plant (example of short-term monitoring)	Chlorine concentration leaving plant must be >0.5 and <1.5 mg/l	Disinfectant residual	At entry point to distribution system	On-line	Chlorine analyser	Water Quality Officer	Activate chlorine non-compliance protocol
Etc. ↴							

A48235836

Case study 1: Australia

Field Experience 6.1 – identifying and monitoring critical control measures

Most control measures identified as 'critical' were assigned as 'critical control points' and were monitored against 'critical limit' criteria. In most cases, critical limits were monitored on-line with automated control in response to adverse results, and/or telemetry alarms being sent to 24-hour call centres and duty operators. In most cases such systems were in place prior to the use of WSPs, but WSPs provided a forum to review and upgrade these systems. Typically, the critical limits set related to filtered water turbidity, chlorine residual, post primary disinfection and maintenance of water pressure in distribution as measured indirectly by tank levels and pump pressures. In addition, many utilities formalized scheduled monitoring and inspection procedures for source waters and for assets such as water tanks. Procedures for sanitary working practices when repairing and installing water mains were often captured as key control measures and were sometimes classified as critical control points. Backflow prevention systems were usually given a renewed priority with WSPs and most utilities with WSPs had active programmes to enforce backflow prevention with various standards depending on the risk posed by the site being served with water.

Field Experience 6.2 – operational monitoring of treatment processes

Operational monitoring of treatment processes was usually fully instrumented using on-line calibrated instruments linked to SCADA systems (a computer system used to monitor and control a process). Alarm levels were typically set to provide an early warning as well as an emergency trigger. Alarms usually called system operators to attend the plant and often started automated processes to stop supplying water into the treated water storage. In practice, the automated monitoring systems required a lot of work due to problems with selecting reliable instruments and reliable control systems. However, most utilities persevered until the systems were sufficiently reliable and are continuing to improve these systems into the future as their WSPs mature. Most systems were designed to have multiple triggers to avoid ever supplying untreated water. For instance, systems often automatically shut down or switched to standby systems, and usually there were early warning alarms that would provide time for problems to be fixed before they affected the customers.

Field Experience 6.3 – operational monitoring along the distribution network

The process of maintaining continuous and quite high pressure to the whole distribution system at all times is well-established in Australian urban centres. Although taken for granted, the maintenance of positive pressure provides a highly effective water quality control which is monitored through water tank level sensors and pressure transducers at key points in the distribution network. Most systems have exceptionally reliable pressurization throughout the network with telemetered, SCADA linked alarms to alert system operators if pressures at any pump station or water levels at any service reservoir start to drop below critical levels. If areas of low pressure are identified through customer notifications, engineering or operational solutions are implemented as low or no pressure at customer supply points is not tolerated. In some isolated areas drought-related water restrictions led to unprecedented peak flows and low pressure events in elevated areas when all properties watered their gardens at once during restricted watering hours. Alternate odd and even property number watering arrangements have been used to alleviate this effect. Legally, the maintenance of sufficient pressure at all times

is a service standard requirement of all large urban Australian water suppliers. Water tanks and pump stations are typically monitored regularly and are usually fully enclosed, roofed, secured and vermin-proofed. Disinfectant residual monitoring within the network is increasingly being automated but is not as reliably maintained and managed as pressure. Most distribution systems have significant proportions of the system that are routinely without an effective disinfectant residual. However, the reliable pressurization means that in most cases this is not considered a health issue and the situation is widely tolerated. Some systems with WSPs do not even provide a disinfectant residual and use UV-only disinfection. In very warm climates with long pipelines, disinfectant residuals are routinely monitored and maintained to prevent bacterial growth in the distribution systems. Testable backflow prevention devices that protect water supplies from high and medium hazard connections are usually tested annually and the utility usually keeps records of these tests and actively follows up failure to report successful test results.

Case study 2: Latin America and the Caribbean (LAC)

Field Experience 6.1 – identifying and monitoring critical control measures

For the key control measures that addressed the hazards identified in Module 3, a monitoring plan was established that indicated an acceptable operational range for each parameter, designated appropriate monitoring locations, established a schedule for frequency of monitoring, and assigned responsible parties. Corrective actions to be taken in the event that monitoring reveals a parameter to be outside of the acceptable range were also established. The monitoring of critical control measures (operational monitoring) facilitated the identification by plant operators and managers of probable causes of non-compliance that may be identified through compliance monitoring.

Field Experience 6.2 – operational monitoring of treatment processes

The WSP team identified coagulation/flocculation/sedimentation, filtration and chlorination as critical control measures to be monitored. To gauge coagulation efficacy, regular measurement of turbidity at the outlet of the sedimentation basin was established. To monitor the efficacy of filtration, turbidity was again measured after filtration; and to gauge chlorine dosing efficacy, chlorine residual was measured at the point of entry to the distribution system. Monitoring at the plant was done by the utility plant operators and results were shared monthly with the utility managers, or immediately if found to be outside of established parameters. Prior to the WSP, these critical control measures were rarely measured or recorded. Because records were not reviewed and plant operators did not receive feedback, they saw little value in maintaining and submitting monitoring records. A schedule for distributing reports of utility operations from each of the treatment plants was established. Providing feedback increased plant operator accountability and adherence to protocol and informed them of any changes or concerns related to water quality.

Field Experience 6.3 – operational monitoring along the distribution network

Insufficient water pressure within the distribution system caused by leaky pipes and unauthorized connections, led to inconsistent water service and the introduction of microbial and chemical contamination. Maintaining water pressure was therefore identified as a critical control measure. Pressure gauges were installed at strategic points along the distribution network, an

A48235836

operator monitoring and recording plan was established, and monitoring records were reviewed monthly by utility managers. This system of increased operator awareness and supervisory oversight improved accountability and adherence to protocol and ensured that operators were better informed of pressure conditions that required immediate corrective action.

Case study 3: United Kingdom (England and Wales)

Field Experience 6.1 – developing a clear operational monitoring strategy

Operational monitoring was a normal and extensive part of the water companies' procedures and had been generally included and reviewed as part of the WSP implementation. A benefit of WSPs is that the methodology requires a clear operational monitoring strategy with defined responsibilities to consider its relevance to the safe production and distribution of drinking-water and for how it is programmed and assessed. This overcomes the tendency to carry out irrelevant tests.

Module 7

Verify the effectiveness of the WSP

A48235836

Introduction

Having a formal process for verification and auditing of the WSP ensures that it is working properly. Verification involves three activities which are undertaken together to provide evidence that the WSP is working effectively. These are:

- Compliance monitoring;
- Internal and external auditing of operational activities;
- Consumer satisfaction.

Verifi cation should provide the evidence that the overall system design and operation is capable of consistently delivering water of the specified quality to meet the health-based targets. If it does not, the upgrade/improvement plan should be revised and implemented.

Key actions

Compliance monitoring

All the control measures should have a clearly defi ned monitoring regime validating effectiveness and monitoring performance against set limits. The water supply organization should expect to fi nd results from verifi cation monitoring that are consistent with the water quality targets. Corrective action plans need to be developed to respond to, and understand the reasons for, any unexpected results. Verification monitoring frequencies will depend on the level of confidence required by the water supply organization and its regulatory authorities. The monitoring regime should include a review at intervals and at times of planned or unplanned changes in the supply system.

Internal and external auditing of operational activities

Rigorous audits help to maintain the practical implementation of a WSP, ensuring that water quality and risks are controlled. Audits may involve internal review and external review by regulatory authorities or by qualified independent auditors. Auditing can have both an assessment and a compliance-checking role. The frequency of audits for verifi cation will depend on the level of confi dence required by the water supply organization and its regulatory authorities. Audits should be undertaken regularly.

Consumer satisfaction

Verification includes checking that consumers are satisfied with the water supplied. If they are not, there is a risk that they will use less safe alternatives.

Typical challenges

- Lack of capable external auditors for WSPs;
- Lack of qualified laboratories to process and analyse samples;
- Lack of human and financial resources;
- Lack of knowledge of consumer satisfaction or complaints.

Outputs

1. Confirmation that the WSP itself is sound and appropriate.
2. Evidence that the WSP is being implemented in practice as intended, and working effectively.
3. Confirmation that water quality meets defined targets.

Example/tool 7.1: Parameters that might be included in routine verification monitoring programmes

For microbial water quality verification, indicator organisms are generally monitored. The most widely used verification system is to use the faecal indicator bacteria *E. coli* or thermotolerant coliforms at representative points in the water supply system. Other indicators may be more appropriate to verify that water is free from viral or protozoan faecal pathogens. Use of other tools, such as heterotropic plate counts, or *Clostridium perfringens* may be used for operational and investigative monitoring in order to better understand the water supply system.

Verification for chemical parameters is carried out by their direct measurement, rather than through the use of an indicator. Most chemical hazards are unlikely to occur at acutely hazardous concentrations and verification frequencies (often quarterly or sometimes biennially) might be less than those used for microorganisms.

Quantitative and qualitative taste and odour may be monitored to ensure the condition of the distribution network and consumer installations.

Example/tool 7.2: Checklist of factors to be considered when establishing a routine verification monitoring programme. (A utility-led verification programme can provide an additional level of confidence, supplementing regulations which specify monitoring parameters and frequencies.)

- ☑ Where appropriate, draw up a verification monitoring programme in accordance with regulatory requirements;
- ☑ Identify appropriate personnel to perform monitoring functions;
- ☑ Establish a system of communication between monitoring staff;
- ☑ Identify appropriate analysts;
- ☑ Ensure appropriate monitoring points are chosen;
- ☑ Ensure monitoring frequency is appropriate;
- ☑ Ensure results are interpreted and unusual or failing results are investigated;
- ☑ Establish a system to ensure the routine reporting of results to the appropriate regulator.

A48235836

Example/tool 7.3: Auditing the WSP itself and the implementation of the WSP

In addition to analysis of the water quality, verification should also include an audit of the WSP and of the operational practice to show good practice and compliance. Auditors will identify opportunities for improvement such as areas where procedures are not being followed properly, resources are insufficient, planned improvements are impractical, or where training or motivational support is required for staff.

When conducting audits, it is essential that the auditor has a detailed knowledge of the delivery of drinking-water and that procedures, not just records, are witnessed in person. Records may not always be factually correct and in some cases, equipment that has been shown to be working through the records may not be working in practice and can lead to unsafe water and waterborne disease outbreak.

Example/tool 7.4: Checklist of factors to consider to ensure all appropriate information is obtained during an audit

- ☑ All feasible hazards/events are taken into account;
- ☑ Appropriate control measures have been identified for each event;
- ☑ Appropriate monitoring procedures have been established;
- ☑ Critical limits for each control measure are set;
- ☑ Corrective actions have been identified;
- ☑ A system of verification has been established.

Example/tool 7.5: Operational monitoring and verification monitoring plan (from Jinga, Uganda)

Unit process	Operational monitoring (see Module 6)			Verification monitoring		
	What	When	Who	What	When	Who
Treatment works	On-line measurement – pH – Chlorine	Daily	Water treatment operators / Analyst	*E. coli*	Weekly	Analyst
				Enterococci	Weekly	
				Record audit	Monthly	
	Jar testing records	Weekly				
	Turbidity	Daily				
	Dosing records	Monthly				
Distribution system	pH	Weekly		*E. coli*	Monthly	
	Turbidity	Weekly				
	Chlorine	Weekly		Turbidity	Monthly	
	Sanitary inspection	Weekly		Enterococci	Monthly	
Etc. ↴						

Case study 1: Australia

Field Experience 7.1 – compliance monitoring

Water utilities had typically made no significant changes to their verification monitoring as part of the introduction of WSPs. In general, this area was a strong focus of regulation in water supply for many decades prior to the advent of WSPs. Both monitoring of customer satisfaction and water quality testing were already well established processes, with data being publicly reported. WSPs have changed the focus to prevention and improved operational monitoring, but have not significantly affected verification monitoring. The major change has been to reposition customer complaint monitoring and water quality testing as 'verification monitoring'. Another effect of WSPs has been to recast verification testing as after-the-fact confirmation whereas in the past verification activities were often the focus of water quality management.

Field Experience 7.2 – creating systems for internal and external auditing

One of the major changes introduced with WSPs has been the auditing of water quality management. Internal, and increasingly external, auditing is becoming commonplace with most Australian water utilities now being audited at roughly annual intervals by external auditors. Within the past year a new drinking-water quality management auditing system had been set up, together with a growing pool of specialist auditors. There has been some opposition to external auditing from many utilities but regulators are increasingly requiring it as part of their oversight roles.

Field Experience 7.3 – selecting appropriate regulatory standards

Each jurisdiction (state and territory) has introduced or is developing a requirement for its major public water utilities to have WSPs. Victoria was the first through its Safe Drinking Water Act 2003 and other states have introduced or are introducing the same requirements through acts, regulations or licences. It is likely that by 2015 all public urban water utilities in all states and territories of Australia will have implemented WSPs that are subject to regulatory audit. The first regulatory audits took place in Victoria in 2008, allowing some time between the Act and the point at which compliance was required. Other states and territories are following this lead.

Case study 2: Latin America and the Caribbean (LAC)

Field Experience 7.1 – developing a compliance monitoring plan

When the utility's water quality monitoring records were collected and reviewed to assess the current state of the piped water supply (see LAC Field Experience 2.2), it became clear that the utility's protocol for testing, recording and reporting finished water quality was not consistently followed by operators. Lapses in data collection were common and the body of data that did exist had never been systematically compiled and reviewed to ensure compliance with water quality standards and to inform operational decisions. Additionally, the majority of samples had been processed at a remote laboratory and the results were never reported back to operators, denying them important feedback on plant operations. These deviations from protocol were attributed to the limited availability of personnel to perform the testing and analyse results; the cost of transporting samples to the remote laboratory; a shortage of necessary testing reagents; and a lack of accountability (both internal and external). The WSP team agreed that addressing these barriers should be given top priority as knowledge of the quality of water being produced is fundamental to safe water provision. The compliance monitoring plan was revised to include detailed guidance on data collection, recording, compilation and analysis, and operator feedback reporting. The revised monitoring plan also describes internal actions to be taken when results indicate non-compliance with water quality standards.

Field Experience 7.2 – creating systems for internal and external auditing

When the WSP process began, there was no formal system in place for internal and external auditing of water quality or utility operations and management practices. The result was a lack of accountability within the utility and routine disregard for established procedures. To address these issues, the utility developed a plan to submit monthly water quality reports (created as part of the compliance monitoring plan described in LAC Field Experience 7.1) to senior management within the utility and to the Ministry of Health. This internal and external reporting of water quality records is expected to encourage consistent compliance monitoring and to facilitate regulatory oversight. In order to ensure that the other key procedures outlined in the WSP are also consistently followed, the utility worked with the Ministry of Health to develop an additional, more comprehensive internal and external WSP auditing plan. The more comprehensive plan involves semi-annual internal reviews with senior utility management and annual external reviews with the Ministry of Health. While the entire WSP is subject to review during these audits, the key focus areas are the standard operating procedures (including operational monitoring and compliance monitoring plans), operator training programmes, and action plans to address high-priority hazards. In addition to improving adherence to established plans and procedures, these audits are expected to improve communication both within the utility and between the utility and the regulatory body.

Case study 3: United Kingdom (England and Wales)

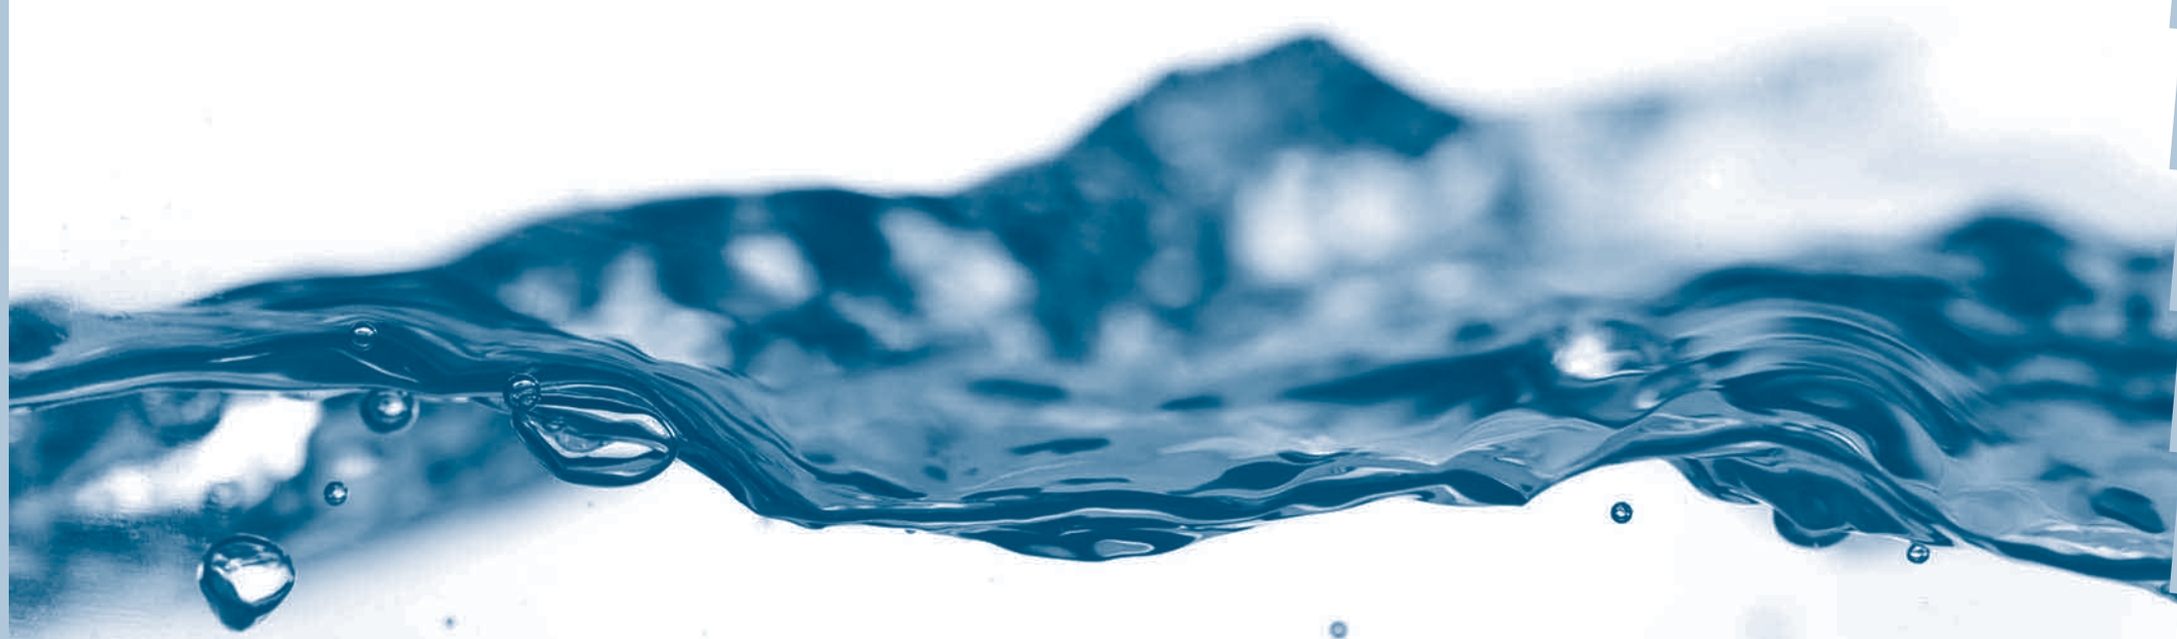
Field Experience 7.1 – verification through compliance and audits

Generally, verification of the effectiveness of the WSP approach is through compliance with regulatory requirements for drinking-water quality, treatment and use of chemicals and materials.

The regulator of drinking-water quality will be the WSP external auditor. It does not anticipate normally auditing a company's WSPs in their entirety but particular elements of the WSP will feature in its other audits including compliance assessment, sample audit trails, incident investigations, site inspections, consumer complaints and stakeholder liaison.

A48235836

A48235836



Module 8

Prepare management procedures

A48235836

Introduction

Clear management procedures documenting actions to be taken when the system is operating under normal conditions (Standard Operating Procedures or SOPs) and when the system is operating in 'incident' situations (corrective actions) are an integral part of the WSP. The procedures should be written by experienced staff and should be updated as necessary, particularly in light of implementation of the improvement/upgrade plan and reviews of incidents, emergencies and near misses. It is preferable to interview staff and ensure their activities are captured in the documentation. This also helps to foster ownership and eventual implementation of the procedures.

Key actions

Documentation of all aspects of the WSP is essential. Management procedures are the actions to be taken during normal operational conditions, and detail the steps to follow in specific 'incident' situations where a loss of control of the system may occur. Management staff have a responsibility to ensure procedures are kept up to date and in place to keep operators and management staff connected and involved, to make it easy for people to 'do the right thing', to provide adequate resources and to ensure that people are willing to come forward instead of withholding information for fear of reprisals. An effi cient, regular review and updating cycle is also important.

If monitoring detects that a process is operating outside of the specifi cations of the critical or operational limits, there is a need to act to restore the operation by correcting the deviation. An important part of the WSP is the development of corrective actions which identify the specific operational response required following deviations from the set limits.

Unforeseen events/incidents or deviations may occur for which there are no corrective actions in place. In this case, a generic emergency plan should be followed. This would have a protocol for situation assessment and identification of situations that require activation of the emergency response plan. It is also important that near misses are assessed as they could be an indicator of a likely future emergency.

Following an emergency, an investigation should be undertaken involving all staff to discuss performance, assess if current procedures are adequate, and address any issues or concerns. Appropriate documentation and reporting of the emergency should also be established. Review of the cause of the emergency or near miss and the response to it may indicate that amendments to existing protocols, risk assessments and the WSP are necessary (see Module 11).

Typical challenges

- Keeping the procedures up to date;
- Ensuring that staff are aware of changes;
- Obtaining information on near misses.

Example/tool 8.1 gives a general outline that can be used to start the development of a list of SOPs that would be typical for a water utility operation. It is impossible to list all the SOPs a facility would require due to the varying nature of the processes at each facility. The SOPs can be prioritized and once documented, additional SOPs can be developed as needed and added to the documentation. The SOP should be developed in a way that allows for revisions as required.

Outputs

Management procedures for normal and incident/emergency conditions which address:

- Response actions;
- Operational monitoring;
- Responsibilities of the utility and other stakeholders;
- Communication protocols and strategies, including notifi cation procedures and staff contact details;
- Responsibilities for coordinating measures to be taken in an emergency;
- A communication plan to alert and inform users of the supply and other stakeholders (e.g. emergency services);
- A programme to review and revise documentation as required;
- Plans for providing and distributing emergency supplies of water.

A48235836

Example/tool 8.1: Typical Standard Operating Procedures for a water utility

Category	Sub-category	Standard Operating Procedure
Facility operations overview	General tasks/information	Daily rounds Site security Record keeping Reporting procedures Cross contamination prevention for operators
	Sampling	Sampling procedure
	Emergency response	Power failure
Intake and pre-treatment	Raw water	Valve operation Screening
	Flow measurement	Meter calibration
	Pump operation	Switching duty pump operation Increasing/decreasing pumping operation
Dosing procedure		
Disinfection procedure		
Etc.		

If monitoring detects that there is a deviation from an operational or critical limit, corrective actions need to be applied.

Example/tool 8.2: Checklist of management procedures (or corrective actions) to deal with incidents

- ☑ Accountabilities and contact details for key personnel and other stakeholders;
- ☑ Clear description of the actions required in the event of a deviation;
- ☑ Location and identity of the SOPs and required equipment;
- ☑ Location of back-up equipment;
- ☑ Relevant logistical and technical information.

A48235836

Quality control procedures should also be recorded for as many aspects of the WSP as possible. All measurements of control measures, for example, should be subject to appropriate quality control procedures, such as internal and external analytical control within laboratories. (Note that this could also be dealt with as a 'supporting programme'.)

Example/tool 8.3: Checklist of characteristics and systems relating to people management which will facilitate ongoing success of the WSP

- ☑ Choosing meaningful parameters on which to report;
- ☑ Having a well-defined and efficient failure reporting system;
- ☑ Including higher-level management in reporting so they are involved in events;
- ☑ Designing 'respected' audits that target likely areas of complacency that lead to adverse consequences;
- ☑ Observing the 'no blame' model where failure is shared by system participants;
- ☑ Having a widely accessible mechanism for presenting improvement opportunities, risk analysis and interpretation and for challenging existing practices;
- ☑ Ensure that all procedures are signed off at senior level. This is an important part of the continuous improvement mechanism.

Example/tool 8.4: Emergency management procedures

During an emergency it may be necessary either to modify the treatment of existing sources or temporarily use an alternative water source. It may be necessary to increase disinfection at the source or to additionally disinfect (e.g. rechlorinate) during distribution. Procedures for such an emergency situation should be documented.

Example/tool 8.5: Checklist of key areas to be addressed in emergency management procedures

- ☑ Response actions, including increased monitoring;
- ☑ Responsibilities and authorities internal and external to the organization;
- ☑ Plans for emergency water supplies;
- ☑ Communication protocols and strategies, including notification procedures (internal, regulatory body, media and public);
- ☑ Mechanisms for increased public health surveillance;
- ☑ Emergency procedure should be practiced regularly.

A48235836

Case study 1: Australia

Field Experience 8.1 – developing standard operating procedures (SOPs)

In general, the Australian water supply industry was fairly informal with limited formal procedures and documentation. Therefore, most WSPs include some associated additional documentation. The lack of formality partly reflected the long careers and extensive experience of most water supply operators, making written procedures less important than the body of experience and hands-on training. In general, the procedures that have been developed for the Australian WSPs are concise statements of what is required to be achieved rather than detailed procedures for how to achieve those objectives. Generally, there is a reliance on training and operator experience and discretion rather than on following documented procedures. However, where large parts of utility operations are outsourced to contractors, most authorities have developed detailed procedures against which contractor activity can be measured and assessed.

