SCOTTISH HOSPITALS INQUIRY

Bundle of documents for Oral hearings commencing from 19 August 2025 in relation to the Queen Elizabeth University Hospital and the Royal Hospital for Children, Glasgow

Bundle 44 - Volume 2
Expert Reports in Response to GGC Expert (HAD) Report and Associated Documentation

This document may contain Protected Material within the terms of Restriction Order 1 made by the Chair of the Scottish Hospitals Inquiry and dated 26 August 2021. Anyone in receipt of this document should familiarise themselves with the terms of that Restriction Order as regards the use that may be made of this material.

The terms of that Restriction Order are published on the Inquiry website.

Table of Contents

1.	A52617217	Prof Peter Hawkey, Dr Lydia Drumright & Dr Samir Agrawal - Draft Joint Response to HAD Questionnaire 1	Page 12
2.	A53050077	Glasgow 4 - Inventory of Documents submitted by Drs Lydia Drumright and Samir Agrawal in support of the HAD Report	Page 48
3.	A52792290	Dr Lydia Drumright - Responses to Data Query by SHI	Page 51
4.	A52792293	Figure 1 Data - 2013 to 2022	Page 78
5.	A52792295	Figure 2 Data - 2013 to 2023	Page 82
6.	A52792294	Figure 4 Data - 2013 to 2023	Page 85
7.	A52792291	Paeds BSI Count Bed Days Rates - 2005 to 2022	Page 88
8.	A52792292	Paeds Bed Days - 2013 to 2023	Page 94
9.	A52792299	Adult Bed Days - 2013 to 2023	Page 98
10.	A52792297	Adult BSI Count Bed days rates sector - 2013 to 2023	Page 102
11.	A52792301	Adult BSI Count Bed Days Rates QEUH - 2013 to 2023	Page 105

Scottish Hospitals Inquiry

Joint Response of Professor Hawkey, Dr Drumright and Dr Agrawal to HAD Questionnaire 1

The Scottish Hospitals Inquiry has been provided with the report you entitled "*Expert Report for the Scottish Hospitals Inquiry on the evidence of risk of infection from the water and ventilation systems at the QEUH & RHC*" dated 24 July 2024 "the Report")[1]. In order to understand your Report, the Inquiry Team need to ask you a series of questions about the work you carried out in preparing the report, your knowledge about the QEUH & RHC and the information you have been supplied with by NHS GGC following your instruction by the Board on 21 November 2022.

To answer the questions in this questionnaire please type your answer in the answer area marked [Type your answer here] below the question, you will note that your type comes up in a different font from that of the question – this is to allow your answer to be read with ease.

Please note that some questions are described as being for just Dr Drumright and some questions are for just Professor Hawkey and Dr Agrawal. If you cannot answer a question because you consider it outwith your expertise, please explain why and which of your colleagues should answer the question.

Please do not insert pictures or documents into your written answers. All our hearing bundles are on our website https://www.hospitalsinquiry.scot/. If you would like to refer to a document within our bundles which captures your answer to the question, then please refer to the relevant document in the format **(Bundle X, Document Y, Page Z)**. If you wish to refer to your own document, then describe the document in your statement, list all such documents at the end of the statement and provide us with a copy of that document in order that we can process the document in accordance with Inquiry protocols.

This document constitutes your Joint Response to HAD Questionnaire 1. Each question has been answered by the expert whose initials appear alongside it. Where no initials are provided, the response is to be taken as jointly given and agreed by all three experts: Professor Hawkey, Dr Drumright, and Dr Agrawal.

A. You confirm that the facts stated in this Joint Response are true to the best of your knowledge and belief. You also confirm that you agree with the contents of the HAD Report. Finally, you understand that this statement may be used as evidence before the Inquiry and may be published on the Inquiry's website. Instruction of Professor Hawkey and Dr Agrawal

1) The Inquiry has been provided with your letter of instruction from the Central

[1] Bundle 44 Vol 1, Document 1, page 5.

Legal Office on behalf of NHS GGC on 21 November 2022[2]. *These questions are for Professor Hawkey and Dr Agrawal*.

a) What discussions did you have with representatives of NHS GGC or their solicitors and counsel about the QUEH/RHC prior to the date of that letter?