Case study 2: Latin America and the Caribbean (LAC)

Field Experience 8.1 – developing standard operating procedures (SOPs)

The WSP team agreed that SOPs would be a critical focus area during the development of the WSP. The treatment plant operators and distribution system maintenance personnel had no reference document to inform and guide day-to-day operations. Operational guidance took the form of verbal instruction from supervisors and was often incomplete and poorly understood. The lack of thorough, clearly defined operating procedures was recognized as a major barrier to safe water provision and was also believed to adversely impact engagement and morale among utility personnel. Considerable time and energy was therefore invested in the development of SOPs. The utility's system-specific SOPs were created by adapting SOPs for another system in the region to the utility's own infrastructure, institutional framework, priorities and constraints. The SOPs contain information on key physical, chemical and microbial contaminants of concern and the role of each treatment process in their removal or inactivation. The SOPs also contain guidance on the optimization of treatment plant operations, such as determining the most effective pH and aluminum sulfate dose for coagulation; recognizing filter backwash and media replacement indicators; and ensuring sufficient chlorine dose and contact time for pathogen destruction. The control measure monitoring plan and the compliance monitoring plan (see LAC Field Experience 6.1 and 7.1) are also important components of the SOPs.

Field Experience 8.2 – delaying emergency response plans due to resource constraints

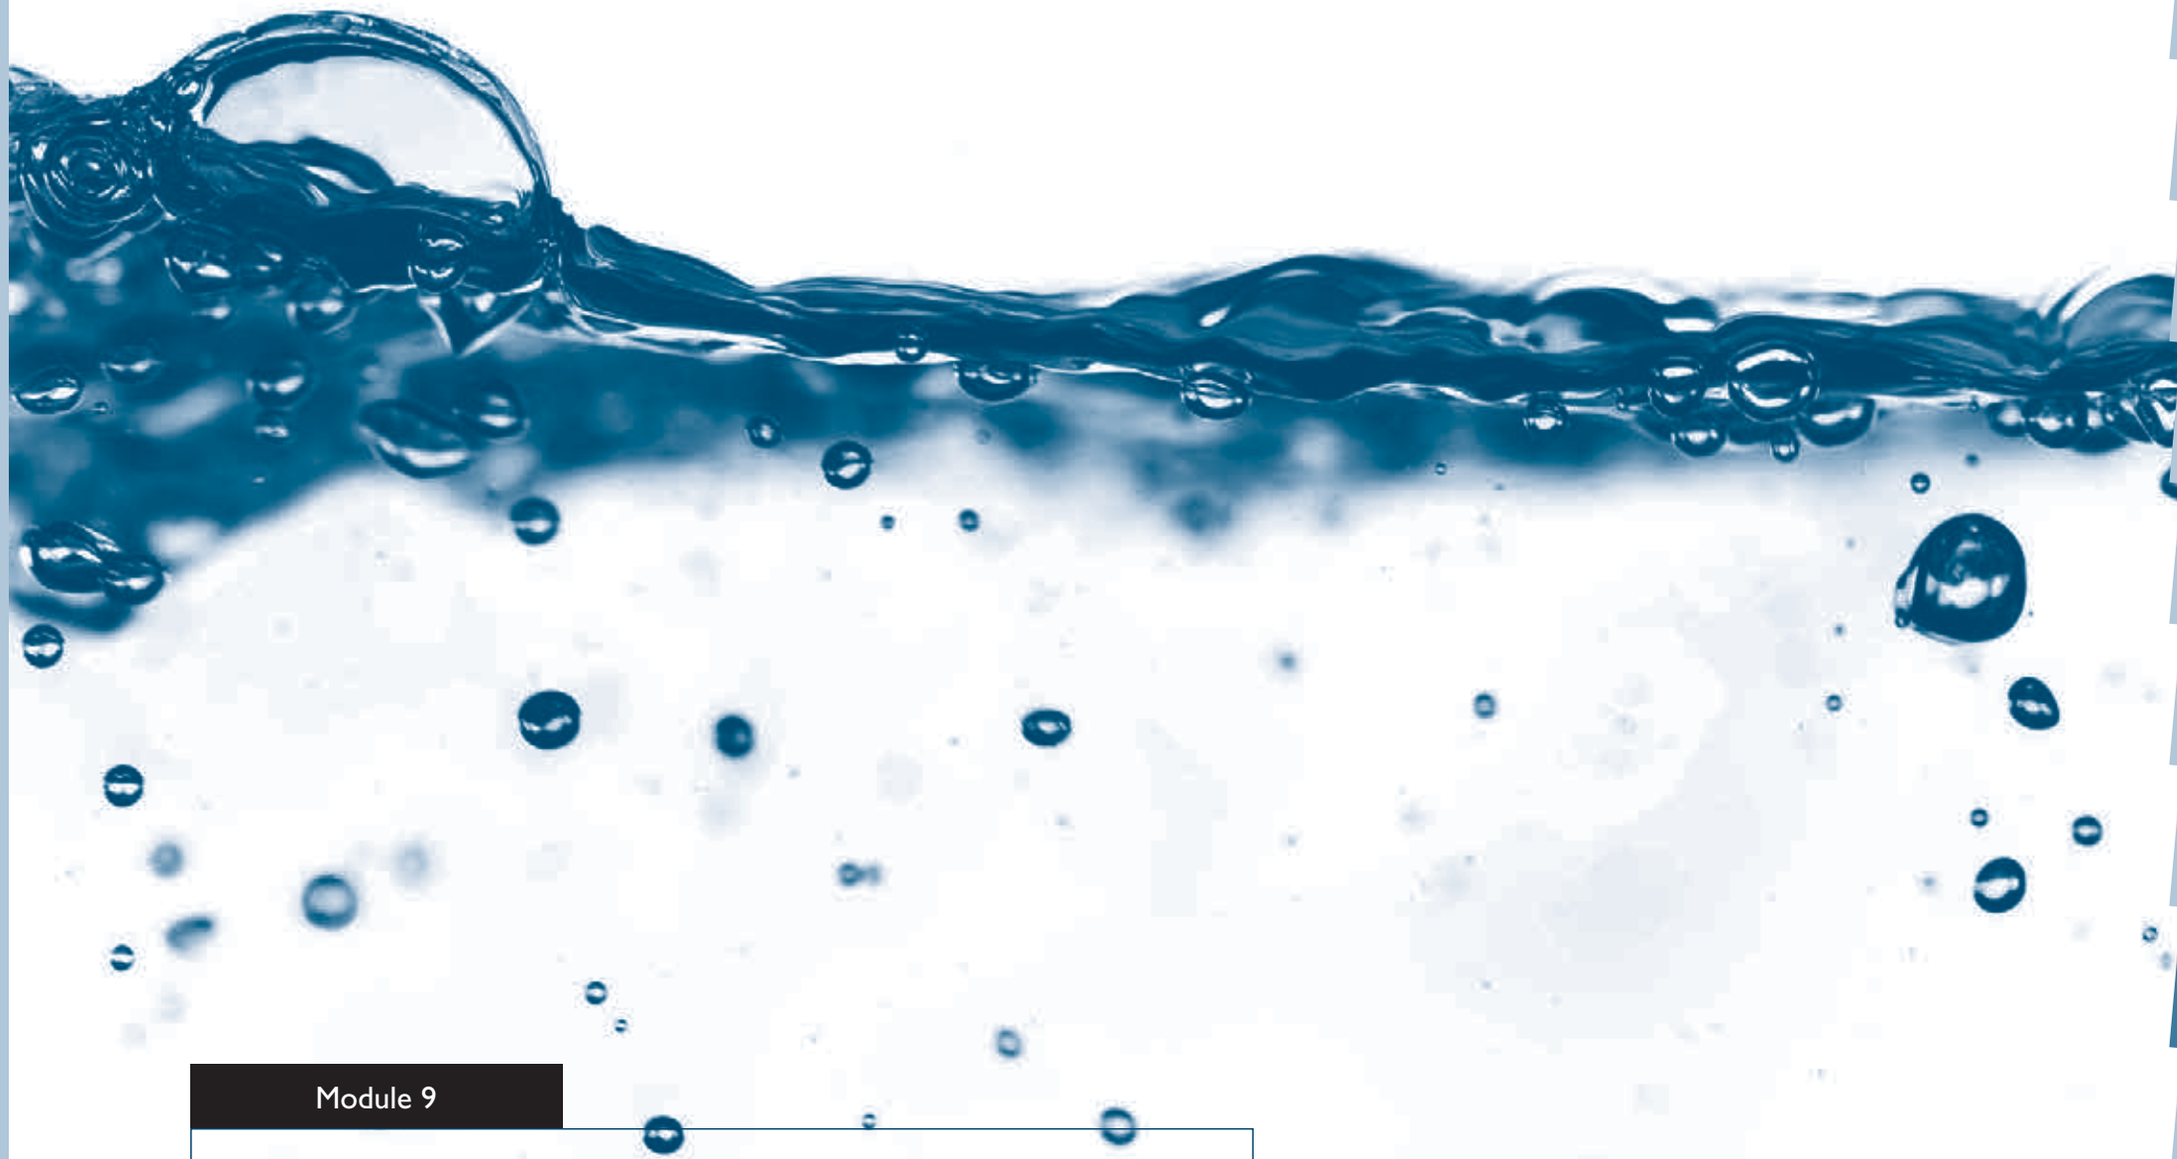
The WSP team made the decision not to develop a formal incident/emergency response plan during the first iteration of WSP development in favor of focusing efforts elsewhere. Team members simply did not have sufficient time in their schedules to address each task recommended in the Manual in a meaningful way, so prioritization was necessary. Because the utility's operations were such that noncompliance with most water quality standards was the rule rather than the exception, the water system was effectively in a constant state of emergency. Consumers were under a continuous boil-water advisory and a system was in place to reinforce the ongoing advisory with additional public service announcements by the Ministry of Health whenever sampling revealed particularly poor water quality. While the WSP team members recognized opportunities to enhance the basic response plan, they determined that the water system would be best served by focusing limited resources on improving water quality.

As improvements to water quality are realized through WSP interventions and further experience, the utility will address gaps in the response plan during subsequent revisions of the WSP (see LAC Field Experience 10.1).

Case study 3: United Kingdom (England and Wales)

Field Experience 8.1 – revising procedures to incorporate WSP outputs

Water companies already had good management and SOPs. The challenge was to modify these in line with the outputs of the WSP and to consider such procedures as part of the WSP.



Module 9

Develop supporting programmes

A48235836

Introduction

Supporting programmes are activities that support the development of people's skills and knowledge, commitment to the WSP approach, and capacity to manage systems to deliver safe water. Programmes frequently relate to training, research and development. Supporting programmes may also entail activities that indirectly support water safety, for example those that lead to the optimization of processes, like improving quality control in a laboratory. Programmes may already be in place, but are often forgotten or overlooked as important elements of the WSP. Examples of other activities include continuing education courses, calibration of equipment, preventive maintenance, hygiene and sanitation, as well as legal aspects such as a programme for understanding the organization's compliance obligations. It is essential that organizations understand their liabilities and have programmes in place to deal with these issues.

Key actions

- Identify the supporting programmes needed for implementing the WSP approach;
- Review, and as necessary, revise existing supporting programmes;
- Develop additional supporting programmes to address gaps in staff knowledge or skills that may impede the timely implementation of the WSP.

Typical challenges

- Human resources;
- Equipment;
- Financial resources;
- Support of management;
- Not identifying procedures and processes as part of the WSP.

Outputs

Programmes and activities that ensure that the WSP approach is embedded in the water utility's operations.

Supporting programmes include training of appropriate staff in all aspects of preparing and implementing the WSP, quality control procedures such as internal and external analytical quality control within laboratories, and research and development programmes to support long-term solutions.

Example/tool 9.1: Reviewing existing programmes

In developing supporting programmes, it may not always be necessary to develop new programmes. Organizations should assess the programmes that are currently in place to identify any gaps that need to be addressed including updates of existing programmes.

All procedures should be documented and dated to ensure that staff follow the most recent version.

Example/tool 9.2: Types of supporting programmes that could be included in the WSP

Programme	Purpose	Examples
Training and awareness	To ensure organization (and contractor) personnel understand water safety and the influence of their actions.	WSP training Competency requirements Induction training Hygiene procedures
Research and development	To support decisions made to improve or maintain water quality.	Understanding potential hazards Research into better indicators of contamination
Calibration	To ensure that critical limit monitoring is reliable and of acceptable accuracy.	Calibration schedules Self-calibrating equipment
Customer complaint protocol	To ensure that customers are responded to if water quality questions are raised.	Call centre Complaints training
Etc. ↴		

A48235836

Case study 1: Australia

Field Experience 9.1 – operator training programmes

In the past there have been limited formal training opportunities and requirements for water supply system operators and managers with most training being provided on the job. However, at present, regulators are driving more formalized training, competency assessments and qualifications and are working on developing training and assessment packages for the Australian water industry. WSPs invariably place a high prominence on training and experience as a supporting programme, but to date, this has been typically relatively informal.

Field Experience 9.2 – calibration and maintenance

Asset management programmes were typically well established within Australian urban water utilities. In general, key civil assets were well maintained and assessed. One area that has improved with the advent of WSPs is the maintenance of process assets and calibration of monitoring equipment. WSPs have driven more detailed review and often resulted in upgrades of how process assets are maintained and of how monitoring devices are calibrated and maintained.

Case study 2: Latin America and the Caribbean (LAC)

Field Experience 9.1 – developing an operator training programme

The utility did not have a formal operator training programme and poorly trained operators were considered among the highest-priority threats to water quality. Training had not been offered in many years and considerable operator turnover had taken place since. Further, past training sessions had been conducted by external experts and in-house capacity had not been developed to address future training needs. The WSP team therefore developed an operator training programme with a focus on sustainability. A senior utility manager was identified as the training lead and a number of utility personnel were selected as trainers. The training lead designed and conducted a 'training of trainers' course, drawing heavily from the material contained in the SOPs (see LAC Field Experience 8.1). An external consultant contributed additional expertise on optimizing system operations and effective troubleshooting techniques. The consultation and the utility's subsequent hands-on experience are expected to build sufficient capacity within the utility to preclude the need for external support in the future. Upon completion of the 'training of trainers' course, the trainers and the training lead designed the operator training course. The full operator training course will be held every three years and each time there is operator turnover. A simplified refresher course will be held annually.

Field Experience 9.2 – improving surveillance monitoring

The WSP team identified surveillance monitoring as an important factor in safe water provision as it provides public assurance and demonstrates due diligence. A review of multiple years of surveillance monitoring records (performed as part of the existing conditions assessment described in LAC Field Experience 2.2) revealed that the Ministry of Health had not consistently performed monthly water quality sampling in the distribution system as required by protocol. On occasions when surveillance monitoring was carried out, findings were not shared with the utility. Instead, utility personnel learned of unacceptable surveillance results alongside their consumer base via public service announcements. The WSP team also learned that surveillance officers had never been formally trained in appropriate microbial sampling techniques, causing the utility to routinely challenge the validity of surveillance results and further contributing to poor

relations between the utility and surveillance officers. To address these concerns, the surveillance monitoring plan was enhanced to include a system of timely communication of results with the utility as well as surveillance officer training on sampling techniques, appropriate sampling locations and key parameters of interest. Senior officials within the Ministry of Health were engaged in the surveillance plan improvement process to ensure follow-through and accountability.

Field Experience 9.3 – increasing cost recovery

Cost recovery was identified as a critical WSP focus area given that effective utility operation is contingent upon a sufficient revenue stream. Existing revenue was well below full cost recovery and even with government subsidies the utility did not have adequate funds to meet basic operational needs such as staffing, purchasing treatment chemicals and testing reagents, replacing filter media, and maintaining equipment. The utility was also unable to afford the high cost of pumping 24 hours a day – a constraint with major implications for water quality and consumer health. Daily breaks in service of eight hours or more made the water supply vulnerable to recontamination by creating routine low-pressure conditions in the distribution network and by giving consumers no option but to store water at home. Poor cost recovery was attributed in part to an ineffective system of billing and collections. Additionally, poor water quality and intermittent service affected consumers' willingness to pay for water (as evidenced by the household survey findings discussed in LAC Field Experience 2.3). The WSP team developed a plan to expedite the utility's ongoing efforts to revamp the billing system and created a public relations strategy to improve consumer-utility relations and increase willingness to pay.

Case study 3: United Kingdom (England and Wales)

Field Experience 9.1 – revising supporting programmes to incorporate WSP outputs

This area was not a significant challenge for water companies as they already had good supporting programmes such as training programmes, hygiene procedures, ISO quality systems, accredited laboratories with internal and external quality control programmes and company and collaborative industry research and development. The challenge was to consider and include such supporting programmes as part of the WSP.

A48235836

Module 10

Plan and carry out periodic review of the WSP

A48235836

Introduction

The WSP team should periodically meet and review the overall plan and learn from experiences and new procedures (in addition to regularly reviewing the WSP through analysis of the data collected as part of the monitoring process). The review process is critical to the overall implementation of the WSP and provides the basis from which future assessments can be made. Following an emergency, incident or near miss, risk should be reassessed and may need to be fed into the improvement/upgrade plan.

Key actions

Keep the WSP up to date

Regularly reviewing and revising the WSP ensures that new risks threatening the production and distribution of safe water are regularly assessed and addressed. An updated, relevant WSP will maintain the confidence and support of staff and stakeholders in the WSP approach.

A WSP can quickly become of out of date through:

- Catchment, treatment and distribution changes and improvement programmes, which can impact on process diagrams and risk assessments;
- Revised procedures;
- Staff changes;
- Stakeholder contact changes.

Convene regular WSP review meetings

The WSP team should agree to meet regularly to review all aspects of the WSP to ensure that they are still accurate. Local operator input or site visits may also be required as part of the review. Operational monitoring results and trends should be assessed. In addition to the regular planned review, the WSP should also be reviewed when, for example, a new water source is developed, major treatment improvements are planned and brought into use, or after a major water quality incident (see also Module 11). During the regular review meeting, the date of the next review should be established.

Typical challenges

- Reconvening the WSP team;
- Ensuring continued support for the WSP process;
- Ensuring that where original staff have left the utility, their duties are maintained by others;
- Keeping records of changes;
- Keeping in contact with stakeholders.

Outputs

A WSP that is up to date and continues to be appropriate to the needs of the water utility and stakeholders.

Example/tool 10.1: When to review the WSP

A WSP should be reviewed immediately when there is a significant change of circumstances or a problem within the water supply chain. A WSP should also be reviewed from time to time, particularly taking into account the results of implementing the WSP. Any change made to the WSP as a result of a review should be documented.

Example/tool 10.2: Example checklist for WSP review

- ☑ Notes of last review meeting;
- ☑ Notes of any interim review;
- ☑ Changes to membership of the WSP team;
- ☑ Changes in catchment, treatment, distribution;
- ☑ Review of operational data trends;
- ☑ Validation of new controls;
- ☑ Review of verification;
- ☑ Internal and external audit reports;
- ☑ Stakeholders communication;
- ☑ Date of next review meeting.

Example/tool 10.3: Changes that can affect the WSP

A housing development increased demand for water within the Hawthorne Water Supply System. This led to a proposal that water from the Dahlia Water Supply System should be fed into the area. Yet the materials used in the piped distribution system of the Hawthorne System could not cope with the more aggressive water chemistry of the Dahlia Supply, leading to corrosion and leaching of metals. This situation could have been avoided if the WSP team had assessed the risks of such a change beforehand. The team would have needed to ensure that the process diagram for the 'joined-up' water supply system had been updated, and whether the risk assessment from the other water supplier was adequate, including data from operational monitoring, and consumer complaints.

A48235836

Case study 1: Australia

Field Experience 10.1 – executive review of the WSP

Most Australian urban water utilities have at least one executive level water quality champion and they report on WSP implementation and outputs at the executive level. Audits of WSPs are typically reported to the utility executive. The WSP provides a useful framework for organizing and presenting water quality management actions in a form that assists executives to make strategic decisions on water quality management.

Field Experience 10.2 – revising the WSP

Australian utilities maintain their WSPs as 'living documents' that are subject to ongoing change to capture improvements. Most WSPs are in fact version-controlled by having an intranet-based electronic version live on the web rather than a hard copy version. The WSPs typically undergo a major revision every couple of years with ad hoc revisions usually scheduled to coincide with audits or other milestones or major asset changes.

Case study 2: Latin America and the Caribbean (LAC)

Field Experience 10.1 – establishing a review committee for the WSP

The WSP team felt that a formal process of WSP review and revision needed to be established to ensure that the WSP is kept current and effective. Owing to the busy schedules of Task Force and Steering Committee members, long-term maintenance of the WSP was considered unrealistic without a clear plan outlining major review activities and identifying responsible parties. A Review Committee was formed and agreed to meet biennially following WSP development to revise the WSP to reflect progress on prescribed corrective actions and to address any shortcomings identified. In addition to scheduled biennial reviews, the Review Committee agreed to meet following any drinking-water-related incidents to revise the WSP as necessary to prevent recurrence.

Field Experience 10.2 – revising the WSP following capital improvements

Several capital improvements were proposed as a result of the WSP. Structural or operational changes to the system can introduce additional risks, such as a lack of knowledge about operating new equipment or changing levels of disinfectants for a modified system. The Review Committee will revisit the WSP following structural improvements to assess and address any unforeseen hazards and update the WSP accordingly following any changes that are implemented. Similarly, as the capacity for improved water quality is realized through capital and operational improvements, standards will be revisited and may need to be modified, such as the step-wise standards established for turbidity, as discussed in LAC Field Experience 7.3.

Case study 3: United Kingdom (England and Wales)

Field Experience 10.1 – staying committed to the WSP approach

Companies that had many paper-based WSPs were challenged by the workload requirements to keep them up to date particularly where many improvements had been identified and implemented. Keeping the WSP initiative embedded in company operations was likely to be a challenge before the WSP risk assessment and risk management approach was made a regulatory requirement.

Module 11

Revise the WSP following an incident

A48235836

Introduction

As outlined previously, to ensure that a WSP covers emerging hazards and issues, it should be reviewed periodically by the WSP team. A particular benefit of implementing the WSP framework is a likely reduction in the number and severity of incidents, emergencies or near misses affecting or potentially affecting drinking-water quality. However, such events may still occur. In addition to the periodic review, it is important that the WSP is reviewed following every emergency, incident or unforeseen event irrespective of whether new hazards were identified to ensure that, if possible, the situation does not recur and determine whether the response was sufficient or could have been handled better. A post-incident review is always likely to identify areas for improvement whether it is a new hazard or revised risk for the risk assessment, a revision for an operating procedure, a training issue or a communication issue, and the WSP must be revised to reflect the changes. In many cases, it will be necessary to include other stakeholders in the review. It is important that water suppliers, within their WSP, have procedures in place to ensure that the WSP team is made aware of the circumstances and details of all incidents, emergencies, and near misses.

Key actions

- Review the WSP following an incident, emergency or near miss;
- Determine the cause of the incident, emergency or near miss and sufficiency of the response;
- Revise the WSP as necessary, including updates to supporting programmes.

Typical challenges

- An open and honest appraisal of the causes, chain of events, and factors influencing the emergency, incident or near miss situation;
- Focusing and acting on the positive lessons learned, rather than apportioning blame.

Outputs

1. Comprehensive and transparent review of why the incident occurred and the adequacy of the utility's response.
2. Incorporation of the lessons learned into WSP documentation and procedures.

Example/tool 11.1: A checklist of questions to be asked following an emergency, incident or near miss includes

- ☑ What was the cause of the problem?
- ☑ Was the cause a hazard already identified in the WSP risk assessment?
- ☑ How was the problem first identified or recognized?
- ☑ What were the most essential actions required and were they carried out?
- ☑ If relevant, was appropriate and timely action taken to warn consumers and protect their health?
- ☑ What communication problems arose and how were they addressed?
- ☑ What were the immediate and longer-term consequences of the emergency?
- ☑ How can risk assessment / procedures / training / communications be improved?
- ☑ How well did the emergency response plan function?

Example/tool 11.2: Following an incident, emergency or near miss the following checklist may be useful to revise the WSP

- ☑ Accountabilities and contact details for key personnel, usually including other stakeholders and individuals, are clearly stated;
- ☑ Clear definition of trigger levels for incidents including a scale of alert levels (e.g. when an incident is elevated to a boil water alert);
- ☑ Review whether the management procedures were appropriate for the incident and if not, revise accordingly;
- ☑ Standard operating procedures and required equipment, including back-up equipment, are readily available, and relevant;
- ☑ Relevant logistical and technical information is in hand and up to date;
- ☑ Checklists and quick reference guides have been prepared and are up to date;
- ☑ Does the risk assessment need revising?
- ☑ Do procedures/ training / communications need improving?
- ☑ Has the incident shown the need for an improvement programme?

A48235836

Case study 1: Australia

Field Experience 11.1 – defining 'incident' and planning review and revision

Even prior to developing WSPs, Australian water utilities typically had incident and emergency response plans. Major water quality problems or threats to water quality typically constituted an 'incident', which was the term used to describe a major event. Agreed criteria were used to mark the start of an incident whereupon an incident management team was formed. The incident management team then managed the incident to minimize harm caused during the event and to return to normal operations as soon as possible. Most water quality incidents involved responding urgently to early warning and mobilizing sufficient resources to ensure that customers were not affected. Such incidents were usually managed internally by the utility. In a few cases, contaminated or inadequately treated water may reach customers. If contaminated or inadequately treated water reaches customers, then typically the incident involves the health department and customers are advised not to drink that water, or to boil the water. Water supplies are not usually shut off even if they may be contaminated. Water is required for sanitation and hygiene purposes, and most contamination events are not so severe that water supply should be terminated. Rather, water supply continues and people are asked to avoid or boil water before use, as a precaution. As a matter of course, following an incident there is a 'debrief' process in which the root cause of the problem is identified and the WSP changed to prevent a recurrence, if possible.

Field Experience 11.2 – post-incident assessment

As an example, many WSPs triggered incidents due to disinfection system failures in their early stages. Prior to WSPs there was not necessarily a critical limit value set below which disinfection was considered suspect. However, with the advent of WSPs, disinfection critical limit values were set and these were breached from time to time. As a result of the root cause analysis following the incidents, many utilities changed their disinfection practices. Utilities introduced full or partial (focusing on vulnerable components) duty and standby systems to allow a change to the standby system in the event of a failure of the duty system. In some suppliers that desire high reliability, there are two independent standby systems to provide further back-up with one system at an independent downstream location. In many systems, automation was introduced to allow switchover to back-up systems and to provide an alert to operators. Treated water storage was augmented in many cases to allow systems to shut down and provide a window of a day or more to repair the systems without affecting customers. Utilities that would experience multiple incidents in the first years of the WSP implementation gradually moved to less than one incident per year through this improvement process.

Case study 2: Latin America and the Caribbean (LAC)

Field Experience 11.1 – defining 'incident' and planning review and revision

The WSP team defined an 'incident' as a violation of water quality that poses an acute or immediate threat to public health. At the time of WSP development, issues potentially satisfying this definition, such as microbial contamination in the distribution system, were commonplace and were largely the motivating factors for initially undertaking the WSP. Hazards such as these were identified as part of Module 3 and 4. The implementation of corrective actions, such as increased chlorine dosing and improved monitoring practices, are expected to address those problems. If post-implementation monitoring reveals recurrent

microbial contamination, the Review Committee will meet to address weaknesses in the plan.

Field Experience 11.2 – post-incident assessment

During the course of WSP development, an incident occurred in which chlorine gas was released into a residential area. Several failings in emergency mitigation and response procedures were identified, including a lack of monitoring of chlorine gas transfer; an unmanned duty station, which caused the leak to go unnoticed by the utility; a lack of prompt reporting to appropriate parties within the utility, to the EPA and to residents; a failure to evacuate appropriately; and a lack of provision of health officers to evaluate the incident. A post-incident evaluation by the utility and the EPA was subsequently conducted that addressed each of the failings and introduced protocol and enforcement procedures to the WSP to prevent the recurrence of such incidents.

Case study 3: United Kingdom (England and Wales)

Field Experience 11.1 – keeping emergency plans up to date

Water companies already had good emergency plans which are tested and kept up to date as part of normal procedures. Again, with such well established procedures, the challenge was to consider these as coming under the WSP umbrella.

A48235836

Acknowledgements

This Manual was conceived to support a series of WSP capacity building workshops convened by WHO, where it was progressively refined. It was significantly revised through subsequent peer and public review, including feedback received during an international conference on WSPs convened by the International Water Association (IWA), the Associação Portuguesa de Engenharia Sanitária e Ambiental (APESB), and co-sponsored by WHO.

The preparation of the WSP Manual was generously supported by the Drinking Water Inspectorate, United Kingdom; the Australian Agency for International Development; the Water and Sanitation Regulatory Agency, Portugal; the Ministry of Health, Labour and Welfare, Japan; the Environmental Protection Agency, USA; the Swedish International Development Cooperation Agency, and the Federal Ministry of Health, Germany.

This Manual would not have been possible without contributions from the following authors: Annette Davison and Dan Deere (Water Futures, Australia), David Drury, (Drinking Water Inspectorate, United Kingdom), Bruce Gordon and Jamie Bartram (World Health Organization, Switzerland), Melita Stevens (Melbourne Water, Australia), Guy Howard (DFID, United Kingdom), and Lana Corrales and Angella Rinehold (CDC, USA).

Bruce Gordon and Jamie Bartram coordinated the development of the Manual.

An international group of experts provided material and participated in the development and review of the Manual, either directly or through associated activities. In this regard, thanks are due to:

Glossary

The following represents terms used in GDWQ and other documents such as Codex Alimentarius and other guiding materials used throughout this Manual.

Term	Definition
Control (noun) (for instance control of water safety):	The state wherein correct procedures are being followed and criteria are being met.
Control (verb) (for instance control of a hazard):	To take all necessary actions to ensure and maintain compliance with criteria established in the WSP.
Control Measure:	Any action and activity that can be used to prevent or eliminate a water safety hazard or reduce it to an acceptable level.
Control Point:	A step at which control can be applied to prevent or eliminate a water safety hazard or reduce it to an acceptable level. Some plans contain *key* control points at which control might be essential to prevent or eliminate a water safety hazard.
Corrective Action:	Any action to be taken when the results of monitoring at the control point indicate a loss of control.
Critical Limit:	A criterion which separates acceptability from unacceptability.
Deviation:	Failure to meet a critical limit.
Flow Diagram:	A systematic representation of the sequence of steps or operations used in the production or manufacture of a particular water item.
HACCP:	Hazard Analysis and Critical Control Point.
Hazard Analysis:	The process of collecting and evaluating information on hazards and conditions leading to their presence to decide which are significant for water safety and therefore should be addressed in the WSP.
Hazard:	A biological, chemical, physical or radiological agent in, or condition of water, with the potential to cause an adverse health effect. Another word for hazard includes "contaminant".
Hazardous Event:	A process whereby a hazard/contaminant is introduced into a water supply.
Monitor:	The act of conducting a planned sequence of observations or measurements of control parameters to assess whether a control point is under control or whether the water meets quality criteria.
Risk Assessment:	For the purposes of this Manual, risk assessment has the same meaning as hazard analysis.
Risk Score:	The score assigned to a hazard based on the risk analysis process.
Step:	A point, procedure, operation or stage in the water supply chain including raw materials, from primary production to final exposure.
Supporting Programmes/ Supporting Requirements:	The foundation activities required to ensure safe water including training, raw material specifications and general good water management practices. These programmes can be just as important as control points in controlling water quality risks but are used where application tends to cover long timeframes and/or broader organizational or geographic areas. Includes general organizational supporting programmes as well as specific programmes targeted to particular risks.
Validation:	Obtaining evidence that the elements of the WSP can effectively meet the water quality targets.
Verification:	The application of methods, procedures, tests and other evaluations, to determine compliance with the WSP, i.e. checking whether the system is delivering water of the desired quality and whether the WSP is being implemented in practice.
WHO:	World Health Organization.
WSP:	Water Safety Plan.

The most effective means of consistently ensuring the safety of a drinking-water supply is through the use of a comprehensive risk assessment and risk management approach that encompasses all steps in water supply from catchment to consumer. In these Guidelines, such approaches are called water safety plans (WSPs).

SURVEILLANCE REPORT

Legionnaires' disease

Annual Epidemiological Report for 2019

Key facts

- Legionnaires' disease remains an uncommon and mainly sporadic respiratory infection with an overall notification rate in 2019 for the EU/EEA of 2.2 cases per 100 000 population.
- There is heterogeneity in notification rates between EU/EEA countries, with the highest rate reported by Slovenia (9.4 cases per 100 000 population).
- The annual notification rate increased in recent years, from 1.4 in 2015 to 2.2 cases per 100 000 population in 2019.
- There was a marginal decrease of less than 1% in the number of reported cases in 2019, compared with 2018.
- Four countries (France, Germany, Italy, and Spain) accounted for 71% of all notified cases in 2019.
- Males aged 65 years and above were most affected (8.4 cases per 100 000 population).
- Only 10% of cases were culture-confirmed (10%) probably meaning that disease caused by *Legionella* species other than *Legionella pneumophila* is under-estimated.

Methods

This report is based on data for 2019 retrieved from The European Surveillance System (TESSy) on 12 January 2021. TESSy is a system for the collection, analysis and dissemination of data on communicable diseases.

The methods used to produce this report are published online by ECDC [1] together with an overview of the national surveillance systems [2]. A subset of the data used for this report is available through ECDC's online *Surveillance atlas of infectious diseases* [3].

The surveillance data were collected through three different schemes:

- annual retrospective data collection of Legionnaires' disease (LD) cases reported in EU Member States, Iceland and Norway;
- annual retrospective data collection of outbreak events detected and reported in EU Member States, Iceland and Norway. The following thresholds for reporting outbreaks are used:
  - ≥ five cases, if these cases were not exposed in same building, there is no evidence of exposure to the same aerosol-producing installation/device, or microbiological evidence of linked cases;
  - ≥ three cases, if these cases were exposed in the same building, or if there is evidence of exposure to the same aerosol-producing installation/device, or if there is microbiological evidence of linked cases;
- near-real-time reporting of travel-associated cases of Legionnaires' disease (TALD) through the European Legionnaires' disease surveillance network (ELDSNet) [4], including reports from countries outside the EU/EEA. This scheme aims primarily to identify clusters of cases that may otherwise not be detected at national level, in order to quickly investigate them and take control measures at the implicated tourist accommodation sites to prevent further infections.

Legionnaires' disease cases should be reported to these surveillance schemes in accordance with the 2018 EU/EEA case definition for confirmed cases or probable cases, which includes at least one positive laboratory test.

Annual case surveillance

Epidemiology

In 2019, 28 countries reported 11 298 cases (Table 1), of which 10 636 (94%) were classified as confirmed. The number of notifications per 100 000 population remained stable at 2.2, being the highest notification rate ever observed for the EU/EEA. In the last five years, the notification rates have nearly doubled in the EU/EEA, from 1.4 in 2015 to 2.2 per 100 000 population. Four countries, France, Germany, Italy and Spain, accounted for 71% of all notified cases, although their combined populations only represent approximately 50% of the EU/EEA population.

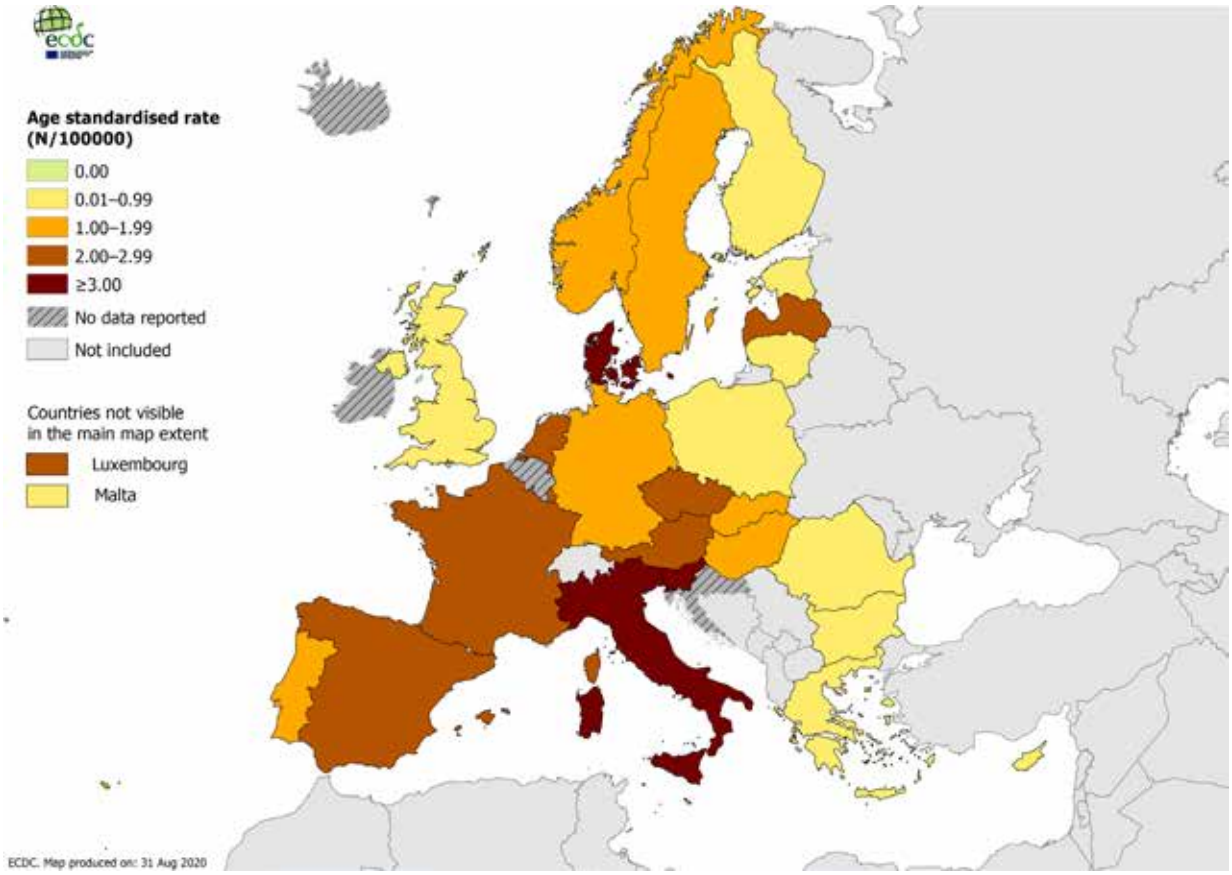
Source: Country reports.
ASR: age-standardised rate.
.: no data reported.
-: no rate calculated.

Of 8 458 cases with known outcome, 630 (7%) were reported to have been fatal.

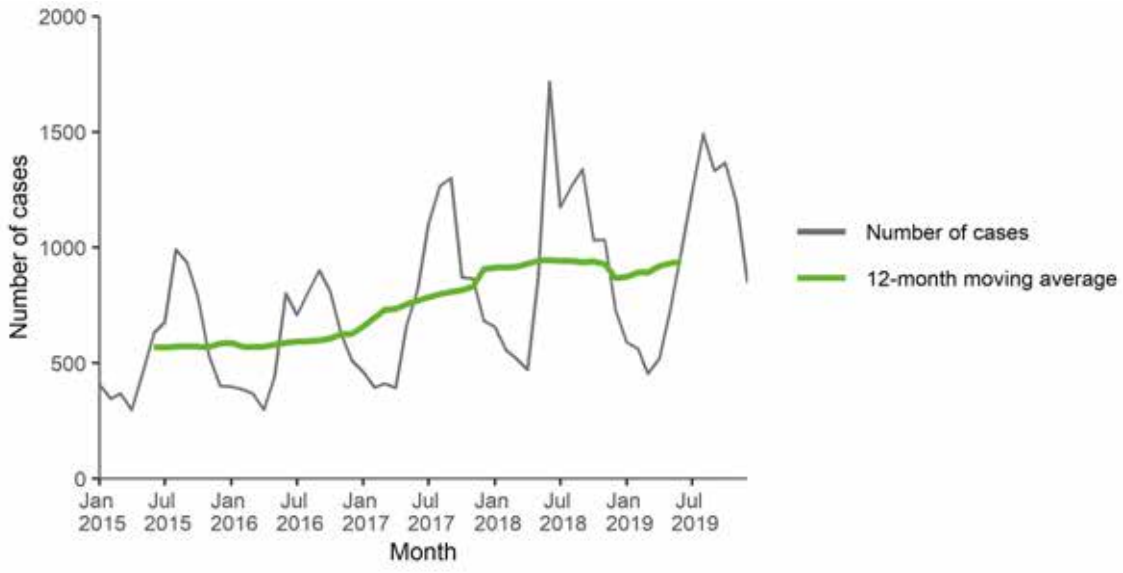
Notification rates ranged from less than 1.0 cases per 100 000 population in 10 countries (Bulgaria, Cyprus, Estonia, Finland, Greece, Ireland, Lithuania, Poland, Romania and the United Kingdom) to 3.0 cases per 100 000 population or more in six countries (Denmark, France, Italy, the Netherlands, Slovenia and Spain); see Table 1 and Figure 1.

Figure 1. Distribution of Legionnaires' disease cases per 100 000 population by country, EU/EEA, 2019



During the period 2015−2019, the number of reported cases increased by 65% from 6 947 to 11 298 showing an increasing trend in recent years (Table 1; Figure 2).

Figure 2. Distribution of Legionnaires' disease cases by month, EU/EEA, 2015−2019

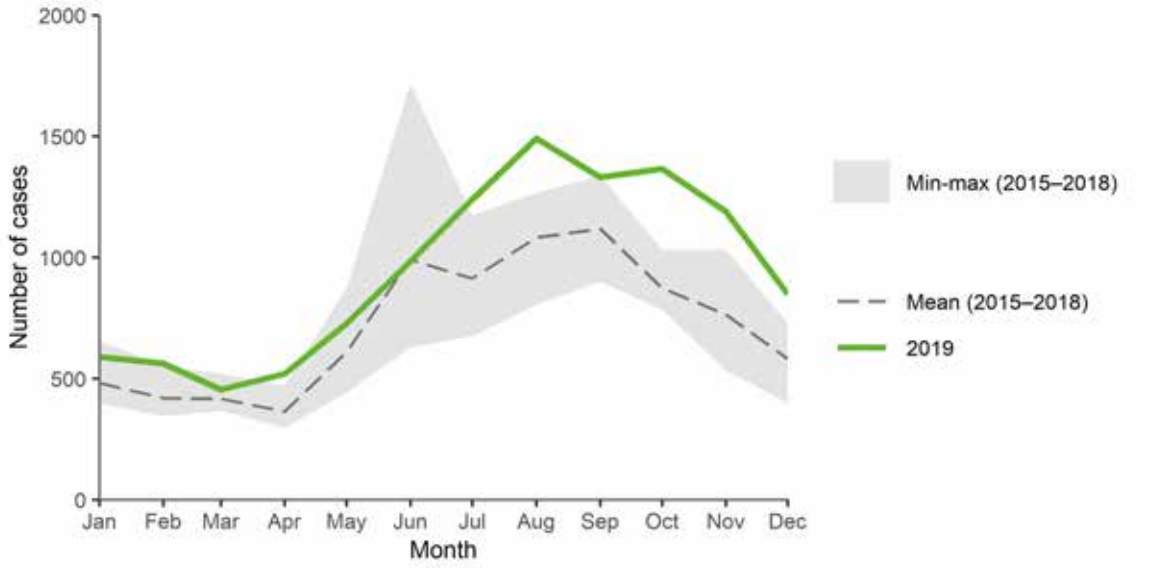


Source: Country reports from Austria, Belgium, Bulgaria, Cyprus, Czechia, Denmark, Estonia, Finland, France, Germany, Greece, Hungary, Ireland, Italy, Latvia, Lithuania, Luxembourg, Malta, the Netherlands, Norway, Poland, Portugal, Romania, Slovakia, Slovenia, Spain, Sweden, the United Kingdom.

The distribution of cases by month of reporting shows that the majority (57%) occurred between June and October, similar to previous years (Figure 3). An increase in cases compared to the maximum in previous years (2015–2018) was observed for every month during the period July to December. The peak of 1 743 cases in June

2018 was the highest monthly number recorded to date under EU/EEA surveillance and was not reached again in 2019. No community outbreaks were reported by any EU/EEA country that could explain the shifted seasonal curve to the later summer and autumn period.

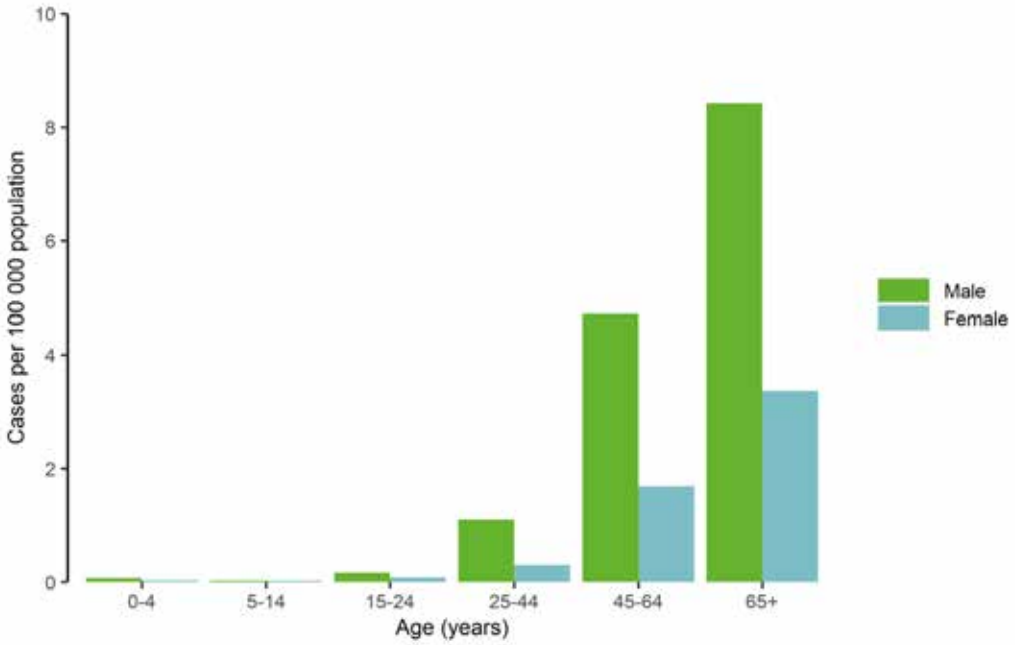
Figure 3. Distribution of Legionnaires' disease cases by month, EU/EEA, 2019 and 2015–2018



Source: Country reports from Austria, Belgium, Bulgaria, Cyprus, Czechia, Denmark, Estonia, Finland, France, Germany, Greece, Hungary, Ireland, Italy, Latvia, Lithuania, Luxembourg, Malta, the Netherlands, Norway, Poland, Portugal, Romania, Slovakia, Slovenia, Spain, Sweden, the United Kingdom

In 2019, people aged 45 years and older accounted for 10 236 of 11 279 cases with known age (91%). The notification rate increased with age, from ≤0.1 cases per 100 000 population in those under 25 years of age to 5.6 cases per 100 000 population in those aged 65 years and above (8.4 cases per 100 000 population in males and 3.4 in females, Figure 4). The overall male-to-female ratio remained unchanged compared to 2018 at 2.3:1.

Figure 4. Distribution of Legionnaires' disease cases per 100 000 population, by age and gender, EU/EEA, 2019



The vast majority of cases in 2019 (90%) were reported using the laboratory method of urine antigen tests (UAT). This was similar to the range of 88−90% cases with UAT testing reported since 2012. In comparison, few cases were reported with a culture test (1 148 cases; 10%) and use of polymerase chain reaction (PCR) method tests was reported for 1 024 cases (9%).

This continues the low-level use of culture as a reported method observed during the same period. Among culture-confirmed cases (1 148) a total of 35 *Legionella* non-pneumophila species were reported: *L. anisa* (1), *L. bozemanii* (2), *L. dumoffi* (1), *L. jordanis* (1), *L. longbeachae* (15), *L. micdadei* (2) and *Legionella* other species (13). As illustrated in Table 2, although *Legionella pneumophila* isolates of all serogroups are detected and reported annually among culture-confirmed cases, over 80% are reported as serogroup 1.

Table 2. Serogroups reported for culture-confirmed cases of *L. pneumophila*, EU/EEA, 2018–2019

Serogroup (SG)	2018		2019

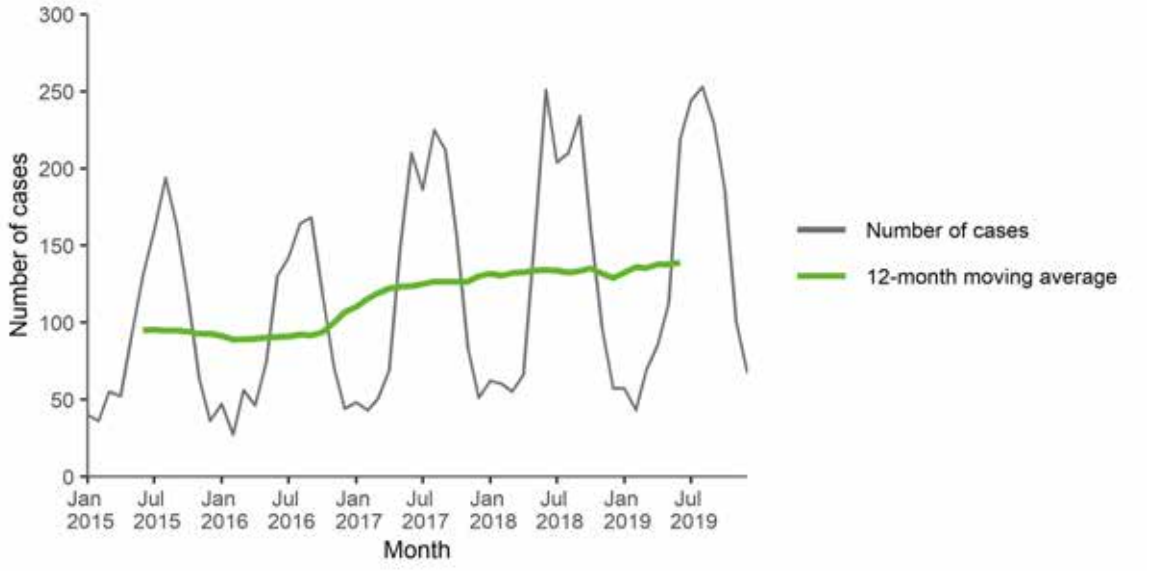
Travel-associated Legionnaires' disease (TALD)

TALD case reports

ELDSNet received reports of 1 657 cases of TALD with date of onset in 2019, 2% more cases than in 2018, and the highest annual number of TALD cases ever reported to the network (Figure 5).

Figure 5. Distribution of travel-associated cases of Legionnaires' disease by month, EU/EEA, 2015–2019

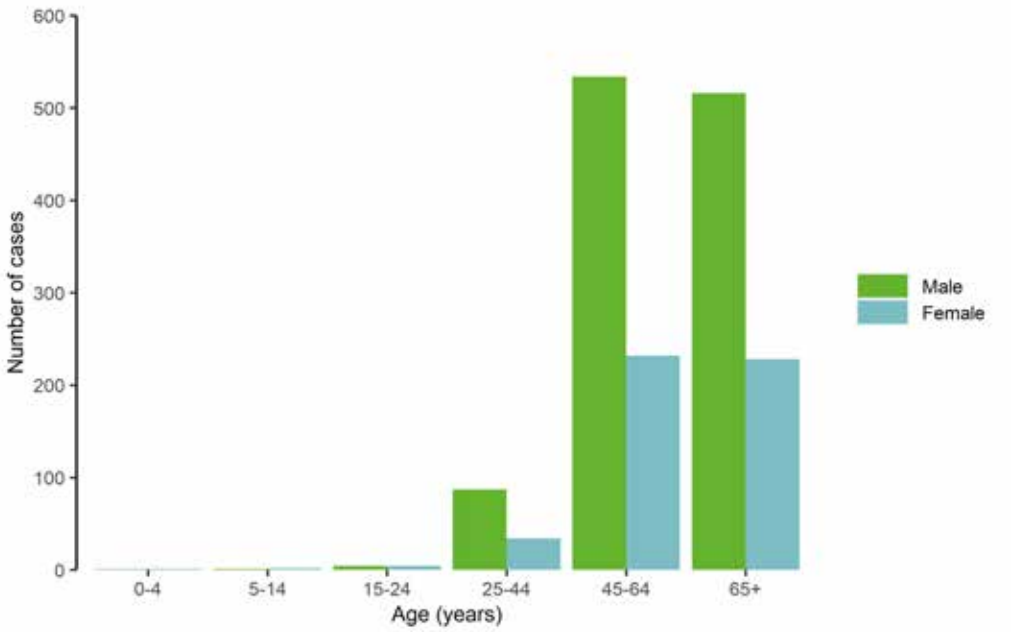


Source: Country reports from Austria, Belgium, Bulgaria, Croatia, Czechia, Denmark, Estonia, Finland, France, Germany, Greece, Hungary, Ireland, Italy, Latvia, Lithuania, Luxembourg, Malta, the Netherlands, Norway, Poland, Portugal, Romania, Slovenia, Spain, Sweden, the United Kingdom.