Dr Samir Agrawal [SA]: See my answer to # 5. I cannot recall the details of any discussions between myself, Professor Hawkey and [redacted] (representing the CLO) prior to the instruction letter. However, I believe we discussed how to approach answering the question of whether patients at QEUH/RHC were at increased risk of infection because of contamination of the hospital's water/ventilation systems.

Professor Hawkey [PMH]: Dr Agrawal's response is in agreement with my recollection. I was first approached by Prof Alistair Leonard who asked if I was willing to prepare a report on the case notes review, when I was in discussion with [redacted] to include other aspects as outlined by SA.

b) At the foot of the second page of that letter it is stated that the purpose of your "instruction was to consider the question of risk, specifically whether there is objective/data that would support the proposition that since the QUEH & RHC opened in 2015 patients were exposed to a greater risk of infection than would be expected due to a widespread issue with the water and/or ventilation systems". Is this an accurate summary of the purpose of your instructions as you then understood it?

SA: No, this is a limited description and hence the points in the appendix which expand on the text in the body of the letter.

PMH: I agree the appendix must be referred to for complete understanding.

c) What role did you understand that the seven questions set out in the Appendix to the letter play in the scope, purpose or production of the Report?

SA: See #1b above. The Appendix was a guide, a framework, to help us address the remit we had been given.

[2] Bundle 44, Vol 1, Documents 3 & 4, pages 234 - 243.

PMH: I agree.

d) The author of the letter then records that they understood following discussions with you that "it should be possible to address this at high level" and then describes "the intended approach". Is the description of "the intended approach" in the letter an accurate summary of the approach that you had proposed?

SA: Yes, it is accurate, with the specific questions in the Appendix being part of the remit.

PMH: I agree

e) How did the data that you required to review in order to address the purpose of the instruction set out in the letter of 21 November 2022 come to be identified. How much of that data was identified by representatives of NHS GGC or their solicitors and counsel propose?

We assume the final word, "propose" is a typo. We requested the complete microbiological blood culture data available from the time QEUH/RHC opened relating to paediatric oncology patients and adult haemato-oncology patients, as well as data available from the sites housing these groups prior to the opening of QEUH/RHC. This information was supplied to us by NHS GGC.

f) The letter informs you that the *"next step would be for you and Dr Agrawal to meet in order to discuss and define the scope of the data that needs to be reviewed"*. When did you first meet or speak to Dr Agrawal about the QUEH/RHC, who else was present and what was the substance of that discussion?

SA: My records indicate we spoke on 08/12/2022 and 19/12/2022. No one else was present. We clarified our understanding of the timing, location and specific organisms involved of the suspected nosocomial infections; the relevant patient populations; and patient ward locations and movements to different locations in the hospital over time. From this we identified and refined the data that would be required and how this might be identified through hospital electronic records.

PMH: My records indicate my first meeting with [redacted] was on 4.11.22 I think it was just myself and we discussed the same topics as SA stated above. I suggested we would need an experienced haem/oncology physician. I think [redacted] suggested SA and I agreed. Thereafter we had a number of meetings together. At some time later it became clear we needed an expert statistician with experience in this area and SA suggested Dr Lydia Drumright [LD] who was included in the group.

g) Was there any particular division of labour in preparing the Report? Did you, Dr Agrawal or Dr Drumright take a particular lead or responsibility in preparing any particular part of the Report? Please set that out here.

SA: The report represents a joint effort from all three of us. Although some sections are principally the work of one or other of us, we all provided input to all areas. The executive summary is a good example of the need to combine our different areas of expertise to address the questions put to us. With these caveats, chapters 2-5 are the focus of PMH; chapter 7 – LD; chapters 6 and 8 – SA.

PMH: I agree.

B. Involvement of Dr Drumright

2) The Inquiry holds the letter of instruction to Dr Drumright date 8 February 2024[3].

a) *This question is for Professor Hawkey and Dr Agrawal*. How was it that Dr Drumright came to be involved in the production of the Report? What role did you play in that decision? What did you consider was the assistance that Dr Drumright would be able to provide to the production of the Report?

SA: It rapidly became clear to Professor Hawkey and myself that given the scale of data that would need to be analysed, it required an experienced statistician, who ideally had a background in infection/epidemiology. As I had previously worked with Dr Lydia Drumright [LD] on infection issues and I was aware of her background working with very large data-sets, I proposed her as an

[3] Bundle 44, Vol 1, Document 5, page 244.

independent person rather than seeking internal statistical support at NHS GGC.