Cases were reported from 28 countries: 26 EU/EEA Member States and two non-EU/EEA countries: Switzerland (32 cases) and the USA (19 cases). Three quarters (76.7 %) of all TALD cases were reported by only five countries: Italy, Germany, France, the United Kingdom, and the Netherlands.

Similar to previous years, and the overall distribution for Legionnaires' disease, over two thirds (69%) of reported TALD cases were male. Cases had a median age of 63 years (IQR 55-71, range 7-99); 83% of cases occurred in people 50 years and older (Figure 6).

Figure 6. Distribution of travel-associated cases of Legionnaires' disease by age and gender, 2019

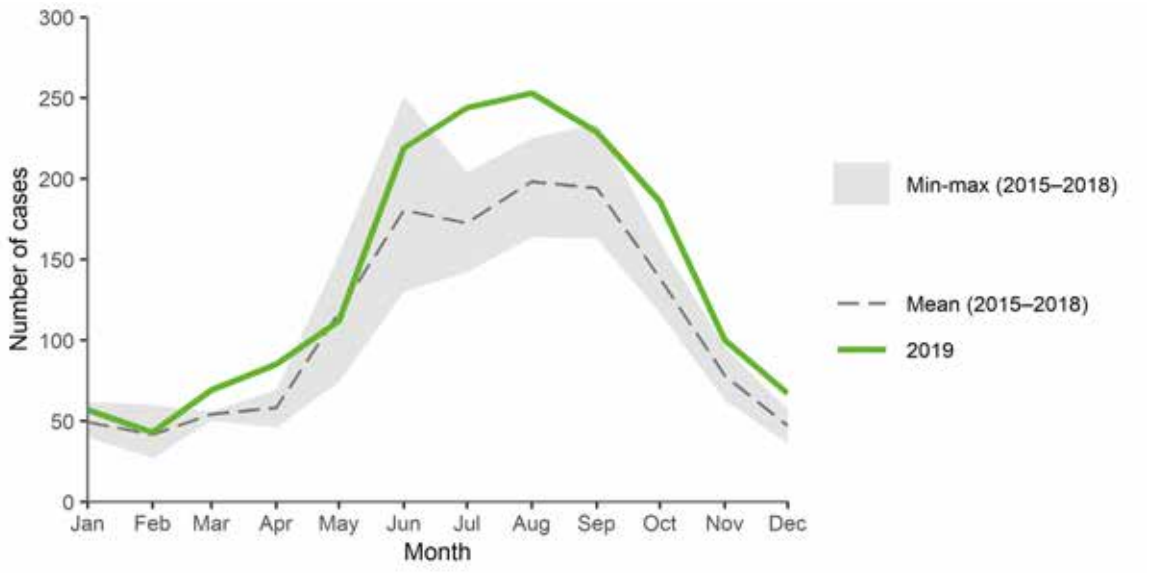


The reported TALD cases were resident in 35 countries. The majority of cases resided in those countries that reported the most cases, but 78 (4.7%) of cases were non-EU/EEA residents, from Switzerland (34), the USA (25), Australia (eight), Canada (four), China (three), Brazil (two), Mexico (one) and New Zealand (one).

The median time from date of onset to reporting to ELDSNet was 18 days, ranging from a minimum of 10−12 days (Latvia, France, Ireland and Norway) to a maximum of 50−53 days (Poland, Hungary and Portugal).

In 2019, two thirds of TALD cases fell ill between June and October, which is in line with the known seasonality for Legionnaires' disease (Figure 7).

Figure 7. Distribution of travel-associated cases of Legionnaires' disease by month, EU/EEA, 2019 and 2015−2018



Source: Country reports from Austria, Belgium, Bulgaria, Croatia, Czechia, Denmark, Estonia, Finland, France, Germany, Greece, Hungary, Ireland, Italy, Latvia, Lithuania, Luxembourg, Malta, the Netherlands, Norway, Poland, Portugal, Romania, Slovenia, Spain, Sweden, the United Kingdom.

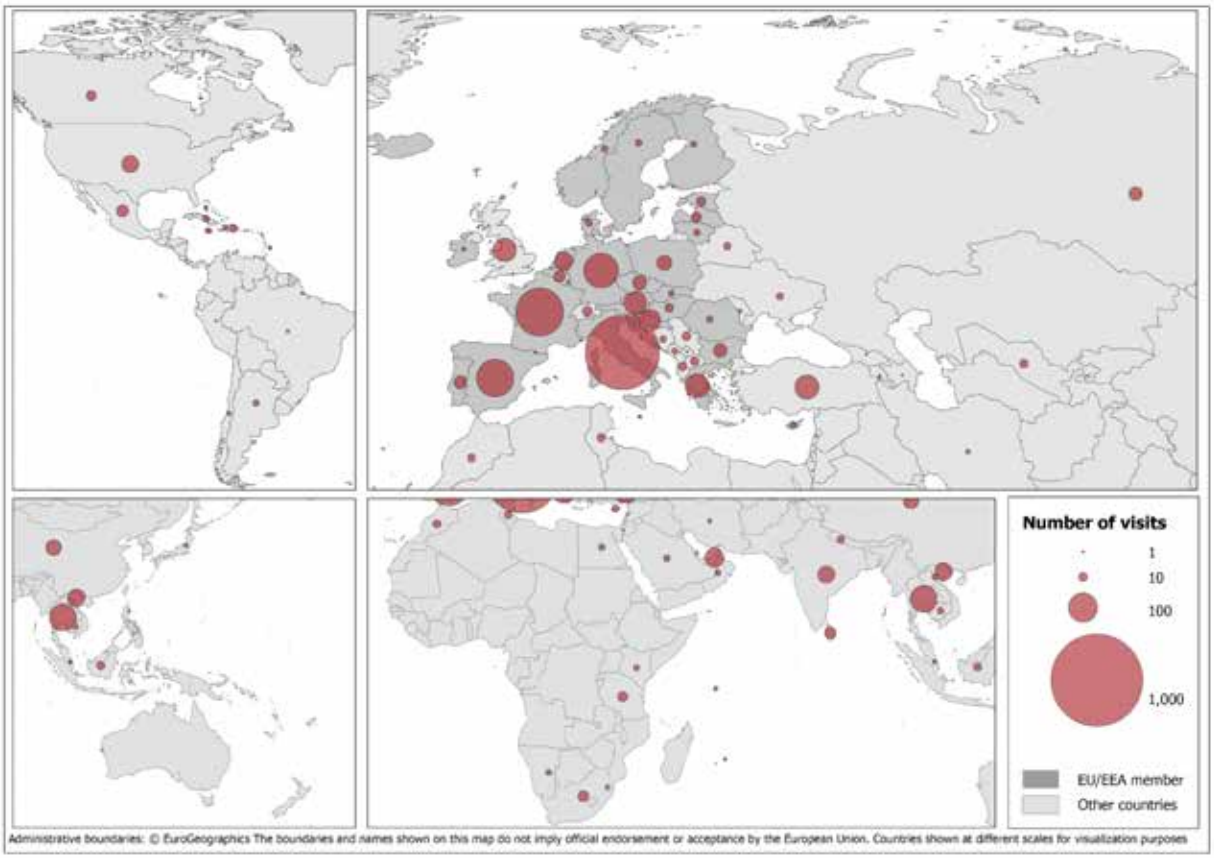
Outcome was provided for 1 036 (62.6%) TALD cases, with 26 (1.6%) known to have deceased by the time of reporting to ELDSNet. Deceased cases were between 43 and 91 years old, and 17 were male. A total of 1 553 TALD cases (94%) were classified as confirmed and 104 (6%) were probable cases. Of 1 801 laboratory tests, 85% were UATs, 12% were molecular tests (polymerase chain reaction, PCR) and 3% were cultures, while less than one percent were serological tests. Monoclonal subtyping results were reported for 14 cases with *L. pneumophila* serogroup 1: Philadelphia (five cases), Allentown/France (two cases), Benidorm (two cases), Knoxville (two cases), Bellingham (one case), Oxfolda (one case), and OLDA (one case). The sequence type was reported to ELDSNet for only 22 TALD cases from three countries: United Kingdom (15), Denmark (4), and Sweden (3). Three of the reported sequence types were ST42, three were ST62, two were ST1, two were ST37, and the others were a variety of single sequence types.

TALD case travel destinations

The 1 657 TALD cases had made a total of 2 410 international journeys. Of these, 1 723 (72%) were within the EU/EEA, 638 (26%) were outside the EU/EEA (Figure 8 and Figure 9), and 41 (2%) journeys were on ships. The three destination countries with most TALD associated travel visits were Italy (n=653, 28%), France (n=270, 11%), and Spain (n=164, 7%). Seventy-nine percent of the overnight stays were in hotels, 7% were in apartments, 6% on camping sites, 2% on ships, and 6% were reported as other types of accommodation.

Figure 8. Distribution of accommodation site visits made by travel-associated Legionnaires' disease cases, by destination country, EU/EEA and neighbouring countries, 2019

Figure 9. Distribution of accommodation site visits made by travel-associated Legionnaires' disease cases, by destination country, worldwide, 2019



In 2019, ELDSNet detected 176 new TALD clusters. A TALD cluster is an event involving two cases having visited the same accommodation site within a two-year period [4].The clusters were associated with accommodations in 30 countries worldwide (14 within the EU/EEA and 16 outside the EU/EEA), and two clusters were associated with vessels. Of the 176 new clusters from 2019, 125 (71%) comprised of only two cases. ELDSNet shared 60 summary reports of type 1 (non-EU/EEA clusters) with tour operators and 36 of type 2 (rapidly evolving clusters - i.e. three or more cases associated within three months).

For all 176 clusters, a preliminary site assessment report within two weeks of notification, followed by a final assessment report within six weeks of notification, were received by ECDC in accordance with the surveillance scheme operating procedures [4]. In 2019, the names of eight accommodation sites were published on ECDC's website, because assessment reports stated that recommendations from the competent authorities were not implemented in a satisfactory manner.

Outbreaks

In 2019, through the annual outbreak reporting surveillance scheme, five countries (France, Germany, Italy, Netherlands, and United Kingdom) reported a total of 29 community- or hospital-acquired outbreaks, ranging from three to nine per reporting country. The number of cases per reported outbreak ranged from two to 28 confirmed cases. Eight outbreaks were reported in association with hospitals and three in geriatric residences. Sixteen EU/EEA countries reported no outbreaks of Legionnaires' disease under 2019.

Discussion

In 2019, both the number and notification rate of Legionnaires' disease in the EU/EEA remained at the highest level observed, continuing an increase ongoing since 2013, although not an increase on the previous year. The main characteristics of Legionnaires' disease cases reported in 2019 were very similar to 2018, with most cases being sporadic and community-acquired and the disease mostly affecting males aged 65 years and above. A number of countries continue to have very low notification rates of below 0.5 cases per 100 000 population, which probably represents underestimation of the incidence in these countries. As only 10% of cases are reported with a culture-confirmed diagnosis there is probably an underestimation of the burden of disease caused by *Legionella* species other than by *Legionella pneumophila* across the EU/EEA.

Outbreaks of Legionnaires' disease of varying size and origin continue to be identified and investigated by public health authorities in the EU/EEA. However, the high number of cases reported annually is not caused by large outbreaks.

The cause for the continuing high levels of notified cases observed in 2019, as in 2018, remains unknown. Factors that could influence this include changes in national testing policy and surveillance systems; an ageing EU/EEA population and increasing travel trends; the design and infrastructure maintenance in building water systems, and changes in climate and weather patterns across Europe and worldwide that can impact both the ecology of *Legionella* in the environment and causes of exposure to water aerosols containing the bacteria.

Public health implications

Legionnaires' disease remains an important cause of potentially preventable morbidity and mortality in Europe and the burden appears to be increasing.

The overall EU/EEA notification rates has seen sharp rises in the last few years. However, variation in rates across EU/EEA countries remain, probably reflecting under-diagnosis of this disease in many Member States. A priority continues to be assisting those countries with very low notification rates in improving both the diagnosis and reporting of Legionnaires' disease to public health authorities.

Outbreaks of Legionnaires' disease of varying size and origin continue to be identified and investigated by public health authorities in EU/EEA countries. Due to the relatively high mortality associated with disease and considerable challenges for the rapid identification and control of environmental sources, it remains important to be vigilant through surveillance for the detection of clusters and outbreak events.

As detection of TALD clusters through the ELDSNet surveillance scheme leads to investigations and preventive action at accommodation sites by participating countries, the continuing detection of clusters primarily through this multi-country joint surveillance scheme shows its value for public health.

To support the strengthening of surveillance and outbreak investigation capacity in European countries, in 2019 ECDC started an annual EQA scheme on clinical and environmental samples of *Legionella* spp. The first report on the findings of the EQA scheme in participating laboratories from EU/EEA countries for the November 2019 distribution was published in 2020 [6].

Regular checks for the presence of *Legionella* bacteria and appropriate control measures applied to engineered water systems [5] may prevent cases of Legionnaires' disease at tourist accommodation sites and in hospitals, long-term healthcare facilities or other settings where sizeable higher-risk populations can be exposed.

World Health Organization

Legionellosis

6 September 2022

العربية | 中文 | Français | Русский | Español

Key facts

- The bacterium L. pneumophila was first identified in 1977, as the cause of an outbreak of severe pneumonia in a convention centre in the USA in 1976.
- The most common form of transmission of Legionella is inhalation of contaminated aerosols produced in conjunction with water sprays, jets or mists of contaminated water sources. Infection can also occur by aspiration of contaminated water or ice, particularly in susceptible hospital patients.
- Legionnaires' disease has an incubation period of 2 to 10 days (but up to 16 days has been recorded in some outbreaks).
- Treatments exist, but there is currently no vaccine available for Legionnaires' disease.
- Death occurs through progressive pneumonia with respiratory failure and/or shock and multi-organ failure.
- Untreated Legionnaires' disease usually worsens during the first week.
- Of the reported cases, 75–80% are over 50 years and 60–70% are male.

Overview

Legionellosis varies in severity from a mild febrile illness to a serious and sometimes fatal form of pneumonia and is caused by exposure to the *Legionella* bacteria species found in contaminated water and potting mixes.

Cases of legionellosis are often categorized as being community, travel or hospital acquired based on the type of exposure.

Worldwide, waterborne *Legionella pneumophila* is the most common cause of cases including outbreaks. *Legionella pneumophila* and related species are commonly found in lakes, rivers, creeks, hot springs and other bodies of water. Other species including *L. longbeachae* can be found in potting mixes.

The bacterium *L. pneumophila* was first identified in 1977 as the cause of an outbreak of severe pneumonia in a convention centre in the USA in 1976. It has since been associated with outbreaks linked to poorly maintained artificial water systems.

The infective dose is unknown but can be assumed to be low for susceptible people, as illnesses have occurred after short exposures and 3 or more kilometres from the source of outbreaks. The likelihood of illness depends on the concentrations of *Legionella* in the water source, the production and dissemination of aerosols, host factors such as age and pre-existing health conditions and the virulence of the particular strain of *Legionella*. Most infections do not cause illness.

The cause

The causative agents are *Legionella* bacteria from water or potting mix. The most common cause of illness is the freshwater species *L. pneumophila*, which is found in natural aquatic environments worldwide. However, artificial water systems which provide environments conducive to the growth and dissemination of *Legionella* represent the most likely sources of disease.

The bacteria live and grow in water systems at temperatures of 20 to 50 degrees Celsius (optimal 35 degrees Celsius). *Legionella* can survive and grow as parasites within free-living protozoa and within biofilms which develop in water systems. They can cause infections by infecting human cells using a similar mechanism to that used to infect protozoa.

Transmission

The most common form of transmission of *Legionella* is inhalation of contaminated aerosols from contaminated water. Sources of aerosols that have been linked with transmission of *Legionella* include air conditioning cooling towers, hot and cold water systems, humidifiers and whirlpool spas. Infection can also occur by aspiration of contaminated water or ice, particularly in susceptible hospital patients, and by exposure of babies during water births. To date, there has been no reported direct human-to-human transmission.

Extent of the disease

Legionnaires' disease is believed to occur worldwide.

The identified incidence of Legionnaires' disease varies widely according to the level of surveillance and reporting. Since many countries lack appropriate methods of diagnosing the infection or sufficient surveillance systems, the rate of occurrence is unknown. In Europe, Australia and the USA there are about 10–15 cases detected per million population per year.

Of the reported cases, 75–80% are over 50 years and 60–70% are male. Other risk factors for community-acquired and travel-associated legionellosis include smoking, a history of heavy drinking, pulmonary-related illness, immuno-suppression, and chronic respiratory or renal illnesses.

Risk factors for hospital-acquired pneumonia are recent surgery, intubation (the process of placing a tube in the trachea), mechanical ventilation, aspiration, presence of nasogastric tubes, and the use of respiratory therapy equipment. The most susceptible hosts are immuno-compromised patients, including organ transplant recipients and cancer patients and those receiving corticosteroid treatment.

Delay in diagnosis and administration of appropriate antibiotic treatment, increasing age and presence of co-existing diseases are predictors of death from Legionnaires' disease.

Symptoms

Legionellosis is a generic term describing the pneumonic and non-pneumonic forms of infection with *Legionella*.

The non-pneumonic form (Pontiac disease) is an acute, self-limiting influenza-like illness usually lasting 2–5 days. The incubation period is from a few and up to 48 hours. The main symptoms are fever, chills, headache, malaise and muscle pain (myalgia). No deaths are associated with this type of infection.

Legionnaires' disease, the pneumonic form, has an incubation period of 2 to 10 days (but up to 16 days has been recorded in some outbreaks). Initially, symptoms are fever, loss of appetite, headache, malaise and lethargy. Some patients may also have muscle pain, diarrhoea and confusion. There is also usually an initial mild cough, but as many as 50% of patients can present phlegm. Blood-streaked phlegm or hemoptysis occurs in about one-third of the patients. The severity of disease ranges from a mild cough to a rapidly fatal pneumonia. Death occurs through progressive pneumonia with respiratory failure and/or shock and multi-organ failure.

Untreated Legionnaires' disease usually worsens during the first week. In common with other risk factors causing severe pneumonia, the most frequent complications of legionellosis are respiratory failure, shock and acute kidney and multi-organ failure. Recovery always requires antibiotic treatment, and is usually complete, after several weeks or months. In rare occasions, severe progressive pneumonia or ineffective treatment for pneumonia can result in brain sequelae.

The death rate as a result of Legionnaires' disease depends on the severity of the disease, the appropriateness of initial anti-microbial treatment, the setting where *Legionella* was acquired, and host factors (for example, the disease is usually more serious in patients with immuno-suppression). The death rate may be as high as 40–80% in untreated immuno-suppressed patients and can be reduced to 5–30% through appropriate case management and depending on the severity of the clinical signs and symptoms. Overall the death rate is usually within the range of 5–10%.

Response

Treatments exist, but there is no vaccine currently available for Legionnaires' disease.

The nonpneumonic form of infection is self-limiting and does not require medical interventions, including antibiotic treatment. Patients with Legionnaires' disease always require antibiotic treatment following diagnosis.

The public health threat posed by legionellosis can be addressed by implementing water safety plans by authorities responsible for building safety or water system safety. These plans must be specific to the building or water system and should result in the introduction and regular monitoring of control measures against identified risks including *Legionella*. Although it is not always possible to eradicate the source of infection, it is possible to reduce the risks substantially.

Prevention of Legionnaires' disease depends on applying control measures to minimize the growth of *Legionella* and dissemination of aerosols. These measures include good maintenance of devices, including regular cleaning and disinfection and applying other physical (temperature) or chemical measures (biocide) to minimize growth. Some examples are:

- the regular maintenance, cleaning and disinfection of cooling towers together with frequent or continuous addition of biocides;
- installation of drift eliminators to reduce dissemination of aerosols from cooling towers;
- maintaining an adequate level of a biocide such as chlorine in a spa pool along with a complete drain and clean of the whole system at least weekly;
- keeping hot and cold water systems clean and either keeping the hot water above 50 °C (which requires water leaving the heating unit to be at or above 60 °C) and the cold below 25 °C and

ideally below 20 °C or alternatively treating them with a suitable biocide to limit growth, particularly in hospitals and other health care settings, and aged-care facilities; and
- reducing stagnation by flushing unused taps in buildings on a weekly basis.

Applying such controls will greatly reduce the risk of *Legionella* contamination and prevent the occurrence of sporadic cases and outbreaks. Extra precautions may be required for water and ice provided to highly susceptible patients in hospitals including those at risk of aspiration (for example, ice machines can be a source of *Legionella* and should not be used by highly susceptible patients).

Control and prevention measures must be accompanied by proper vigilance on the part of general practitioners and community health services for the detection of cases.

WHO makes available technical resources to support the management and control of legionellosis and advises Member States when specific queries are raised.

SURVEILLANCE REPORT

Legionnaires' disease

Annual Epidemiological Report for 2021

Key facts

- In 2021, the highest annual notification rate of Legionnaires' disease to date in the EU/EEA was observed, at 2.4 cases per 100 000 population.
- The rates are heterogenous across the EU/EEA region, with age-standardised rates varying by country between <1–5 cases per 100 000 population.
- Four countries (Italy, France, Spain, and Germany) accounted for 75% of all the notified cases.
- Males aged 65 years and above were the most affected group (8.9 cases per 100 000 population).
- Only 11% of the cases were reported as culture-confirmed. This is likely leading to an underestimation of cases of Legionnaires' disease caused by *Legionella* species other than *Legionella pneumophila*.
- The majority of the cases were considered to be community-acquired.
- Occurrence of at least one outbreak of Legionnaires' disease was reported by eight of the 27 EU/EEA countries reporting data to the outbreak reporting scheme.
- A total of 19 outbreaks involving 137 confirmed cases were reported.
- The travel-associated Legionnaires' disease (TALD) surveillance scheme observed a 38% increase in cases compared with 2020.
- Similar to previous years, 90% of the TALD cases occurred in individuals aged 45 years and above. A similar age distribution was observed in the annual retrospective data collection of cases of Legionnaires' disease.

Introduction

Legionnaires' disease is a multi-system disease which causes pneumonia due to an infection with the *Legionella* bacteria, most commonly of the species *Legionella pneumophila*. The bacteria are found in the natural environment, soil and water, but they can become a health risk when they grow within engineered systems that can produce inhalable water aerosols. Cooling towers, evaporative condensers, humidifiers, decorative fountains, hot tubs, showers, etc. are examples of water systems with identified *Legionella* risks. Conditions that are favourable for *Legionella* growth are water temperatures in the range of 25–42 °C, stagnant water with sediment build-up and low biocide levels. The aerosolisation of the contaminated water may cause sporadic cases or outbreaks.

Methods

This report is based on data for 2021 retrieved from The European Surveillance System (TESSy) on 9 September 2022. TESSy is a system for the collection, analysis, and dissemination of data on communicable diseases.

The methods used to produce this report are published by ECDC and can be found in the 'Introduction to the Annual Epidemiological Report' [1] together with an overview of the national surveillance systems [2]. A subset of the data used for this report is available through ECDC's online 'Surveillance Atlas of Infectious Diseases' [3].

The surveillance data were collected through three different schemes:

- annual retrospective data collection of cases of Legionnaires' disease (LD) reported in EU Member States, Iceland, Liechtenstein, and Norway;
- annual retrospective data collection of outbreak events detected and reported in EU Member States, Iceland, Liechtenstein, and Norway. The following thresholds for reporting outbreaks are used:
  - ≥ five cases, if these are not exposed in the same building, and there isn't evidence of exposure to the same aerosol-producing installation/device, nor microbiological evidence of linked cases;
  - ≥ three cases, if these are exposed in the same building, or if there is evidence for exposure to the same aerosol-producing installation/device, or microbiological evidence of linked cases;
- near real-time reporting of travel-associated cases of Legionnaires' disease (TALD) through the European Legionnaires' disease surveillance network (ELDSNet) [4], including reports from countries outside the EU/EEA. This scheme primarily aims at identifying clusters of cases that may otherwise not be detected at the national level, in order to quickly investigate them and take control measures at the implicated tourist accommodation site(s) to prevent further infections.

Cases of Legionnaires' disease should be reported to these surveillance schemes in accordance with the 2018 EU/EEA case definition [5] for confirmed or probable cases, that includes at least one positive laboratory test and a clinical diagnosis of pneumonia.

Annual case surveillance

Epidemiology

In 2021, 29 countries reported 10 723 cases (Table 1), of which 10 004 (93%) were classified as confirmed. The number of notifications per 100 000 population increased to 2.4, which was higher than any precedent year under surveillance. Four countries, Italy, France, Spain, and Germany, continued to account for the majority of notified cases (75%), although their combined populations represented approximately 50% of the EU/EEA population. Out of 8 054 cases with known outcome, 704 (9%) were reported to have a fatal outcome.

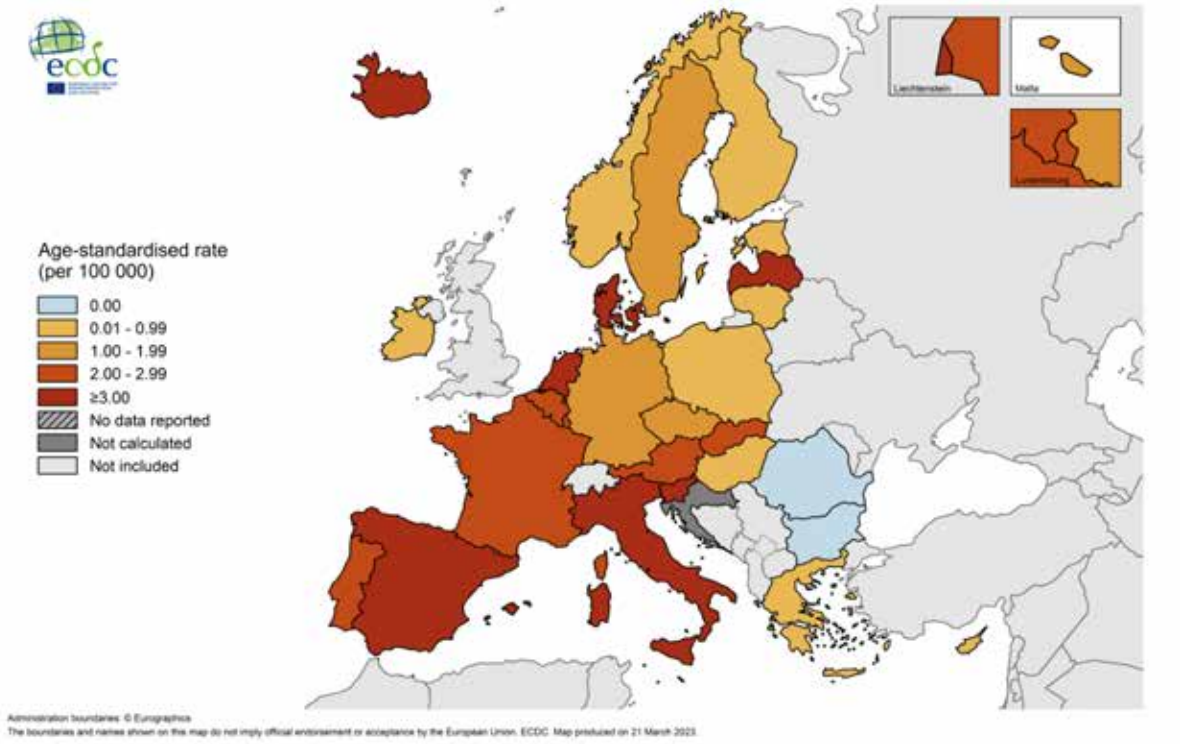
ND: no data reported
NR: no rate calculated.

[1] The United Kingdom (UK) was a former Member State of the European Union (EU). The UK withdrew from the EU on 31 January 2020.

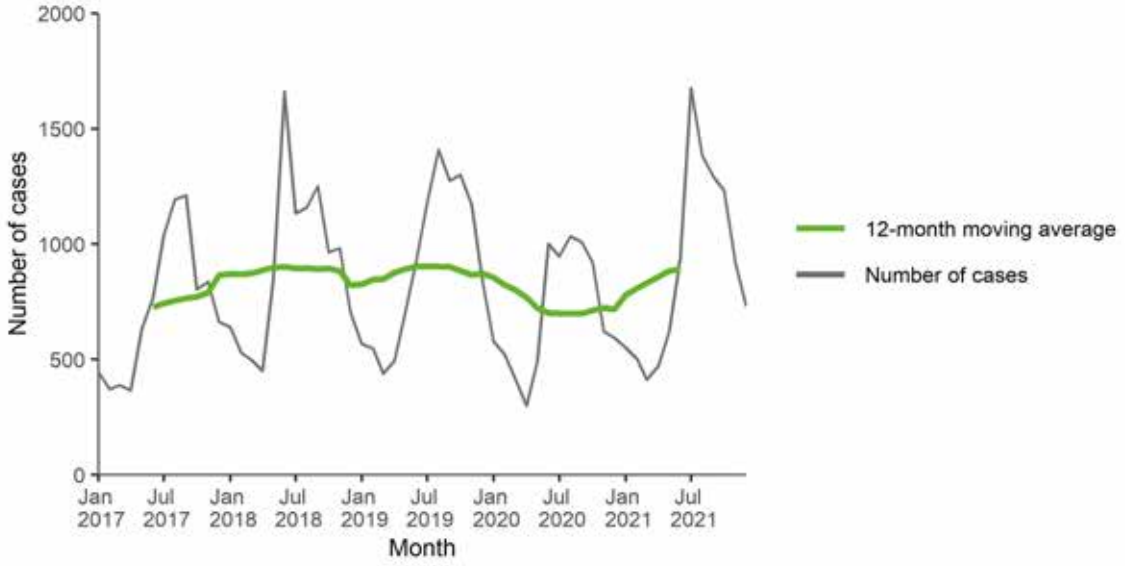
Age-adjusted notification rates ranged from less than 1.0 cases per 100 000 population in 11 countries (Bulgaria, Cyprus, Estonia, Finland, Greece, Hungary, Ireland, Lithuania, Norway, Poland, and Romania), to 3.0 cases or more per 100 000 population in eight countries (Denmark, Iceland, Italy, Latvia, Liechtenstein, Netherlands, Slovenia, and Spain; see Table 1 and Figure 1).

Figure 1. Distribution of cases of Legionnaires' disease per 100 000 population by country, EU/EEA, 2021



The general trend in the 2017–2021 period, has been of an increasing number of reported cases, other than the decrease during the COVID-19 pandemic period (Table 1; Figure 2).

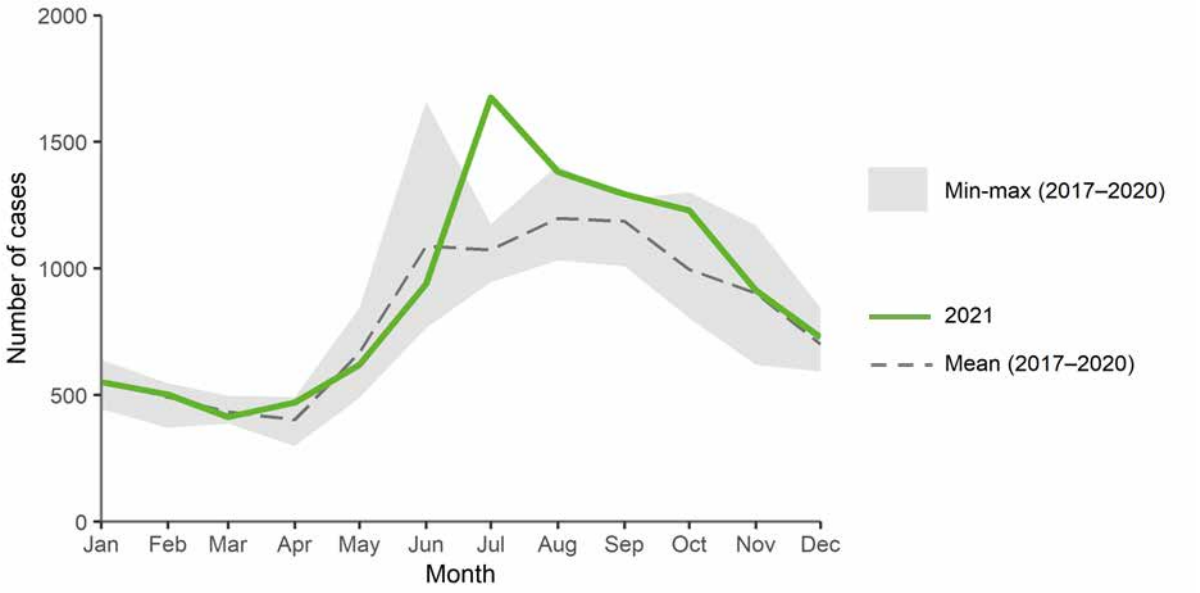
Figure 2. Distribution of cases of Legionnaires' disease by month, EU/EEA, 2017–2021



Source: Country reports from Austria, Belgium, Bulgaria, Cyprus, Czechia, Denmark, Estonia, Finland, France, Germany, Greece, Hungary, Iceland, Ireland, Italy, Latvia, Luxembourg, Malta, the Netherlands, Norway, Poland, Portugal, Romania, Slovakia, Slovenia, Spain, and Sweden.

In 2021, the distribution of cases by month of reporting shows that the majority (6 521; 61%) of cases occurred between June and October, similar to previous years (Figure 3). An unusual peak in the number of cases was reported in July (1 676 cases), which was similar to that observed in June 2018 (shown in the range distribution in Figure 3). These peaks occurred in the absence of any specific outbreak event in a country. The overall distribution for all other months was within the range of the previous four years.

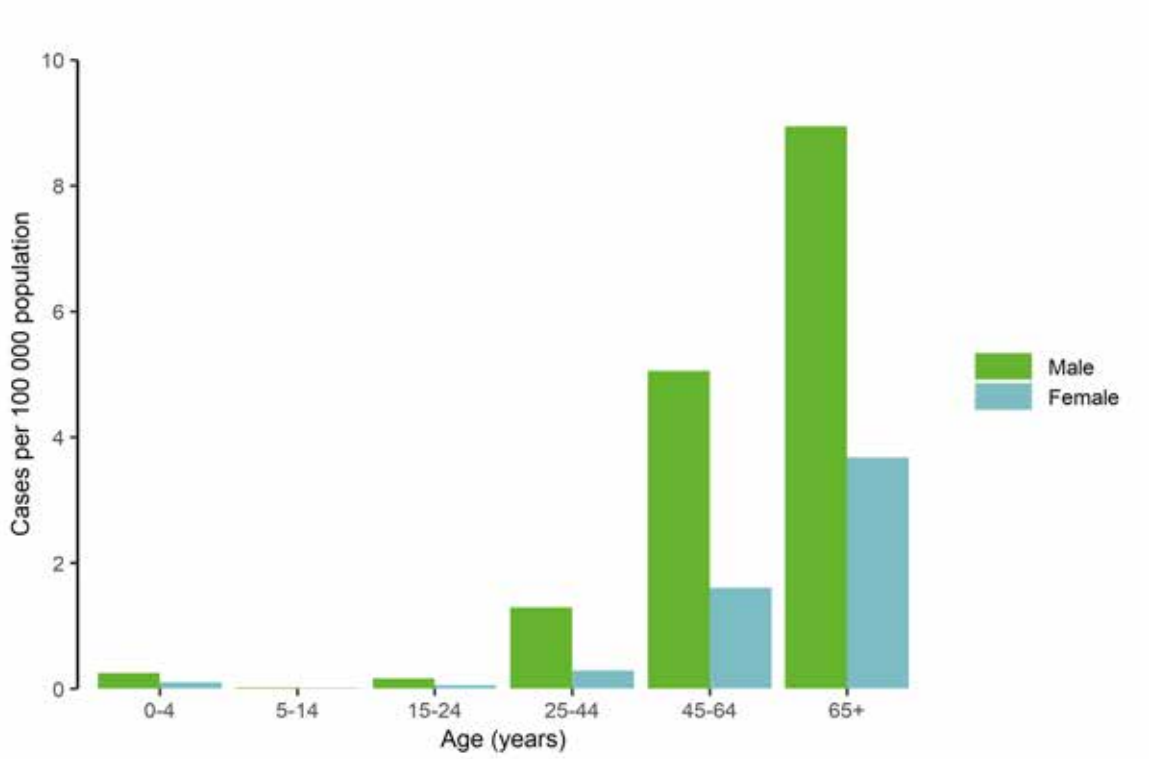
Figure 3. Distribution of cases of Legionnaires' disease by month, EU/EEA, 2021 and 2017–2020



Source: Country reports from Austria, Belgium, Bulgaria, Cyprus, Czechia, Denmark, Estonia, Finland, France, Germany, Greece, Hungary, Iceland, Ireland, Italy, Latvia, Luxembourg, Malta, the Netherlands, Norway, Poland, Portugal, Romania, Slovakia, Slovenia, Spain, and Sweden.

In 2021, people aged 45 years and above accounted for 9 706 (91%) of the 10 720 cases reported with known age. The notification rate increased with age, from ≤0.2 cases per 100 000 population in the age groups under 25 years, to 6.0 cases per 100 000 population in persons aged 65 years and above. The overall male-to-female ratio was 2.4:1, which remained comparable to previous years (range 2.3–2.4:1, from 2017–2020). The notification rate differed by gender, with the highest rate of 8.9 cases per 100 000 population reported in males aged 65+ years (3.7 cases per 100 000 population for females; Figure 4).

Figure 4. Distribution of cases of Legionnaires' disease per 100 000 population, by age and gender, EU/EEA, 2021



The majority of cases in 2021 (9 566/10 723; 89%) were reported to be diagnosed with a urinary antigen test (UAT). This was within the range of cases (88–90%) diagnosed with UAT testing reported since 2012. In comparison, fewer cases were reported having been diagnosed with a culture test (1 183 cases; 11%). This is in line with the low-level use of culture as a reported method of diagnosis, observed during the same period. The use of polymerase chain reaction (PCR) method tests was reported for 1 255 cases (12%).

Among culture-confirmed cases with the pathogen reported (1 133; 11%), a total of 32 *Legionella* non-*pneumophila* species were reported (3%): *L. anisa* (2), *L. bozemanii* (4), *L. longbeachae* (22), *L. micdadei* (3) and *L. cincinnatiensis* (1). Of the 1 133 cases, 14 were reported as *Legionella* species unknown.

Table 2 further illustrates that *Legionella pneumophila* isolates other than serogroup 1 were also detected and reported, but with a low proportion (<20%).

Table 2. Serogroups reported for culture-confirmed cases of *L. pneumophila*, EU/EEA, 2020 and 2021

Serogroup (SG)	2020		2021	
	Number	%	Number	%
1	685	83	890	82
2	5	<1	14	1
3	22	3	46	4

L. pneumophila serogroup mixed	3	<1	3	<1
L. pneumophila serogroup unknown	70	8	93	9
TOTAL	828		1 087	

For over 75% of the cases (8 276), the setting of infection was reported as community-acquired. The increase in comparison with 2020 (Table 3) may be due to fewer cases reported with the setting of infection as unknown (19% to 5%). Healthcare-associated infection was identified as the source in 5% of all the cases reported, which was similar to previous years (range: 5–6%, from 2017–2020). The proportion of cases attributed to travel (domestic and international travel, including stays at private accommodations) was 10%, which was still lower than the travel-associated cases prior to the COVID-19 pandemic.

Table 3. Reported settings of infection for cases of Legionnaires' disease, EU/EEA, 2020 and 2021

Setting	2020		2021	
	Number	%	Number	%
Community-acquired	5 643	67	8 276	77

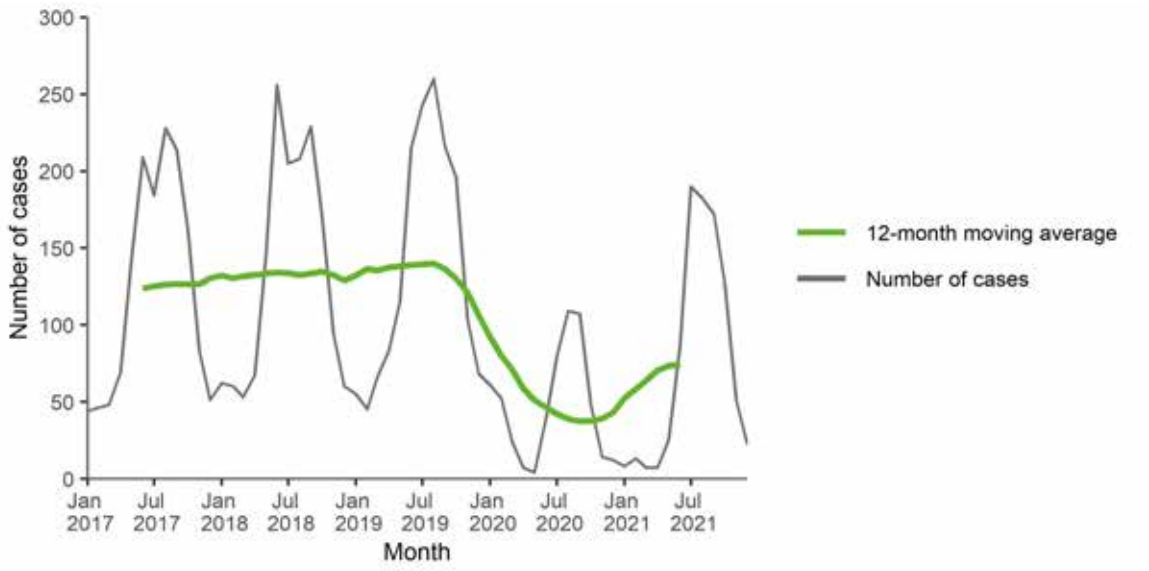
Travel-associated Legionnaires' disease (TALD)

TALD case reports

The European Legionnaires' disease surveillance network (ELDSNet) received reports of 895 cases of TALD with dates of onset in 2021, which is 38% more cases compared to 2020. The overall EU/EEA trend of reported cases of TALD (Figure 5) remained stable between 2017 to 2019, but decreased notably in 2020. This was probably an effect of the COVID-19 pandemic and associated travel restrictions. In 2021, the easing of travel restrictions is the likely reason for the observed increase in notified TALD cases compared to 2020.

Figure 5. Distribution of travel-associated cases of Legionnaires' disease by month, EU/EEA, 2017–2021

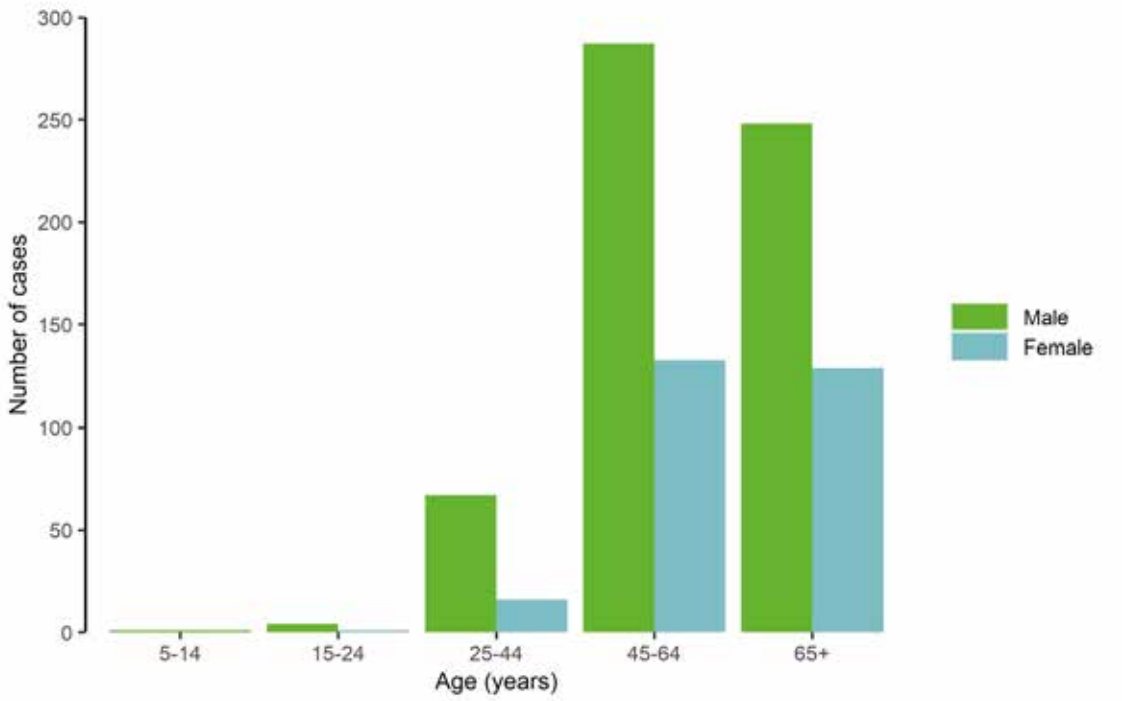


Source: Country reports from Austria, Belgium, Bulgaria, Croatia, Czechia, Denmark, Estonia, Finland, France, Germany, Greece, Hungary, Ireland, Italy, Latvia, Lithuania, Luxembourg, the Netherlands, Norway, Poland, Portugal, Romania, Slovenia, Spain, Sweden, and the United Kingdom (inclusive of data from 2017–2020). The other reporting countries have been excluded from this figure due to missing data from 2017–2021.

TALD cases were reported from 19 countries: 17 EU/EEA countries and two countries outside the EU/EEA. The two countries were, United States (one case) and Switzerland (19 cases). The UK no longer participated in the ELDSNet TALD surveillance scheme from January 2021. The majority (86%; n=722) of all the TALD cases were reported by only four countries: Italy (n=257; 36%), France (n=196; 27%), Germany (n=156; 22%), and the Netherlands (n=113; 16%).

Approximately two-thirds (68%; n=611) of the reported TALD cases were male, which is consistent with previous years. The cases had a median age of 62 years (interquartile range – IQR: 17.5, age range: 10–98 years); 90% of the cases occurred in people aged 45 years and above (Figure 6).

Figure 6. Distribution of travel-associated cases of Legionnaires' disease by age and gender, 2021

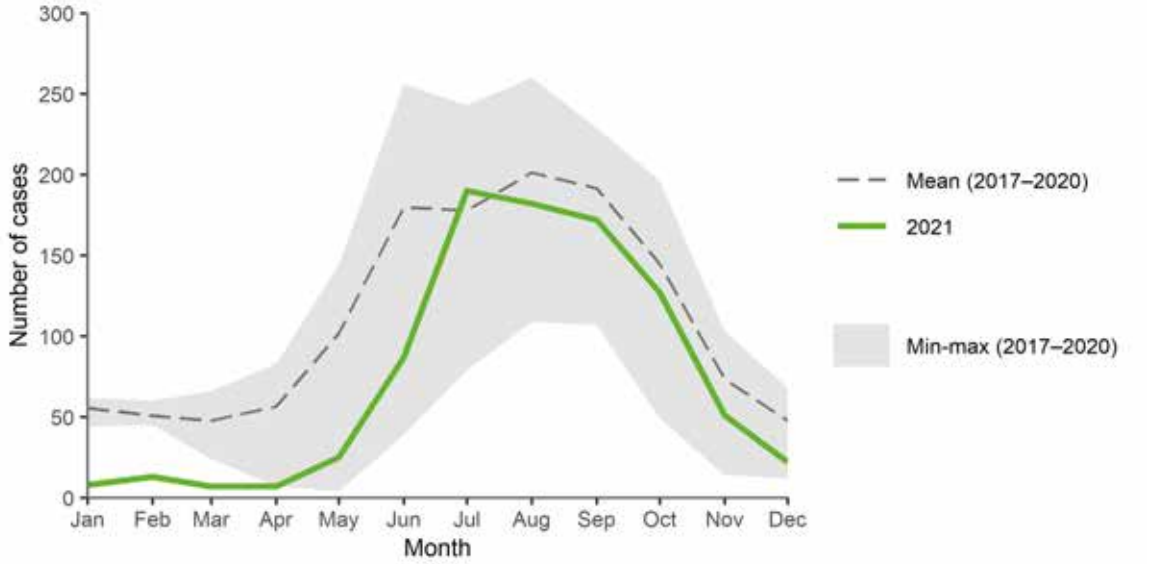


The reported TALD cases were resident in 20 countries. The majority of the cases resided in those countries that reported the most number of cases (Italy, France, Germany, and the Netherlands), while 26 of all cases (3%) were resident outside of the EU/EEA: Switzerland (19), the UK (5), and the United States (2).

In 2021, the median reporting time among countries (from the date of onset of illness, to reporting to ECDC) across countries was 18 days (IQR: 23 days) compared to 22 days (IQR: 42 days) in 2020.

In 2021, three quarters (n=662; 74%) of TALD cases fell ill between July and October, which is consistent with the known seasonality of Legionnaires' disease in Europe. However, there was a slightly delayed start of the summer peak season. This was likely due to the pandemic-related travel restrictions (Figure 7).

Figure 7. Distribution of travel-associated cases of Legionnaires' disease by month, EU/EEA, 2021 and 2017–2020



Source: Country reports from Austria, Belgium, Bulgaria, Croatia, Czechia, Denmark, Estonia, Finland, France, Germany, Greece, Hungary, Ireland, Italy, Latvia, Lithuania, Luxembourg, the Netherlands, Norway, Poland, Portugal, Romania, Slovenia, Spain, Sweden, and the United Kingdom (inclusive of data from 2017–2020). The other reporting countries have been excluded from this figure due to missing data from 2017–2021.

The disease outcome was provided for 473 (53%) TALD cases, with 11 (2%) known to have deceased by the time of reporting to ECDC. The deceased cases were between 47 and 95 years old, and 10 were male. A total of 859 TALD cases (96%) were classified as confirmed, and 36 (4%) as probable. Of 945 total laboratory tests reported in the diagnosis of 895 TALD cases, 90% were UATs, 7% were molecular tests (PCR), 3.5% were cultures, and less than one percent were serologic tests.

Among the cases with known information (n=860), the majority of pathogens were labelled as serogroup 1 *Legionella pneumophila* (n=797; 93%) or *Legionella pneumophila* serogroup unknown (n=40; 5%). A few cases were reportedly infected with other *L. pneumophila* serogroups, including serogroup 10 (three cases), serogroup 3 (one case), serogroup 6 (one case), serogroup 14 (one case), and non-serogroup 1 (16 cases). Monoclonal subtyping results were reported for five cases with *L. pneumophila* serogroup 1: France (one case), Allentown/France (one case), Philadelphia (one case), and Benidorm (two cases). The sequence types were reported to ECDC for only nine TALD cases from three countries: Czechia (three), Denmark (four), and Sweden (two). The sequence types reported for each of the nine cases were different (ST1, ST9, ST23, ST42, ST93, ST114, ST213, ST222 and ST1362).

Travel destinations for TALD cases

The 895 TALD cases reported in 2021 had made a total of 1 125 international journeys. Of these, 1 040 (92%) were within the EU/EEA, 75 (7%) were outside the EU/EEA, and 10 (1%) journeys were on ships. The three destination countries with most TALD-associated travel visits were Italy (n=475, 42%), France (n=220, 20%), and Spain (n=80, 7%). Seventy-seven percent of the overnight stays were in hotels, 10% were on camp sites, 10% in rentals, 1% on ships, and 2% were reported as other types of accommodation.

TALD clusters

In 2021, the ELDSNet surveillance scheme detected 79 new TALD clusters. A TALD cluster is the event of two cases having visited the same accommodation site within a two-year period [4]. The clusters were associated with accommodations in 14 countries worldwide (10 within the EU/EEA, and four outside the EU/EEA) and two ships. Of the 79 new clusters, 51 clusters (65%) comprised only two cases, 26 (33%) had between three and six cases, and one cluster each had 10 and 11 cases, respectively. In 2021, ECDC shared 11 summary reports of type 1 TALD clusters (clusters outside the EU/EEA) with tour operators, and 19 summary reports of type 2 TALD clusters (rapidly evolving clusters, i.e. three or more cases associated within a period of three months) [4].