PMH: I agree - see my comment above.

b) *This question is for Professor Hawkey and Dr Agrawal*. What specifics did you provide to Dr Drumright following her instruction on 8 February 2024? Please produce your correspondence with her.

SA: As far as I can recall, neither I nor Professor Hawkey gave Dr Drumright specific instructions. Once Dr Drumright was aware of the remit of the work and the questions we had been posed, we discussed together the data and the various statistical analyses to be performed.

PMH: I agree.

c) *This question is for Dr Drumright.* How was it that you came to be involved in the production of the Report? What role did Professor Hawkey and Dr Agrawal play in that decision? What was the assistance that you were thought to be able to provide to the production of the Report?

LD: Dr Agrawal is a longtime collaborator of mine, starting from when I was faculty at the University of Cambridge. We work together studying the natural history of and risk factors for healthcare associated infections among haemato-oncology patients. I am an epidemiologist, expert in statistical modelling, and health informatician. Dr Agrawal and Prof Hawkey identified the need for statistical and epidemiological expertise in their report and Dr Agrawal recommended me based on his knowledge of my expertise. He and Prof. Hawkey discussed this and agreed to recommend me. They sent my name to the CLO. I met with [redacted] from the CLO, the CLO vetted my credentials and expertise and invited me to serve as an expert consultant.

d) *This question is for Dr Drumright*. What specifics did Professor Hawkey and Dr Agrawal provide to you following you instruction on 8 February 2024? Please produce your correspondence with them?

LD: This is an oddly worded question and slightly unclear, my apologies if it is not answered correctly. No “instruction” was provided. Prof Hawkey, Dr

Agrawal, Dr Rebello and I met to discuss the objectives, the available data and reports, and how we could examine these to provide evidence for environmental microorganisms resulting in increased bacterial bloodstream infection cases among QEUH patients due to environmental contamination.

3) *This question is for Professor Hawkey, Dr Agrawal and Dr Drumright*. The letter of instruction to Dr Drumright of 8 February 2024 refers to "data from Dr Agrawal's hospital etc". Was the data from St Bartholomew's hospital referred to in paragraph 8.1.2 of the Report the only data from that hospital made available to you, Dr Drumright and Dr Agrawal? If other data from that hospital was available, what was it?

This data in section 8.1.2 of the report is in the published literature, as referenced in the report. It is not the data referred to in the letter of instruction to Dr Drumright of 8 February 2024. The data referred to in the letter of instruction to Dr Drumright was not, in fact, used (nor even looked at) for the Report.

The remaining questions are for Professor Hawkey, Dr Agrawal and Dr Drumright.

C. Other involvement with or about the QUEH/RHC

4) The copy of the Report provided to the Inquiry is identified as version 1.7. In what way did the report develop in draft from version 1.1 to version 1.7 and why were these changes made by you and your fellow authors? Please provide the Inquiry with a copy of each version 1.1 to 1.6.

Versioning of reports, manuscripts and other documents is a standard procedure in scientific inquiry that helps keep everyone working off the same document and prevents confusion. It is standard scientific behaviour to share early versions of analyses, literature reviews and interpretation of findings and then meet to discuss. This was the purpose of our document versioning. Please not that Inquiry team member, [redacted] confirmed by email on 28/03/2025 that we did not need to provide every version of the report.

5) Have you received any other instructions from representatives of NHS GGC or their solicitors and counsel to consider issues, to give advice, provide reports or to issue an opinion that are in any way related to the QUEH/RHC? If the answer is yes, please provide details including dates upon which such advice was given.

SA: Yes. I was asked to produce a report for Greater Glasgow Health Board (GGHB) with respect to an Improvement Notice (IN) that was served on them by the Health and Safety Executive (HSE) in December 2020. The IN alleged the GGHB, “failed to ensure, so far is reasonably practicable, that the ventilation system within Ward 4C [of QEUH] is suitable and sufficient to ensure that high risk patients who are vulnerable to infection are protected from exposure to potentially harmful airborne microbiological organisms”. The GGHB had appealed. My report addressed the issues of ventilation, the risk of infection in highly vulnerable patients, and the observed infection rates on 4C. My report (from May 2021) is already included in the evidence submitted to the SHI.

PMH: I was initially approached by Prof Leonard. No further instructions after contact with AR.

LD: No.

6) Have you produced any other reports, opinions or written advice for NHS GGC about issues that relate to the QUEH/RHC? What subjects were addressed, when were they instructed and when did you produce any such reports, opinions or written advice?