The names of five accommodation sites were published by ECDC, because country assessments reported that recommendations from the competent authorities were not implemented in a satisfactory way.

Outbreak

In 2021, 27 out of 30 countries participated in the annual outbreak reporting surveillance scheme. Eight EU/EEA countries (Belgium, Germany, Italy, France, Finland, the Netherlands, Portugal, and Spain) reported a total of 19 outbreaks, ranging from one to five per reporting country. In total, 137 outbreak-related confirmed cases were reported. The number of cases per reported outbreak ranged from 3–18 confirmed cases.

Nineteen EU/EEA countries (Austria, Bulgaria, Cyprus, Czechia, Denmark, Estonia, Greece, Hungary, Ireland, Latvia, Liechtenstein, Lithuania, Luxembourg, Malta, Norway, Romania, Slovakia, Slovenia, and Sweden) reported no outbreaks of Legionnaires' disease in 2021.

Seven (37%) of the 19 reported outbreaks in the EU/EEA in 2021, were reported as community outbreaks, which were proportionally more than the previous years of reporting. During the period 2016–2020, the number of reported community outbreaks ranged between 2–8, contributing to about 14% of annual outbreaks. One outbreak was reported to be associated with a car wash, and another was reported to be linked with a municipal water system. Five outbreaks had a positive match with environmental samples. However, this information was only available for 12 out of the 19 outbreaks reported.

Discussion

The notification rate of cases of Legionnaires' disease increased in 2021 in comparison with 2020, reaching the highest level ever reported through ECDC surveillance in the EU/EEA. This increased annual notification rate may not be unexpected considering the increasing trend observed in recent years prior to the COVID-19 pandemic [6]. The seasonality pattern was similar to previous years, despite a higher peak in the number of cases observed in July. The occurrence of a sporadic high monthly count as noted in July had been previously observed in June 2018. No surveillance-related cause for this increase could be identified, e.g. reporting, definitions, or diagnostic practice. Similar to other years within the last decade, climate records indicate that temperatures are increasing in Europe in summer, with 2021 being among the highest recorded to date. Of note, some countries were also affected by severe flooding in July 2021 [7].

The main characteristics of cases of Legionnaires' disease reported in 2021 were similar to 2020, with most cases being sporadic, community-acquired, and among those aged over 45 years. The disease continues to affect males more than females, and reaches the highest rates in those aged 65 years and above.

A number of countries continue to have very low notification rates below 0.5 cases per 100 000 population. This probably represents an underestimation of the case incidence in these countries. As only 11% of cases are reported with a culture-confirmed diagnosis, there is a likely underestimation of the burden of disease caused by the *Legionella* species across the EU/EEA other than *Legionella pneumophila*.

In 2021, outbreaks were detected and investigated in several countries. Proportionally more community outbreaks were reported compared to previous years, though the number of cases per outbreak were similar.

The cause of the higher notification rate observed in Europe both in the years immediately preceding 2020, and in 2021 during the COVID-19 pandemic, remains unknown. Factors that may explain these increases include: changes in national testing policies and surveillance systems, an ageing EU/EEA population, the design, infrastructure, and maintenance of water systems used in buildings. Changes in climate and weather patterns across Europe and worldwide can also impact both the ecology of *Legionella* in the environment and the exposure to water aerosols containing the bacteria.

Public health implications

Legionnaires' disease remains an important cause of potentially preventable morbidity and mortality in Europe.

The overall EU/EEA notification rates have been rising in the last few years, although there was a decrease observed in 2020 during the first phase of the pandemic when stringent restrictions were in place. Variation in rates across EU/EEA countries remain, which likely reflect the under-diagnosis of this disease in many Member States. Support to countries with very low notification rates remains a priority to improve both the diagnosis and reporting of Legionnaires' disease to public health authorities.

Outbreaks of Legionnaires' disease with varying sizes and causes continue to be identified and investigated by public health authorities in EU/EEA countries. Due to the relatively high mortality associated with the disease and the considerable challenges for the rapid identification and control of environmental sources, it remains important to be vigilant to detect clusters and outbreak events through surveillance.

As the detection of TALD clusters through the ELDSNet surveillance scheme leads to investigations and preventive actions at accommodation sites by participating countries, cluster detection through this multi-country joint surveillance scheme shows its importance for public health.

To support the strengthening of surveillance and outbreak investigation capacity in European countries, in 2019, ECDC started an annual external quality assessment (EQA) scheme on clinical and environmental samples of *Legionella* species. Annual summary reports for the results of this EQA scheme are published by ECDC [8].

Regular checks for the presence of *Legionella* bacteria and appropriate control measures applied to engineered water systems [9] can prevent cases of Legionnaires' disease at tourist accommodation sites, hospitals, long-term healthcare facilities, or other settings where sizeable populations at higher risk may be exposed to aerosols containing the bacteria.

ABSTRACT Carbapenem-resistant *Enterobacteriaceae* (CRE) represent a health threat, but effective control interventions remain unclear. Hospital wastewater sites are increasingly being highlighted as important potential reservoirs. We investigated a large *Klebsiella pneumoniae* carbapenemase (KPC)-producing *Escherichia coli* outbreak and wider CRE incidence trends in the Central Manchester University Hospital NHS Foundation Trust (CMFT) (United Kingdom) over 8 years, to determine the impact of infection prevention and control measures. Bacteriology and patient administration data (2009 to 2017) were linked, and a subset of CMFT or regional hospital KPC-producing *E. coli* isolates ($n = 268$) were sequenced. Control interventions followed international guidelines and included cohorting, rectal screening ($n = 184{,}539$ screens), environmental sampling, enhanced cleaning, and ward closure and plumbing replacement. Segmented regression of time trends for CRE detections was used to evaluate the impact of interventions on CRE incidence. Genomic analysis ($n = 268$ isolates) identified the spread of a KPC-producing *E. coli* outbreak clone (strain A, sequence type 216 [ST216]; $n = 125$) among patients and in the environment, particularly on 2 cardiac wards (wards 3 and 4), despite control measures. ST216 strain A had caused an antecedent outbreak and shared its KPC plasmids with other *E. coli* lineages and *Enterobacteriaceae* species. CRE acquisition incidence declined af-

ter closure of wards 3 and 4 and plumbing replacement, suggesting an environmental contribution. However, ward 3/ward 4 wastewater sites were rapidly recolonized with CRE and patient CRE acquisitions recurred, albeit at lower rates. Patient relocation and plumbing replacement were associated with control of a clonal KPC-producing *E. coli* outbreak; however, environmental contamination with CRE and patient CRE acquisitions recurred rapidly following this intervention. The large numbers of cases and the persistence of bla_{KPC} in *E. coli*, including pathogenic lineages, are of concern.

KEYWORDS antimicrobial resistance, carbapenemase-producing *Enterobacteriaceae*, genome sequencing, infection control, molecular epidemiology

Carbapenem-resistant *Enterobacteriaceae* (CRE) represent a global public health threat (1). Major carbapenemases include the metallo-β-lactamases, some oxacillinases, and the *Klebsiella pneumoniae* carbapenemase (KPC) (encoded by bla_{KPC}), one of the most common carbapenemases globally (2). Transfer of carbapenemase genes on mobile genetic elements has resulted in rapid interspecies dissemination of carbapenem resistance (3, 4). Since few therapeutic options remain for CRE infections (5, 6), effective control is critical.

Escherichia coli is a major human pathogen, but it also a gastrointestinal commensal and can be transmitted between humans and the environment. Carbapenem resistance in *E. coli*, including that encoded by bla_{KPC}, is increasing (7, 8) but is uncommon, and KPC-producing *E. coli* outbreaks have not been observed to date. The emergence and persistence of carbapenem resistance in *E. coli* in human and/or environmental reservoirs are of concern.

CRE detections in England have increased since 2008 (9) and are approximately 10 times the national average in Greater Manchester (10). Central Manchester University Hospital NHS Foundation Trust (CMFT) has experienced an ongoing, multispecies, bla_{KPC}-associated CRE outbreak since 2009. Intensive infection prevention and control (IPC) measures, in line with national and international recommendations (11–13), have been implemented in response.

In 2015, a sudden increase in cases of fecal colonization with KPC-producing *E. coli* was detected in the Manchester Heart Centre (MHC) at the Manchester Royal Infirmary (part of CMFT). We retrospectively investigated the genomic epidemiology and evidence for nosocomial transmission of KPC-producing *E. coli* and KPC plasmids isolated from patients and the environment in this context, and we assessed the impact of guideline-compliant IPC bundles on CRE and KPC-producing *E. coli* incidence.

RESULTS

High prevalence of CRE colonization in the MHC. Between 1 April 2014 and 30 December 2014, 23 new CRE-colonized individuals were detected in the MHC, including 2 with *E. coli* (Fig. 1A). A CRE outbreak was declared on 2 January 2015, when 6 new CRE-colonized individuals were identified (4 with bla_{KPC} and 2 with bla_{NDM}; no *E. coli*). Consequently, intensified IPC measures were implemented (Fig. 1B; also see Table S1 in the supplemental material), and wards 3 and 4 were closed (on 6 January 2015), terminally cleaned (with hypochlorite), and decontaminated (with hydrogen peroxide vapor). Ward 3 was reopened on 11 January 2015, and ward 4 was reopened on 23 January 2015. High-risk patients (with previously detected CRE or a history of hospitalization abroad or in a UK hospital with known CRE transmission in the past 12 months) were screened; CRE-positive patients were transferred to a cohort ward or, if they required cardiac monitoring, to side rooms.

By January 2015, CMFT was operating a Trustwide CRE screening program (>110 screens/day) (Table S2). Between 1 September 2014 and 30 December 2014, screening transitioned from culture-based methods to PCR-based methods; during this period, 16,612 samples from 7,239 inpatients were screened using either culture (9,808 samples) or PCR and culture (6,804 samples), with an overall CRE prevalence of 3.8% (438

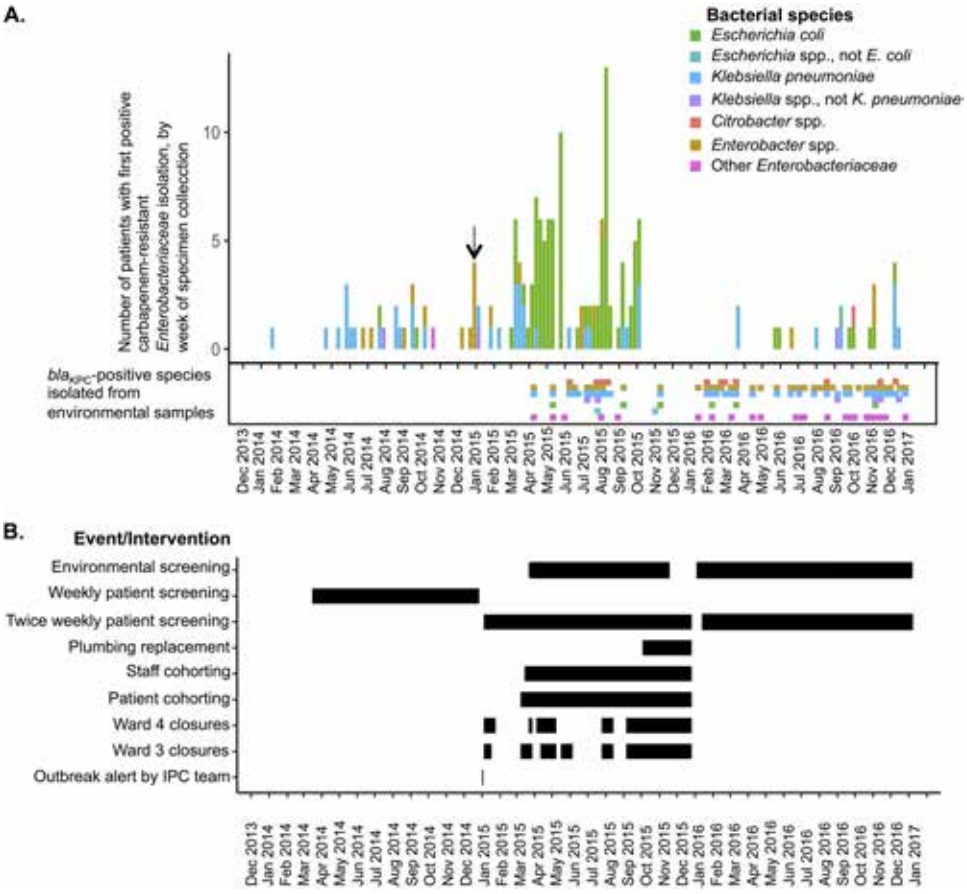

FIG 1 (A) Numbers of individuals in MHC wards with first CRE-positive detection, by week, stratified by genus group and species of the organism isolated. The bla_{KPC}-positive *Enterobacteriaceae* strains detected in environmental samples over the same time frame are also shown. The MHC outbreak was declared by the IPC team in the first week in 2015 (arrow). (B) Timeline of IPC measures instituted.

positive samples from 272 patients). Molecular mechanism data for 135/163 PCR-positive samples (83%) indicated that bla_{KPC} accounted for most carbapenem resistance (97%).

KPC-producing *E. coli* outbreak despite IPC interventions. Following the implementation of enhanced IPC activity, there was a further sharp increase in the number of CRE-colonized patients detected from 9 March 2015 (carbapenem-resistant [CR] *E. coli* and other species, mostly containing bla_{KPC} and a few with bla_{NDM}) (Fig. 1A). Ward 3 was again closed to admissions (from 11 March 2015 to 28 March 2015), and environmental decontamination was repeated; the following week, ward 4 was closed after detection of additional CRE-colonized patients (Fig. 1A and B). From 1 April 2015, KPC-producing *E. coli* predominated in the outbreak (Fig. 1A).

From April to September 2015, wards 3 and 4 were closed repeatedly, with 2 peaks in KPC-producing *E. coli* patient colonization (in April to May and in August) (Fig. 1B). Ward 3 capacity was reduced to 10 day-case beds (on 12 August 2015; day-case patients were not screened for CRE) and ward 4 capacity to 12 inpatient beds. Between 10 August 2015 and 28 September 2015, there were 27 new KPC-producing *E. coli* colonizations detected in the MHC (Fig. 1A) and 2 cases with other KPC-producing *Enterobacteriaceae* species. Of 88 KPC-producing *E. coli* cases between 24 February 2015 and 28 September 2015, 86 (98%) represented colonizations only; 1 individual additionally had a urinary tract infection and 1 a sternal wound infection (treated with gentamicin and ciprofloxacin, respectively, to which the isolates were susceptible).

CR *E. coli* cases in CMFT. CR *E. coli* had been isolated in CMFT prior to the 2015 MHC outbreak, with 514 CR *E. coli* cases (considering first positive results by patient from

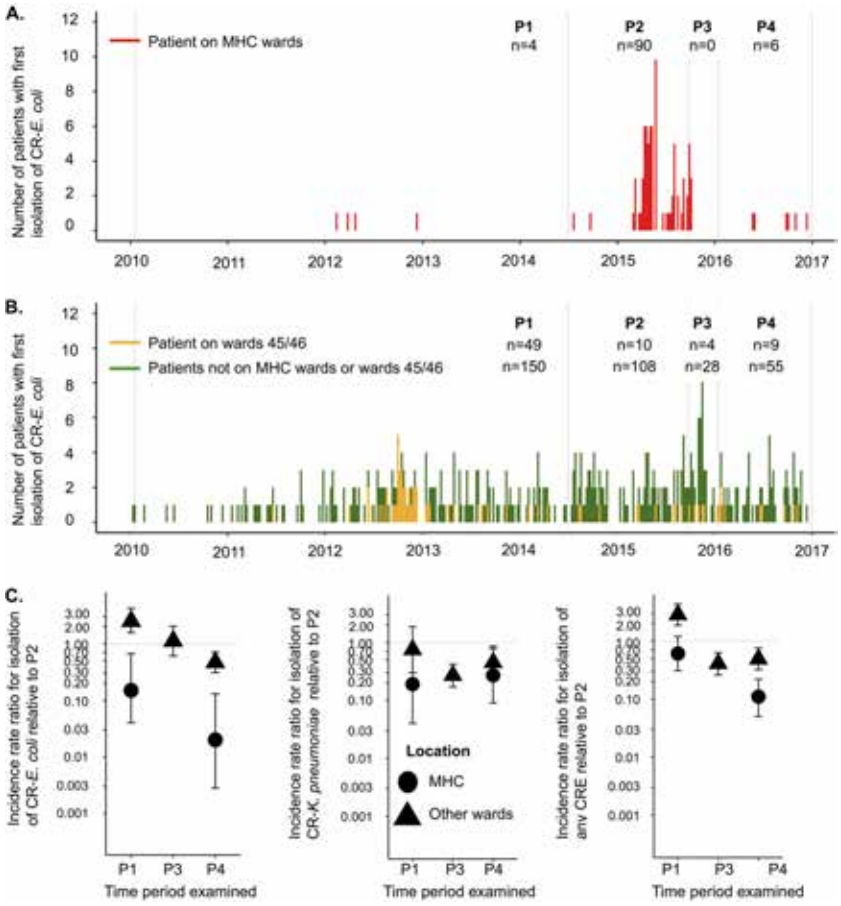

FIG 2 (A and B) Counts of individuals with first CR *E. coli* detection by ward location. Detections on days 0 and 1 of admission are excluded. Faint vertical lines correspond to the boundaries of the 4 time periods, as follows: period 1 (P1), prior to implementation of a systematic CPE rectal screening policy; period 2 (P2), implementation of a CPE rectal screening policy consistent with national guidance; period 3 (P3), closure of wards 3 and 4 and replacement of plumbing infrastructure; period 4 (P4), reopening of wards 3 and 4 to patient admissions. (C) Incidence rate ratios for rates of first positive CR *E. coli* detection, carbapenem-resistant *K. pneumoniae* detection, and any CRE detection ≥2 days postadmission, relative to period 2 in the same location (MHC versus the rest of CMFT). An incidence rate ratio is not shown for period 3 in the MHC due to unit closure during this period, to facilitate plumbing replacement.

clinical/screening isolates) in 2010 to 2016 (inclusive), including a separate outbreak on the gerontology wards (wards 45 and 46) in late 2012 (Fig. 2A and B). Of those, 434 cases were detected on day ≥2 of admission and 80 on day 0 or 1 of admission. Case peaks were not related to screening policy changes or rates (Fig. S6). CR *E. coli* strains were detected almost invariably from rectal screening samples (420/434 cases [97%]).

Environmental sampling yielding CRE from sinks and drains. Intermittent environmental sampling was undertaken to identify potential reservoirs. Overall, 927 samples from 833 sites were obtained between 9 April and 17 November 2015; 355 samples (38%) from 333 sites (40%) were from ward 3 or ward 4, and the remainder were from 11 other wards. A total of 850 samples were from sink/drain/shower/bath sites, 18 from toilets, hoppers, or sluices, and 33 from high-touch sites (including keyboards, door handles, and sponges; the labeling was unclear for 26 samples). Eighty-five samples (9%) and 72 sites (9%) were CRE positive, including 26/355 samples (7%) from 21/333 sites (6%) in wards 3 and 4. CRE-positive sites included shower drains ($n = 19$), sink taps ($n = 7$), sink drain tailpieces ($n = 10$), sink drain strainers ($n = 8$), sink trap water ($n = 1$), toilet bowls ($n = 1$), and other sites ($n = 26$). Common isolates cultured included *Klebsiella* spp. ($n = 34$), *Enterobacter* spp. ($n = 25$), and *E. coli* ($n = 11$) (Fig. 1A). All CRE-positive cultures were from wastewater/plumbing-associated sites; no other sites tested were CRE positive.

[a]Four time periods were evaluated, as follows: period 1, prior to implementation of a systematic CPE rectal screening policy; period 2, implementation of a CPE rectal screening policy consistent with national guidance; period 3, closure of wards 3 and 4 and replacement of plumbing infrastructure; period 4, reopening of wards 3 and 4 to patient admissions. Period 2 was chosen as the reference period because of the change in screening policies between period 1 and period 2 (see Table S2 and Fig. S6 in the supplemental material), meaning that a greater incidence would be expected in period 2, due to more patients being screened every week. IRR, incidence rate ratio; CI, confidence interval.

Of 10 sites yielding 11 KPC-producing *E. coli* isolates, 5 were in the ward 3/ward 4 kitchen (14 to 18 May 2015 [$n = 4$] and 10 September 2015 [$n = 1$]), 1 was a ward 4 staff sink (14 May 2015), and 4 were kitchen sinks or drains on wards 31 and 32 (sampling in response to a separate ward 31/32 outbreak, 12 to 17 November 2015). Ward 3/ward 4 sink-specific interventions included sink trap replacement for CRE-colonized sinks (16 April 2015, 31 July 2015, and 11 August 2015) and horizontal pipework cleaning with a brush to try to remove biofilms (11 August 2015).

Cardiac service relocation and decline in CRE colonization incidence. Given the ongoing difficulty in preventing KPC-producing *E. coli* acquisitions and the isolation of KPC-producing *E. coli* from sink and drain sites, wards 3 and 4 were closed from 25 September 2015 and patients were relocated to another ward to allow replacement of the plumbing infrastructure back to the central drainage stacks. Replaceable sink plughole devices designed to prevent water aerosolization in the sink U-bend and to limit biofilm formation (HygieneSiphon; Aquafree) were installed.

Controlling for screening and compared to the period immediately before intervention (when screening policies were the same), the incidence of first detection of any CRE or *E. coli* strain decreased significantly following the plumbing intervention, both in the MHC and elsewhere in the hospital (Fig. 2C and Table 1). The decline in incidence was significantly greater in the MHC (heterogeneity $P < 0.001$), where incidence fell by 89% for any CRE strain and by 98% for CR *E. coli*. The incidence of CR *K. pneumoniae* also decreased significantly in both settings, but there was no evidence that the declines differed between the two settings (heterogeneity $P = 0.31$) (Table 1). However, when patients were transferred back to wards 3 and 4 (from 18 January 2016), CR *E. coli* continued to be detected in patients (6 first detections in 2016) (Fig. 2A). Patient colonization with other CRE strains was also observed, in numbers similar to those for 2014 (Fig. 1A); environmental contamination with CRE in sink and wastewater sites recurred rapidly (Fig. 1A), and 2 environmental sites (both ward utility room sink drains) were CRE positive even prior to patient readmissions to the ward, suggesting residual contamination after the plumbing replacement or reintroduction following the plumbing replacement but prior to patient readmissions.

Genomic epidemiology of KPC-producing *E. coli*. A total of 268 clinical and environmental CR *E. coli* isolates were sequenced, including 82 isolates from the MHC

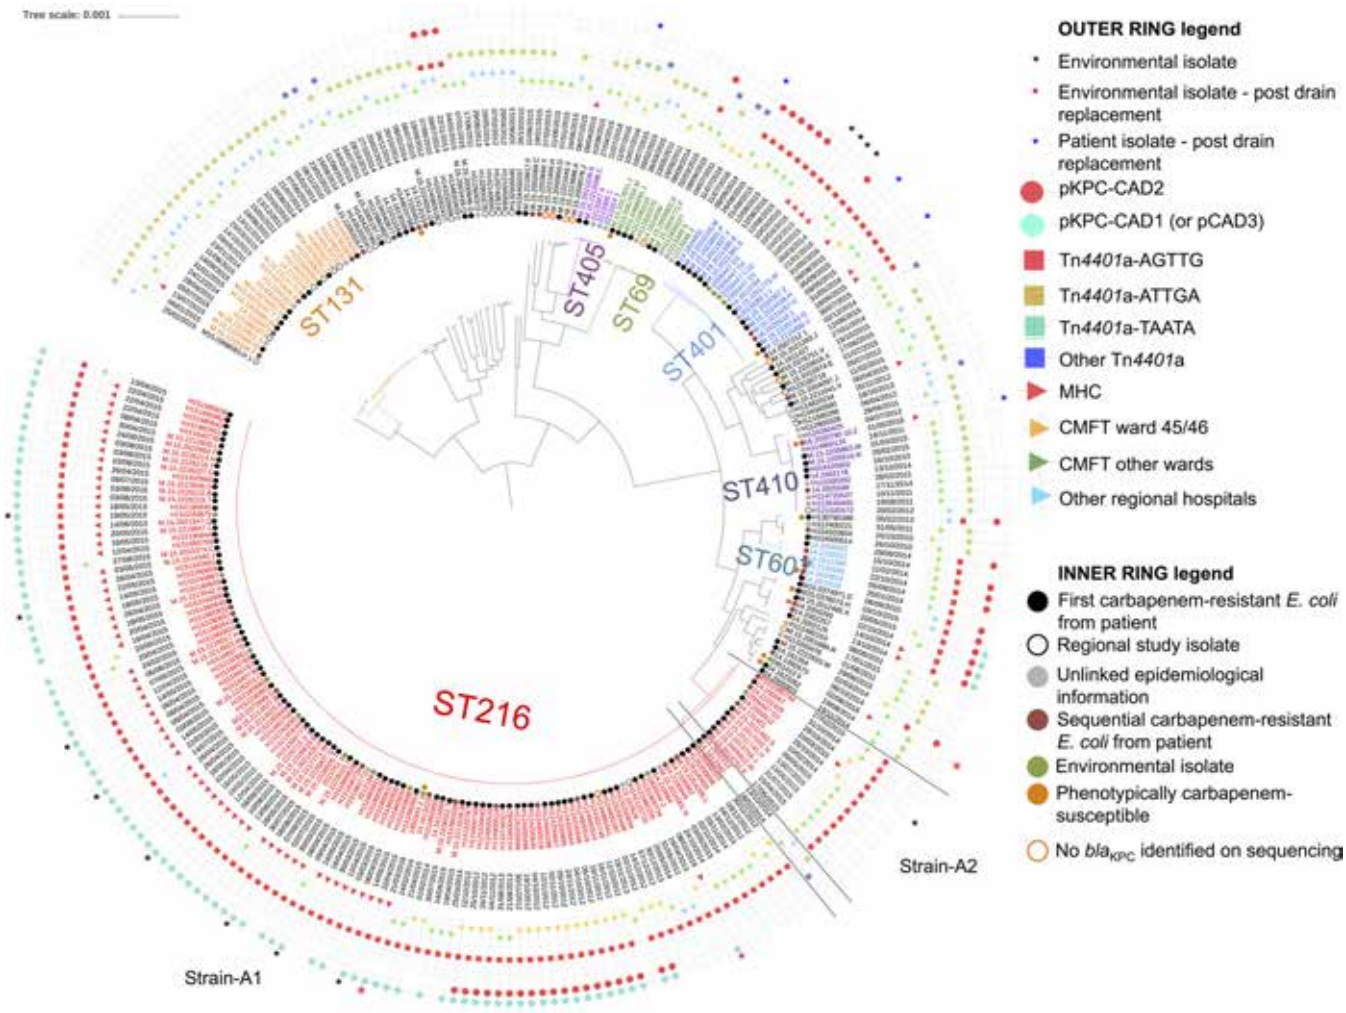

FIG 3 Recombination-corrected phylogeny of 259 sequenced KPC-producing *E. coli* isolates (and 9 *E. coli* isolates that were bla_{KPC} negative on sequencing) from CMFT and other regional hospitals in northwest England, annotated with collection date, ward/center location, Tn*4401* type, and outbreak plasmid types. The earliest available sequences per patient are denoted "first carbapenem-resistant *E. coli* from patient" if the stored isolate collection date was ≤7 days from the first isolation date in the TRACE database or "sequential carbapenem-resistant *E. coli* from patient" if the stored isolate date was after that. KPC-producing *E. coli* isolates from a Public Health England (PHE) project that sequenced the first 10 KPC-producing *Enterobacteriaceae* strains from hospitals in northwest England (2009 to 2014) are denoted "regional study isolate." "Environmental isolate" denotes KPC-producing *E. coli* strains cultured during an initial environmental prevalence survey on wards 3 and 4 (10 March 2015), any KPC-producing *E. coli* strain isolated as part of subsequent, intermittent, IPC-associated environmental sampling (9 April 2015 to 17 November 2015), and isolates available at the time of analysis from environmental and patient samples from a separate ongoing study (commenced January 2016).

(2015 to 2016 [16 environmental isolates]), 36 from wards 45 and 46 (2010 to 2016), 109 from other CMFT wards or units, and 41 from other regional hospitals (Table S3). Nine isolates were bla_{KPC} negative on sequencing; 5 of those isolates contained bla_{OXA-48}, 1 $bla_{OXA-181}$, and 1 bla_{NDM-5}, with no known carbapenem resistance mechanisms identified for the remaining 2. The 259 KPC-producing *E. coli* isolates included all 16 environmental CR *E. coli* isolates, 158 isolates that were the first CR *E. coli* isolates cultured from patients, and 38 sequentially cultured CR *E. coli* isolates from patients (longitudinal cultures from 12 patients); sequencing and patient epidemiological identifiers could not be linked for 47/259 isolates.

Forty sequence types (STs), including known pathogenic lineages (e.g., ST131), occurred among the KPC-producing *E. coli* isolates (Fig. 3; also see Table S3), highlighting regional KPC-producing *E. coli* diversity. In contrast, 67/80 MHC isolates (84%) were ST216, compared with 59/179 (33%) elsewhere. ST216 has rarely been reported in other settings.

ST216 KPC-producing *E. coli*. The ST216 KPC-producing *E. coli* group ($n = 126$, including 1 bla_{KPC}-negative isolate [H134880341]; 9,118 variable sites) was represented by 2 main genetic subgroups, consisting of 112 isolates (the main outbreak strain [strain A1 in Fig. 3]; ≤65 single-nucleotide variations [SNVs] among isolates in this cluster [2012 to 2016]) and 12 isolates (the secondary outbreak strain [strain A2 in Fig. 3]; ≤25 SNVs among isolates in this cluster and >7,800 SNVs divergent from strain A1 isolates [2012 to 2015]). Although the SNV-based distances between strains A1 and A2 were large, review of the ClonalFrameML output suggested that these differences represented a single "mega-recombination event" affecting ~1 Mb of the genome (Fig. S7).

All except 3 ST216 isolates carried bla_{KPC-2} in a Tn*4401*a transposon (14), which is typically associated with high-level bla_{KPC} expression (15), flanked by a 5-bp target site duplication, AGTTG, which was previously observed only with the Tn*4401*b isoform in an isolate from Colombia (Fig. 3; also see Table S3). This relatively unique transposon-flanking sequence unit was also observed in other lineages within CMFT (e.g., ST401) (Fig. 3). However, plasmid and resistance gene profiles varied considerably, even to some extent within the ST216 KPC-producing *E. coli* outbreak strains (Fig. 3; also see Fig. S8). Overall, these results demonstrated clonal expansion of specific KPC-producing *E. coli* strains, with significant accessory genome mobility. Most notable were the emergence and persistence of ST216 KPC-producing *E. coli* strain A1, which was isolated from patients and the environment over 4 years and caused outbreaks in wards 45 and 46 (2012) and the MHC (2015).

Long-read sequencing demonstrated that the ST216 KPC-producing *E. coli* strain A1 isolate H124200646 (ward 46 [2012]) contained 2 plasmids, pKPC-CAD2 (307 kb; IncHI2/HI2A, with bla_{KPC} present) and pCAD3 (152 kb; IncFIB/FII, with bla_{KPC} absent); 83% of pKPC-CAD2 was highly similar (99% sequence identity) to pKPC-272 (282 kb, *Enterobacter cloacae*; GenBank accession no. CP008825.1), which was identified in a sink drain in the National Institutes of Health Clinical Centre in 2012 (16). The other long-read sequence, H151860951 (ward 4 [April 2015]), which was also an ST216 KPC-producing *E. coli* strain A1 isolate, contained a bla_{KPC} plasmid, pKPC-CAD1 (200 kb; IncFIB/FII), which had 99% sequence identity to pCAD3 over 76% of its length, together with a 48-kb contiguous region including bla_{KPC} that was 99% identical to part of pKPC-CAD2 (Fig. 4A). These results suggest the evolution of a bla_{KPC} plasmid similar to pKPC-272 in CMFT within ST216 KPC-producing *E. coli* strain A from 2012 to 2015, including recombination between pKPC-CAD2 and pCAD3, giving rise to pKPC-CAD1. Although plasmid typing based on mapping of short-read data to plasmid references should be interpreted cautiously, sequence comparisons with the outbreak plasmids pKPC-CAD1 and pKPC-CAD2 were consistent with the emergence of pKPC-CAD1 and its domination within ST216 KPC-producing *E. coli* strain A after 2014, as well as exchange of pKPC-CAD1, pKPC-CAD2, and pCAD3 with other *E. coli* STs (Fig. 3 and 4B).

Environmental CRE isolates. Thirty environmental CRE isolates from wards 3 and 4 were sequenced, 27 of which were isolated prior to the plumbing replacement and 16 of which were CR *E. coli*, as described above (13 isolated prior to the plumbing replacement). Eleven of the 16 *E. coli* isolates were ST216 KPC-producing *E. coli* strains (10 strain A1 and 1 strain A2), isolated on 8 separate days (in March, May, and September 2015 and February 2016), consistent with transmission between patients and the environment (Fig. 3) and persistence or reintroduction following the plumbing replacement. The other 14 isolates represented diverse KPC-producing CRE species, including *K. pneumoniae* ($n = 7$), *Citrobacter freundii* ($n = 4$), *Klebsiella oxytoca* ($n = 1$), *Enterobacter cloacae* ($n = 1$), and *Kluyvera intermedia* ($n = 1$). The KPC plasmids in these KPC-producing CRE isolates likely included the outbreak plasmids pKPC-CAD1 and pKPC-CAD2, pKpQIL, and other plasmids, consistent with the interspecies transfer of a diverse set of bla_{KPC} plasmids.

DISCUSSION

Our detailed analyses of the largest institutional KPC-producing *E. coli* outbreak described to date demonstrate a complex genetic and epidemiological picture, includ-

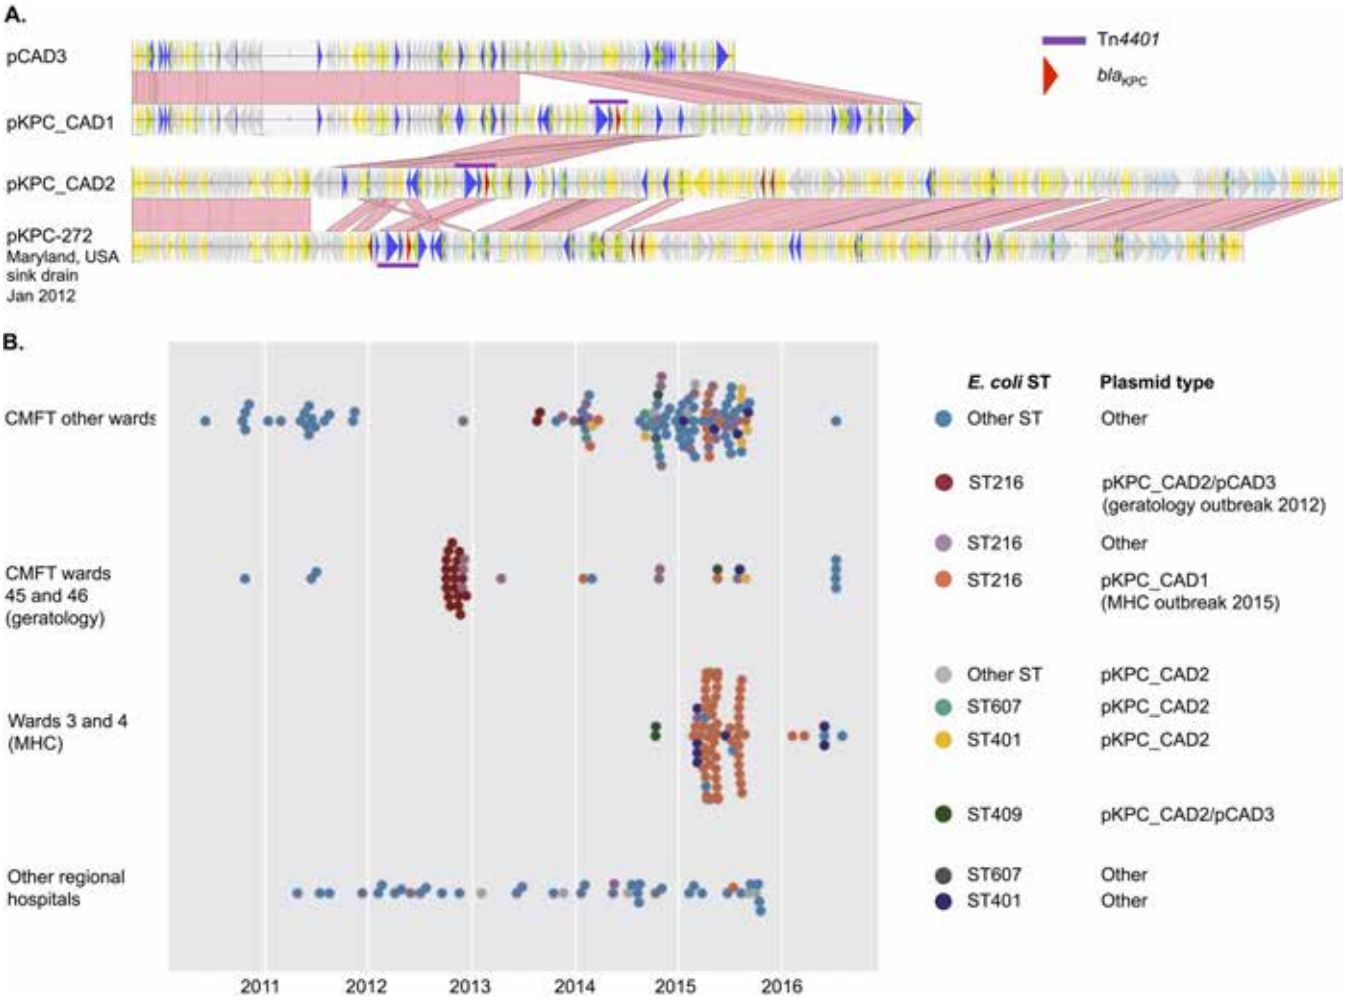

FIG 4 (A) Alignments of the 2012 MHC outbreak KPC plasmid pKPC-CAD2 (wards 45 and 46; Tn*4401a* plus bla_{KPC}) and the 2015 MHC KPC plasmid pKPC-CAD1 (Tn*4401a* plus bla_{KPC}), highlighting the recombination of the Tn*4401a*- and bla_{KPC}-harboring 48-kb segment from pKPC-CAD2 with pCAD3 to generate pKPC-CAD1. Regions of sequence homology are represented by pink links drawn between alignments. pKPC-272 (GenBank accession no. CP008825.1), a plasmid identified in an isolate from a sink drain at the National Institutes of Health Clinical Centre in Maryland in 2012, demonstrates significant sequence homology with pKPC-CAD2. (B) Incidence plot of different *E. coli* STs and likely MHC-related KPC plasmid types across hospital locations.

ing the emergence of ST216 KPC-producing *E. coli* strain A1 as a significant clone in CMFT, causing the major 2015 MHC outbreak, an antecedent outbreak in 2012, and sporadic cases and small clusters in other wards and regional health care settings. Plasmid-associated dissemination of bla_{KPC} to other *E. coli* lineages, including recognized high-risk clones such as ST131, was evident and the problem was substantial, with 514 confirmed patient acquisitions of CR *E. coli* over a 6-year period.

Environmental sampling on wards 3 and 4 confirmed that sinks and drains were colonized by multiple CRE strains, including the ST216 KPC-producing *E. coli* strains A1 and A2 and other CRE strains containing the outbreak KPC plasmids (pKPC-CAD1 and pKPC-CAD2), potentially representing a persistent reservoir between patient-associated outbreaks and plausibly explaining why this large outbreak was refractory to standard IPC bundles. Supporting this, the incidence of new CR *E. coli* detections declined substantially after ward plumbing replacement and temporary relocation of patients (Fig. 1A and 2A and C), consistent with a major contribution from the ward environment. After wards 3 and 4 reopened, however, the environment was rapidly recontaminated, including with ST216 KPC-producing *E. coli* strain A1, and CRE strains were again detected in patients, suggesting that this type of intervention has limited durability. National and international guidelines on CRE management recommend

A48235836

rectal screening, strict contact precautions, isolation/cohorting of cases, and antimicrobial stewardship to limit transmission (12, 13, 17), all measures already being implemented in CMFT. Current guidelines do not address the control of large persistent outbreaks or provide advice on the sampling and management of environmental reservoirs, and there is limited evidence in support of any given measure (18). It is unclear why a particular strain of KPC-producing *E. coli* predominated in the outbreak described, as opposed to other CRE strains found contemporaneously in the environment; differences in the gastrointestinal colonization ability of species or an unidentified point source are potential hypotheses.

The response to this outbreak caused major disruption to the hospital and regional cardiac services. Given that almost all cases represented colonizations and not infections, the risks of associated delays in cardiac interventions were debated, although the impacts were not formally quantified. The estimated cost to CMFT of CRE in the first 8 months of 2015 was £5.2 million (19), and the MHC outbreak contributed significantly to this, with approximately £240,000 being spent on the ward 3/ward 4 plumbing replacement.

The study has several limitations, including its observational nature, with only 1 year of follow-up monitoring after the ward 3/ward 4 plumbing replacement. Limited environmental sampling might have meant that the extent of contamination and the diversity of CRE in environmental niches were underestimated. Environmental sampling was restricted to wards in which CRE outbreaks had been detected, and it focused predominantly on sink/drain sites (because initial sampling suggested that those sites were most heavily contaminated); however, component parts of each sink drainage system were not sampled consistently due to resource issues, and the relative prevalence of CRE isolation from any given site type needs to be interpreted with caution. We sequenced only single isolates cultured from individuals at any given time point, due to resource limitations, and therefore might have underestimated the CRE strain diversity within patients. Other non-*E. coli Enterobacteriaceae* strains were not comprehensively sequenced, possibly underestimating dissemination of pKPC-CAD1 and pKPC-CAD2; however, even our limited sequencing of CRE strains from the environment in 2015 identified those plasmids (and other KPC plasmids) in multiple species. Although genetic overlap between environmental and patient isolates was consistent with transmission between these compartments (Fig. 3), the numbers were too small to infer directionality. Of the predominant KPC plasmid types present within the ST216 KPC-producing *E. coli* strain A1 outbreak clone, one (pKPC_CAD2) was transferred to multiple *E. coli* STs (Fig. 3 and 4B), and another (pKPC_CAD1) might have contributed to the clone's success from 2014 (Fig. 4B), although the genetic and biological mechanisms underpinning this have not been explored.

Our experience highlights the limited evidence for managing large CRE outbreaks, including environmental sampling protocols and interventions, despite numerous centers reporting similar experiences with wastewater sites acting as CRE reservoirs (18, 20–23). Widespread colonization with KPC-producing *E. coli* is a concern, as *E. coli* is a common gastrointestinal colonizer and cause of infection, and any stable association between *bla*$_{KPC}$ and *E. coli*, particularly in pathogenic lineages such as ST131 (Fig. 3), represents a significant clinical and transmission threat. Although our analyses focused on CRE, similar wider environmental contamination and dissemination of carbapenem-susceptible *Enterobacteriaceae* seem plausible. A more robust evidence base delineating transmission networks (including initial contamination of sink sites), drivers, and effective control measures (including differential impacts of decontamination methods on particular species and strains) is needed to minimize the financial, clinical, and social impacts of CRE outbreaks.

MATERIALS AND METHODS

Setting. CMFT is one of the largest hospital trusts in northwest England. The MHC manages >10,000 patients/year and in 2015 included two 28-bed inpatient wards (wards 3 and 4), an acute facility (ward 35), an intensive care unit, and a cardiac catheter laboratory. Ward 3 and ward 4 both included 3 bays and 4 single-patient side rooms, with a shared kitchen (see Fig. S1A and B in the supplemental material).

Downloaded from http://aac.asm.org/ on January 7, 2020 by guest

A48235836

IPC measures. CRE screening and IPC measures, based on UK guidelines (11), were implemented Trust-wide from mid-2014. Enhanced measures were introduced in April 2015 in response to the MHC KPC-producing *E. coli* outbreak (Table S1). In addition, wards 3 and 4 (where most KPC-producing *E. coli* cases were observed) were closed to replace the plumbing infrastructure back to the drainage stacks (Fig. S2) from September 2015. Staff screening was not undertaken, consistent with national guidelines (11).

Patient CRE screening. Rectal swabs were screened for CRE using selective chromogenic agar, i.e., ChromID CARBA (bioMérieux) (published sensitivity, 89 to 100%; specificity, 95% [24–26]) to August 2014 and the Cepheid Xpert Carba-R assay (published sensitivity, 97 to 100%; specificity, 99% [27, 28]) from August 2014, along with an in-house multiplex PCR (bla_{KPC}, bla_{NDM}, and bla_{OXA-48}) from November 2014. The Cepheid assay was used for specimens from patients with admissions to the Trust in the past 12 months, those admitted from overseas, or those due to be transferred to a district general hospital (to facilitate transfer planning). All other samples were tested using the multiplex PCR. Species identification of isolates was performed using matrix-assisted laser desorption ionization–time of flight (MALDI-TOF) mass spectrometry (Bruker).

Epidemiological analyses. CMFT electronic bacteriology records were linked, based on NHS numbers, to patient administration data (1 January 2010 to 1 January 2017) and anonymized, and the first CRE-positive test result per patient (rectal screening or clinical specimen) was considered in the evaluation of CRE incidence trends. Trends and the impact of IPC interventions were analyzed retrospectively.

Because CMFT CRE screening rates changed over time in response to national guidance and local IPC interventions and a key aim was to evaluate specifically the impact of ward closure and a radical plumbing intervention in the MHC on CRE acquisition rates, we considered CRE detection rates in 4 periods delineated by 3 time points, namely, the implementation of national carbapenemase-producing *Enterobacteriaceae* (CPE) IPC policy in mid-2014 (which substantially increased the number of screens performed), the beginning of the MHC-specific intervention (patient relocation and plumbing infrastructure replacement in wards 3 and 4), and the end of the MHC intervention.

First CRE-positive screens were used as a pragmatic proxy for CRE acquisition (i.e., a "case"), given that 89% of patients with first CRE-positive results in the MHC had a negative rectal screen within the preceding 14 days (79% within 7 days) (Fig. S3 to S5). Information on specific carbapenemase mechanisms was not consistently available for all isolates, hampering our ability to perform these analyses specifically by carbapenemase gene family (Table S2).

We tested the hypothesis that CRE acquisitions (reflected by first CRE-positive screens) changed in the MHC more than in other hospital wards following the ward 3/ward 4 closure and plumbing intervention, using negative binomial regression models for the weekly counts of first (per person) CRE detection ≥2 days postadmission (i.e. cases), using weekly numbers of persons screened ≥2 days postadmission as an offset (i.e., adjusting for screening rates), and counting each patient as screened as long as they had ≥1 screen per week. Models were fitted (R v3.4.1) for CRE, CR *E. coli*, and CR *K. pneumoniae*. We included period and ward location (MHC versus other wards) as independent variables, with interaction terms for period and location (see the supplemental material for details).

Environmental sampling and sample processing. In 2015, environmental samples were taken from ward sites using charcoal swabs and were cultured on ChromID CARBA for 18 h at 37°C. After January 2016, ~20 ml of wastewater was aspirated from sink P-traps, shower drains, or toilets. Aspirates were centrifuged at 4,000 rpm for 10 min, 15 ml of supernatant was discarded, and the pellet was resuspended in the remaining 5 ml. One milliliter of sample was then incubated aerobically overnight at ~37°C in 5 ml of trypticase soy broth with an ertapenem disc; the multiplex PCR (as above) was performed on broths to identify bla_{KPC}-positive samples for subsequent culture on ChromID CARBA. Environmental sampling prior to January 2016 was not systematic; after January 2016, 75 wastewater sites on wards 3 and 4 were sampled fortnightly on rotation (one half of the sites 1 week and the other half the next); these sites included toilets, sink basins, and sink drains.

Genome sequencing and sequence data analysis. To provide genetic context for the outbreak, we sequenced retrievable, archived, KPC-producing *E. coli* patient and environmental isolates from CMFT and patient isolates collected for regional public health surveillance (see the supplementary methods and Table S3 in the supplemental material). We also sequenced a small subset of non-*E. coli* environmental CRE isolates that had been stored ($n = 14$) *ad hoc* as part of outbreak sampling prior to the plumbing replacement.

For Illumina sequencing (HiSeq 2500; 150-bp PE reads), DNA was extracted using the QuickGene system (Fujifilm, Japan), with an additional mechanical lysis step following chemical lysis (FastPrep; MP Biomedicals, USA). Two outbreak isolates (H124200646 and H151860951) were selected for long-read sequencing based on Illumina data. For long-read sequencing (with a PacBio [$n = 1$] or MinION [$n = 1$] system), DNA was extracted using the Qiagen genomic tip 100/G kit (Qiagen, Netherlands) (see the supplementary methods).

In silico species identification was performed using Kraken (29). Illumina reads were then mapped to species-specific references (*E. coli* CFT073 [GenBank accession no. AE014075.1] and the ST216 reference H151860951), and base-calling was performed as described previously (30). *De novo* assembly was performed using SPAdes v3.6 (31), and resistance gene, bla_{KPC} plasmid, and Tn*4401* typing was performed using BLASTn and mapping-based approaches (see the supplementary methods and Table S3).

Two-dimensional reads were extracted from MinION sequence data using poretools (32); hybridSPAdes (31) and Canu (33) were used to generate *de novo* hybrid assemblies from MinION and Illumina data (see the supplementary methods in the supplemental material). PacBio sequence data were *de novo*

Downloaded from http://aac.asm.org/ on January 7, 2020 by guest

assembled using HGAP3 (34). *E. coli* phylogenies were reconstructed using IQ-Tree (35) and ClonalFrameML (36) and were visualized in iTOL (37) (see the supplementary methods).

Ethics approval. Because the investigations formed part of a Trust board-approved outbreak response, ethics approval was not required under NHS governance arrangements (see the supplementary methods).

Accession number(s). Sequencing data are available under NCBI BioProject PRJNA379782.

SUPPLEMENTAL MATERIAL

Supplemental material for this article may be found at https://doi.org/10.1128/AAC.01689-18.

SUPPLEMENTAL FILE 1, PDF file, 1 MB.

ACKNOWLEDGMENTS

We are grateful for and acknowledge the contributions of the clinical and support staff working in the MHC, CMFT; the microbiology laboratory staff and infection control teams at CMFT; the staff of the Manchester Medical Microbiology Partnership; and the research laboratory (in particular, Ali Vaughan) and informatics and project management teams working as part of the Modernising Medical Microbiology consortium (Oxford). We thank Jeff Scott, Ashley Sharp, and Theresa Shryane (Public Health England [PHE] North West) and Suzan Trienekens (Field Epidemiology Service, PHE) for data collection and Karen Mathieson (CMFT), Jane Turton, and Claire Perry (PHE) for outbreak investigation and support. We thank the Health Protection Research Unit Steering Group for review of the draft manuscript.

The Transmission of Carbapenemase-producing *Enterobacteriaceae* (TRACE) study investigators are listed alphabetically, with those also included as named individuals in the author list in parentheses: (Zoie Aiken), (Oluwafemi Akinremi), (Julie Cawthorne), (Paul Cleary), (Derrick W. Crook), (Valerie Decraene), (Andrew Dodgson), Michel Doumith, Matthew Ellington, David W. Eyre, (Ryan George), (Malcolm Guiver), Robert Hill, Katie Hopkins, Rachel Jones, (Cheryl Lenney), (Amy J. Mathers), (Ashley McEwan), Ginny Moore, Sarah Neilson, Tim E. A. Peto, (Hang T. T. Phan), Mark Regan, (Anna C. Seale), (Nicole Stoesser), Jay Turner-Gardner, (Vicky Watts), Jimmy Walker, (A. Sarah Walker), (David H. Wyllie), (William Welfare), and (Neil Woodford).

This work was supported by the National Institute for Health Research, Health Protection Research Unit in Healthcare Associated Infections and Antimicrobial Resistance, Oxford University, in partnership with PHE (grant HPRU-2012-10041). The report presents independent research funded by the National Institute for Health Research. The views expressed in this publication are those of the authors and not necessarily those of the NHS, the National Institute for Health Research, the Department of Health, or PHE. N.S. is funded by a PHE-University of Oxford Clinical Lectureship. Contemporaneous outbreak investigation by CMFT and PHE was undertaken as part of routine activity.

We have no conflicts of interest to declare.

Abstract

Objectives: Clinical utility of carbapenem antibiotics is under threat because of the emergence of acquired metallo-β-lactamase (MBL) genes. We describe an outbreak in an intensive care unit (ICU) possibly associated with contaminated sinks.

Design, setting and participants: Four clusters of gram-negative bacteria harbouring the MBL gene bla_{IMP-4} were detected in the ICU at Dandenong Hospital between November 2009 and July 2012. Epidemiological investigations were undertaken in order to identify a common point source. During September 2012, screening using rectal swabs for all ICU patients, and environmental swabs targeting all ICU handwashing sinks and taps were collected. Samples were cultured onto selective carbapenem-resistant Enterobacteriaceae (CRE) agar. Suspected CRE isolates were further characterised using the modified Hodge test and VITEK 2 and confirmed by polymerase chain reaction and sequencing of MBL genes. Clinical and environmental CRE isolates were typed by pulsed-field gel electrophoresis.

Results: Ten clinical isolates and one screening isolate of CRE (consisting of *Klebsiella pneumoniae* [5], *Serratia marcescens* [4], *Enterobacter cloacae* [1] and *Escherichia coli* [1]) were detected with the bla_{IMP-4} gene over the 30-month period. *S. marcescens* was isolated persistently from the grating and drain of eight central sinks. Molecular typing confirmed that clinical and environmental isolates were related. Tap water cultures were negative. Several attempts to clean and decontaminate the sinks using detergents and steam cleaning proved unsuccessful.

Conclusion: This report highlights the importance of identification of potential environmental reservoirs, such as sinks, for control of outbreaks of environmentally hardy multiresistant organisms.

One of the most concerning emerging resistance traits among gram-negative bacteria is the ability of these organisms to produce carbapenem-hydrolysing β-lactamases, which confer resistance to almost all β-lactams.[1] Carbapenem-resistant Enterobacteriaceae (CRE) are increasing in prevalence worldwide, causing growing concern, as they are often combined with non-β-lactam resistance to produce isolates that are multidrug resistant, have few treatment options available and are associated with high mortality rates.[2]

Although multiple resistance mechanisms have been identified, carbapenem resistance is often plasmid-encoded, allowing gene dissemination and a propensity to cause nosocomial outbreaks.[3-6]

We describe a CRE outbreak due to the presence of the metallo-β-lactamase gene bla_{IMP-4} in an intensive care unit (ICU) associated with contaminated sinks. This report highlights the key role of bacterial environmental contamination and sink design and usage in the propagation of CRE outbreaks.

Methods

Dandenong Hospital is a 440-bed tertiary referral hospital in Melbourne, Australia. The ICU has a 14-bed capacity, admitting both medical and surgical patients and averaging 1400 admissions yearly.

Ten ICU patients were found to have clinical specimens with Enterobacteriaceae harbouring the bla_{IMP-4} gene between November 2009 and July 2012. The ICU routinely screens for vancomycin-resistant enterococci (VRE) carriage using rectal swabs on admission, weekly and on discharge. During the 4-week period from 6 September to 4 October 2012, CRE screening was performed in addition to the routine screen for VRE.

Environmental screening for CRE targeting all 28 wet area locations (including 11 sinks and taps, as well as water fountains and ice machines) was performed. Samples were recollected from CRE positive locations after successive decontamination attempts. A total of 97 samples were collected from taps, water, grates and drains (10 cm down and above the water trap interface where biofilm may be expected to persist).

All environmental and patient screening swabs were cultured onto chromogenic agar (*Brilliance* CRE Agar, Oxoid). Suspect colonies were further characterised using the modified Hodge test and VITEK 2 (Biomérieux). All isolates with a meropenem minimum inhibitory concentration (MIC) ≥ 0.25 mg/L and a positive modified Hodge test result were forwarded for confirmation by polymerase chain reaction and molecular sequencing. Molecular typing using pulsed field gel electrophoresis (PFGE) was conducted on clinical and environmental isolates and interpreted as per the reference guidelines.[7]

Guidelines on ICU handwashing sink styles were reviewed to establish whether sinks met clinical design standards.[8]

Results

Ten clinical isolates (*Klebsiella pneumoniae* [$n = 5$], *Serratia marcescens* [$n = 4$] and *Enterobacter cloacae* [$n = 1$]) and one screening isolate (*Escherichia coli*) containing the bla_{IMP-4} gene were detected over the 30-month period. There were four distinct CRE clusters, commencing with three cases of *K. pneumoniae* in November 2009, followed by two cases of *S. marcescens* 6 months later, three cases (two *S. marcescens* and one *E. cloacae*) after another 11 months, and three cases of *K. pneumoniae* in July 2012.

Clinical characteristics, patient demographics and ICU admission details of all 11 patients are summarised in Box 1. Patients acquired CRE after a median length of stay in ICU of 10 days (range, 3–134 days). No

1 Demographics and intensive care unit (ICU) admissions for patients with carbapenem-resistant Enterobacteriaceae isolates

Patient	Underlying condition	Year of first positive culture	Culture type	Organism	Total hospital stay (days)	ICU stay (days)	ICU admissions in past 12 months	Total carbapenem therapy (days)	Outcome
1	Small bowel perforation, post-hernia repair	2009	Blood	*Klebsiella pneumoniae*	229	134	0	14	Discharged
2	Urosepsis, multiorgan failure	2010	Urine	*K. pneumoniae*	44	16	0	0	Discharged
3	Bilateral pneumonia	2010	Bronchial washings	*K. pneumoniae*	61	33	0	0	Discharged
4	Pneumonia	2010	Intercostal catheter swab	*Serratia marcescens*	44	32	0	2	Discharged
5	Pneumonia	2010	Endotracheal aspirate	*S. marcescens*	46	6	0	0	Discharged
6	Buttock abscess	2011	Urine	*S. marcescens*	49	10	0	0	Discharged
7	Pneumonia	2011	Penile swab	*S. marcescens*	46	22	0	3	Discharged
8	Congestive cardiac failure	2011	Sputum	*Enterobacter cloacae*	57	4	0	0	Died
9	Ischaemic stroke	2012	Sputum	*K. pneumoniae*	31	3	0	3	Died
10	Periprosthetic hip fracture	2012	Urine	*K. pneumoniae*	46	8	0	0	Discharged
11	Ketoacidosis	2012	Rectal screen swab	*Escherichia coli*	11	4	2	0	Discharged

patient died due to clinical CRE infection. Patient 1 had a prolonged CRE bacteraemia that responded to removal of a central venous catheter, the presumed source of infection.

A total of 111 rectal swabs were collected from 71 patients. Only one patient (Patient 11) was CRE-positive with an *E. coli* isolate detected.

Antibiotic resistance profiles of clinical isolates indicated resistance to β-lactams and meropenem with MICs ⩾1 mg/L. All *S. marcescens* clinical isolates were sensitive to piperacillin/tazobactam, ciprofloxacin and amikacin, while *K. pneumoniae* and *E. coli* were only sensitive to amikacin. *S. marcescens* environmental isolates showed a higher meropenem MIC of ⩾16 mg/L.

S. marcescens was the only species recovered from environmental samples and was isolated persistently, even after six attempts to decontaminate the grates and drains of eight of the 11 central sinks in the ICU. Tap spout and water cultures were negative for CRE.

Three of the four *S. marcescens* clinical isolates from 2010 and 2011 were indistinguishable or closely related by PFGE to four isolates from sinks. *S. marcescens* was isolated from an intercostal catheter swab of Patient 4, matching two sink isolates; Patient 5 had an endotracheal aspirate identical to two different sink locations; and the urine isolate from Patient 6 was closely related to a different sink. The isolate from Patient 7 was unable to be typed by PFGE.

Sink inspection revealed aged and deteriorating porcelain, even though sinks were only installed in 2005. Sink design did not comply with Australasian clinical design standards,[8] with a small, shallow sink and a tap that directed water over the drain (Box 2). The design of the ICU sinks led to poor use for hand hygiene (although measured hand hygiene compliance using alcoholic hand rub was around 70% within the unit) and the potential for organisms residing down the drain to be splashed back onto staff hands or contaminate patient areas. It was also revealed that the handwashing sinks had been used incorrectly, with staff disposing clinical waste and residual antibiotics directly into drains. Further enquiry also revealed that a single brush had been used to clean down the drains of all sinks in the ICU without disinfection between sinks.

Cleaning was attempted in an effort to rid the organisms from the sinks.

2 Existing design of intensive care unit sink compared with a design that complies with Australasian standards[8]

A: Existing sink, showing water spray directly over drain. **B:** Compliant sink design, showing larger basin and less forceful water flow directed away from drain, to prevent splash back and contamination with drain contents. ◆

A48235830

First, cleaning of grates and drains using single-use, soft brushes was attempted, but repeat screening revealed continued CRE growth. Next, in addition to the brushes, hypochlorite deep cleaning was used after the scrub; however, heavy CRE growth was again evident 1 week later. Finally, an attempt using pressurised steam decontamination (Jetsteam Maxi with plunger tool attachment, Duplex) for 1 minute at 170°C on grates and drains appeared to eradicate almost all CRE at Day 1 (one sink remained colonised); however, repeat testing 3 days after steam treatment showed re-emergence of CRE in all previously affected sinks.

Discussion

We report an outbreak of CRE in an ICU with identical organisms isolated from patients and an environmental source (sinks).

Dissemination of carbapenemase-resistant bacteria has been reported previously in an ICU in Australia, with 62 patients infected or colonised with gram-negative bacteria from multiple genera containing the bla_{IMP-4} gene.[9] The gene is carried on a highly mobile plasmid making it efficient for nosocomial transmission. The gene can reside in multiple genera of hardy environmental organisms that can establish a reservoir within biofilm.

Identifying the outbreak using molecular methods allowed us to establish clonality between clinical and environmental isolates and to propose a mechanism whereby patient contamination may have occurred. Although we cannot prove that the sinks were the source of patient infection, the persistence of the organism within the environment was a concern. Attempts at sink sterilisation were futile, and complete eradication will require future sink removal and replacement with appropriately designed sinks.

Others have reported outbreaks of multiresistant bacteria such as extended-spectrum β-lactamase-producing *K. pneumoniae* linked to imperfect sink design requiring sink cleaning, replacement and/or improved sink practices to successfully control the outbreaks.[10]

Our data should act as a reminder on the importance of appropriate hospital design, adequate environmental cleaning and antimicrobial stewardship in the hospital setting.

Stamps of greatness

Karl Landsteiner (1868–1943)

LANDSTEINER was born on 14 June 1868 in Vienna, Austria. He studied medicine at the University of Vienna and graduated in 1891. For 5 years he studied chemistry in Wurzburg (with Emil Fischer) and Munich, but then returned to Vienna and transferred his interest to pathological anatomy.

In 1898 he became an assistant to the institute of pathological anatomy in Vienna, in 1908 the prosector at the Wilhelminaspital, and in 1911 professor of pathology at the University of Vienna. After the upheavals of World War I he went first to Holland and then, in 1922, to the Rockefeller Institute for medical research in New York, where he continued work even after being made Emeritus Professor in 1939.

From 1900 he studied the agglutination of blood from different individuals, and in 1909 he outlined the human blood types, thus making blood transfusion possible. Landsteiner received the Nobel Prize in Medicine in 1930 for this work, which he continued at the Rockefeller Institute.

During his time in Vienna he also studied (in collaboration with others) poliomyelitis, first showing that the disease was infectious, and then isolating the causative virus.

In the early 1940s at the Rockefeller Institute, he was part of the team that discovered the Rh factor in blood, adding to his work on blood transfusion and compatibility of donors.

Throughout his career he contributed many fundamental principles to the science of immunology and knowledge of antigens and anaphylaxis, and was the recipient of many academic honours and awards. He died on 26 June 1943 after suffering a heart attack while working in his laboratory two days earlier.

Philatelically he was honoured on the centenary of his birth in 1968 by both Austria and Germany.

INFECTION CONTROL & HOSPITAL EPIDEMIOLOGY JANUARY 2015, VOL. 36, NO. 1

ORIGINAL ARTICLE

A Cluster of Central Line–Associated Bloodstream Infections Due to Rapidly Growing Nontuberculous Mycobacteria in Patients with Hematologic Disorders at a Japanese Tertiary Care Center: An Outbreak Investigation and Review of the Literature

Yasuaki Tagashira, MD;[1,3] Yasuji Kozai, MD, PhD;[2] Hitomi Yamasa, CNIC;[3] Masako Sakurada, MLT;[4] Tetsuya Kashiyama, MD;[5] Hitoshi Honda, MD, PhD[1,3]

BACKGROUND. Rapidly growing nontuberculous mycobacteria (RGM) are considered rare pathogens, causing central line–associated bloodstream infection. We identified an outbreak of central line–associated bloodstream infection due to RGM at a hematology-oncology ward during a 5-month period.

DESIGN. Outbreak investigation and literature review.

SETTING. A Japanese tertiary care center.

PATIENTS. Adults who were hospitalized at the hematology-oncology ward from October 15, 2011, through February 17, 2012.

RESULTS. A total of 5 patients with a bloodstream infection due to RGM (4 cases of *Mycobacterium mucogenicum* and 1 case of *Mycobacterium canariasense* infection) were identified; of these, 3 patients had acute myeloid leukemia, 1 had acute lymphocytic leukemia, and 1 had aplastic anemia. Four of the 5 patients received cord blood transplantation prior to developing the bloodstream infection. All central venous catheters in patients with a bloodstream infection were removed. These patients promptly defervesced after catheter removal and their care was successfully managed without antimicrobial therapy. Surveillance cultures from the environment and water detected *M. mucogenicum* and *M. canariasense* in the water supply of the hematology-oncology ward. The isolates from the bloodstream infection and water sources were identical on the basis of 16S-rRNA gene sequencing.

CONCLUSIONS. The source of RGM in the outbreak of bloodstream infections likely was the ward tap water supply. Awareness of catheter-related bloodstream infections due to nontuberculous mycobacteria should be emphasized, especially where immunocompromised patients are at risk. Also, using antimicrobials after catheter removal to treat central line–associated bloodstream infection due to RGM may not be necessary.

Infect Control Hosp Epidemiol 2015;36(1):76–80

The ubiquitous nontuberculous mycobacterium (NTM) constitutes a potential source of infectious disease in a broad range of animal species, including humans. Environmental studies have isolated NTM from natural and potable water sources worldwide. Water obtained from municipal treatment facilities, hospitals, and homes grew NTM in 10% to 95% of the samples in European and American surveys.[1]

Rapidly growing nontuberculous mycobacteria (RGM), a subset of NTM, are defined as mycobacteria that grow within 7 days.[2,3] RGM are capable of forming a protective biofilm that is important for their survival in a given environment. Among RGM, *Mycobacterium mucogenicum*, established as a separate species in 1995, is one of the most common organisms for central line–associated bloodstream infection (CLABSI).[4] *Mycobacterium canariasense* is a newly proposed RGM that is most closely related to *Mycobacterium diernhofer*.[5,6] We describe herein an outbreak of suspected CLABSI due to RGM including *M. mucogenicum* and *M. canariasense* during a 5-month period in a hematology-oncology ward at a Japanese tertiary care center. The investigations undertaken to identify clinical cases and sources of bloodstream infection are discussed together with the prevention and control measures implemented.

METHODS

Setting

An outbreak investigation was performed in the hematology ward at Tokyo Metropolitan Tama General Medical Center, a

A48235836

789-bed tertiary care center in Tokyo, Japan. The hematology-oncology ward has 15 inpatient beds, including 7 transplant-unit beds (all single room accommodations with en-suite showers and toilets) where patients undergoing bone marrow transplantation are treated in protective isolation. The remaining 8 inpatient beds are located in an adjacent ward, which has 4-bedded rooms, communal showers, sinks, and toilets. The hematology-oncology ward performs approximately 20 new transplantation operations annually.

Case Finding

Cases were initially identified with the assistance of the microbiology laboratory as all patients showing a positive NTM blood culture result from October 15, 2011, through February 17, 2012. We then reviewed the medical charts of patients with an RGM bloodstream infection to determine whether the epidemiologic link was identical for all of the patients. Demographic characteristics, clinical data including the grade of graft-versus-host diseases,[7] and microbiologic data were collected. No cases were detected before or afterward during a period of follow-up.

Standard Central Venous Catheter (CVC) Maintenance

The study institution's standard protocol for CVC dressing care at the time of the outbreak included hand hygiene prior to changing the dressing, wearing nonsterile clean gloves when doing so, using povidone-iodine or a chlorhexidine-based antiseptic to disinfect the site, and covering the site with a sterile, transparent dressing. Frequency of dressing change was every 7 days if the dressing barriers were intact. However, dressing changes were performed at intervals of less than 7 days if there were signs of blood, precipitate, submersion of water after showering or bathing, or other defects.

Environmental Investigation

To investigate potential sources of infection within the environment, a total of 74 different water and environmental samples were obtained. Water samples were obtained from the room faucets, bathroom faucets, showers from each single and 4-bedded room, and faucets in the nursing station, whereas environmental samples were obtained from the showerheads in each single room, showerheads and bathtubs from the communal shower room, and disposable wet wipes in the hematology-oncology ward. The municipal water system supplied water to the patient care units, lavatories, toilets, and showers in the patient rooms. The potable water in the transplant unit had been sterilized both by chlorination and by purification using a hollow fiber membrane ultrafiltration filter. Prior to collecting the samples, the taps were run for 2 min to minimize contamination from tap spouts. The water was collected in a sterile 0.2-L container for sampling[8,9] then centrifuged at 3000 rpm for 20 minutes and cultured on 2% Ogawa medium (Serotec) for 4 weeks at 37°C.

Bacterial Identification

Blood cultures from patients with an RGM bloodstream infection were grown using an automated BacT/Alert 3D (Sysmex, bioMérieux). Colonized catheter tips were sent for microbiologic analysis and were processed by qualitative culture. Acid-fast staining was performed with the colonies grown on sheep's blood. Species identification was performed using the standard method.[10] Isolates from the blood and the environmental/water cultures were sent to the Tokyo Metropolitan Institute of Public Health for final identification, after initial isolation by the Clinical Microbiology Laboratory at our hospital. To confirm the identity of the acid-fast bacteria from the blood cultures and environmental/water samples, the fragments encompassing the 16SrRNA gene were amplified by polymerase chain reaction and the amplified products were sequenced. Sequences were compared with those in the DNA Data Bank of Japan databases using blast analysis.[11–16] Pulsed-field gel electrophoresis of *Xbal*-digested genomic DNA was performed and banding patterns were compared visually.[10] In addition, amplification was performed using random amplified polymorphic DNA polymerase chain reaction. Similar isolates with the same banding pattern were assigned to the same random amplified polymorphic DNA type.[10,17]

RESULTS

Epidemiology

During the study period, a bloodstream infection due to RGM developed in 5 patients with a CVC (Table 1). The pathogens implicated in these cases were *M. mucogenicum* (n = 4) and *M. canariasense* (n = 1). All of the patients received a long-term CVC (i.e., Hickman catheter) inserted into the internal jugular vein. Four patients underwent cord blood transplantation for acute myeloid leukemia and acute lymphatic leukemia, and the remaining patient received antithymocyte globulin for aplastic anemia. None of the patients showed signs of disseminated NTM infection on the basis of examination and imaging studies. Long-term CVCs were immediately removed when RGM was identified in the blood culture. All of the patients defervesced immediately after catheter removal and were carefully monitored without antimicrobial therapy against RGM. All patients have had no evidence of relapses. In March 2012, the CVC management protocol and covering of the catheter-implantation site during bathing were also reinforced. No CVC-related mycobacterial bloodstream infections occurred during the following year.

Description of the Catheter Care after Insertion

The frequency of dressing changes was documented in the nursing notes on the electronic patient records. Four of 5 patients required frequent changes at the catheter insertion site (every 2–5 days) for reasons that included submersion of the catheter site during showering or bathing. Only 1 patient (case

Absolute neutrophil count (/μL) at the time of bacteremia	6059	1	322	180	5
Time from catheter insertion to BSI, d	30	51	37	32	29
Duration of bacteremia, d	10	6	7	9	7
Isolated organism(s)	*M. mucogenicum*	*M. canariasense*	*M. mucogenicum*	*M. mucogenicum*	*M. mucogenicum*

NOTE. All patients had a Hickman catheter, and all patients were cured. ALL, acute lymphocytic leukemia; AML, acute myeloid leukemia; ATG, antithymocyte globulin; BSI, bloodstream infection; CBT, cord blood transplantation; CyA, cyclosporine; GVHD: graft-versus-host disease; MMF, mycophenolate mofetil; MTX, methotrexate; N/A, not applicable; S/P, status post. The grading of GVHD was based on the Glucksberg grade.

patient 3) required a dressing change every 7 days, even without submersion of the catheter.

Microbiological Results

Clinical Samples. All of the patients had multiple blood cultures performed, and for each patient more than 1 blood culture result was positive for mycobacteria. The median time from catheter insertion to a positive blood culture was 32 days (range, 29–51 days). The median duration of bacteremia was 7 days (range, 6–10 days). Four of 5 catheter tip cultures (80%) showed mycobacterial growth.

Environmental/Water Samples. Water samples from different sites in the unit were cultured for NTM. NTM was not isolated from sterilized potable water. However, *M. mucogenicum* was isolated from shower water from 1 of the single rooms and a communal shower room. *M. canariasense* was also isolated from toilet water from 1 of the 4-bedded rooms. The remaining water and environmental cultures showed no mycobacterial growth.

Water chlorination in the main water tank at the hospital was measured daily. This hospital considers chlorine levels between 0.10 to 0.40 ppm to be adequate for maintaining sterility. During the outbreak, the chlorination level was kept at approximately 0.11 ppm.

Microbiologic Analysis

Typing by pulsed-field gel electrophoresis and random amplified polymorphic DNA revealed a genetic match between blood isolates of *M. mucogenicum* from patients 1, 3, and 4 and a shower water isolate of *M. mucogenicum* from the single rooms. A blood isolate of *M. canariasense* from patient 2 matched *M. canariasense* isolated from a toilet of the 4-bedded room. The other isolate of *M. mucogenicum* from patient 5 was found to have different patterns from that of patients 1, 3, and 4 by pulsed-field gel electrophoresis and random amplified polymorphic DNA typing. No organism genetically matched with that from patient 5 was isolated from the water or the environmental culture.

DISCUSSION

We experienced a cluster of RGM bloodstream infections in a hematology ward over a 5-month period. This outbreak was caused by 2 different clones of *M. mucogenicum* as well as *M. canariasense*. *M. mucogenicum* is commonly implicated in outbreaks of bloodstream infections resulting from contaminated hospital equipment and contaminated tap water, whereas *M. canariasense* is a rare species of RGM and the spectrum of clinical diseases attributable to it is not clearly understood.[5,6]

Although the incidence of CLABSI due to RGM, especially *M. mucogenicum*, in hematopoietic stem cell transplant recipients or patients on intense immunosuppressive agents, appears to be low, 6 outbreaks of bloodstream infections among such patients have been reported between 2004 and 2012 (although the outbreak reported in 2004 actually occurred in 1998; Table 2).[8,9,11,18–20]

In this outbreak, 4 of 5 patients received dressing changes at the catheter site owing to submersion of the catheter during showering. Moreover, the result of the environment/water culture and type matching of isolates from the blood cultures with isolates from the environmental/water cultures indicated that the origin of these organisms was the tap water supply. As with previous instances,[8,9,19] we considered the portal of entry for both of these organisms into the bloodstream in this outbreak was likely to be the submersion of CVC during bathing, showering, or toileting. Enhancing the CVC dressing prior to bathing or showering is crucial. The latest US guideline

TABLE 2. Outbreaks of Central Line–Associated Bloodstream Infection Due to Rapidly Growing Non-Tuberculous Mycobacteria

Author	Publication year	Patient population (no. of cases)	Contamination of RGM	Management	Outcome
Kline et al.	2004	Adult/pediatric BMT and oncology patients (6)	Hospital water supply	N/D	N/D
Livni et al.	2008	Pediatric patients with hematologic malignancies, solid organ malignancies, and aplastic anemia (5)	Hospital water supply	Catheter removal and antimicrobial therapy	One patient died without catheter removal and antimicrobial therapy
Cooksey et al.	2008	Adult oncology patients (5)	Hospital water supply	N/D	N/D
Shachor-Meyouhas et al.	2011	Pediatric oncology patients and a patient with thalassemia major with BMT (8)	Unknown	Catheter removal and antimicrobial therapy	All patients were cured with no recurrences
Baird et al.	2011	Adult patients with leukemia and lymphoma (5)	Hospital water supply	Catheter removal and antimicrobial therapy	One patient died of unrelated posttransplant complications
Ashraf et al.	2012	Adult patients with sickle cell disease (4)	Hospital water supply	Port removal and antimicrobial therapy	All patients were cured with no recurrences

NOTE. BMT, bone marrow transplant; N/D, not documented; RGM, rapid growing mycobacteria.

regarding prevention of catheter-related bloodstream infections also noted that submerging a catheter in water should be avoided and an impermeable covering should be applied to the catheter during showering.[21]

The present study also highlighted the treatment strategies for CLABSI due to RGM. Given the lack of high-quality evidence, ideal treatment strategies remain unclear. In the outbreak discussed here, all of the patients defervesced after prompt catheter removal following the detection of the bloodstream infection, and all were carefully observed without antimicrobial therapy. Follow-up blood cultures revealed no bacterial growth, and there was no clinical evidence of recurrence. In most case series or outbreaks of NTM bloodstream infection, catheter removal was the most important step to achieving a successful outcome although many patients in these studies also received antimicrobial agents against NTM.[22–26] Single case series also demonstrated successful management of RGM CLABSI by prompt catheter removal without antimicrobial therapy.[27] Furthermore, removal of the catheter was associated with a significant decrease in the rate of bacteremia relapse.[24] These findings correlate with the pathogenicity of RGM species, specifically with reference to their tendency to form a microbial biofilm matrix on the surface of the indwelling catheters.

In summary, we experienced a cluster of CLABSI due to RGM among patients with hematologic disorders. Since hospital tap water can be contaminated even with adequate chlorination, it is imperative that precise instructions for infection control in patients with an indwelling vascular catheter should be provided to the patients themselves, the healthcare workers, and family members/friends who may be providing care, especially when patients shower or bathe.

ACKNOWLEDGMENTS

We thank Tokyo Metropolitan Institute of Public Health for performing the microbiologic investigation.