SA: See answer to (5).

PMH: No.

LD: No

D. Information considered by you

7) In the Report you list at Item 10 a total of 101 documents to which you and your colleagues have referred to within the report.

a) What criteria did you use in selecting journal articles for citation and then citing them at various points in the body of the report?

Literature review is a standard scientific process. It is a comprehensive, critical summary of existing research on a particular question. It involves systematically searching for, evaluating, and synthesizing scholarly

information, including journal articles, books, conference abstracts, grey literature, and other academic information to understand the current state of knowledge in the field. Normally, scientists start by using one or more search engines, such as PubMed, Google Scholar, Scopus, etc., to identify articles, books and abstracts to review. They will read these and continue to search cited documents in the references of these papers to expand their search. They will also search the grey literature, such as government white papers and other documents that may exist. It is an iterative process with the objective of identifying what is known and what gaps exist in knowledge regarding the topic of interest. This approach was used. Any abstract, manuscript, report, etc. that provided sufficient information on the subject was included and cited as a standard scientific approach.

b) For what reason do you cite journal articles that relate to particular factual circumstances that may, or may not, be comparable to the circumstances in the QUEH from 2015 to 2020?

SA: I am not clear as to what this question is alluding to? The scientific literature was used to provide evidence to support specific points, to provide context, to provide expected rates of infection etc. Of course, no two hospitals can have the same circumstances. However, without comparative data, it would be impossible to assess if the infection rates at QEUH represent an increase, a decrease, or the expected rates of infection in these at-risk populations.

PMH: I agree I carried out a standard literature search which was informed as we analysed the data.

LD: This question is unclear. The information provided in the chapters including literature review sets the background of our knowledge for the topic area. For example, if one is worried about the hospital environment increasing risk of bloodstream infection among patients, then information on which organisms can survive in the environment and subsequently colonize a patient, risk factors for developing bloodstream infections in different patient groups, previous observations of this occurring, etc. are relevant pieces of information to support a scientific inquiry into whether or not a given patient population in

a given hospital could have acquired microorganisms that were present in the environment, become colonized and subsequently ended up with a bloodstream infection. Without this background, there would be no biological plausibility in which to examine existing data or justify the role of the environment in risk of a bloodstream infection among patients.

c) Have you considered any other information in preparing the Report? If, yes please describe this information at the end of this questionnaire and the use you made of it.

SA: Not that I am aware of.

PMH: No.

LD: No

d) Is the report by Dr Chaput referenced at Item 13 on that list the report that can be found within the Inquiry's hearing bundle, Bundle 18, Volume 1, Document 2.

SA: Yes - as far as I can ascertain.

PMH: I agree.

LD: It appears to be the same report, however, given that we are no longer accessing the Teams site set up by NHS GGC, we cannot confirm that these two reports are identical.

e) Is the HPS report reference at Item 41 the report that can be found within the Inquiry's hearing bundle, Bundle 18, Volume 1, Document 11, Page 819.

SA: Yes - as far as I can ascertain.

PMH: I agree.

LD: It appears to be the same report, however, given that we are no longer accessing the Teams site set up by NHS GGC, we cannot confirm that these two reports are identical

f) Do you still have access to the Microsoft Teams site said (in the letter of instruction to Dr Drumright date 8 February 2024[4]) to contain "The relevant documentation and data")? What is contained on that site?

SA: We were all provided access by the CLO as a secure platform for documentation. I cannot know when I last accessed the site, but I have certainly not accessed this site after June 2024. The contents of the site are in the hands of the CLO.

PMH: I agree.

LD: During the period of time that we were working on our report we had access to this Teams site. No screen shot or other factual documentation confirming what was made available on this site is available, as the information provided were considered confidential information and properly handled as such. I have not tried to access this site since submission of the report in June 2024. As we have now signed the Novation Agreement, trying to access the site is now is likely to be a violation of the Novation agreement. Therefore, we cannot confirm what was on this site previously or currently or whether or not we can access the site. The NHS GGC (or CLO) is likely to be able to answer this question for you accurately.

E. The decision to consider the work of the Case Notes Review

8) The letter of instruction dated 21 November 2022 makes no reference to the Case Notes Review and the extent to which it might be of assistance to the Inquiry in determining whether the built environment at the QEUH and RHC posed an increased risk of infection, yet this appear to be a significant part of the scope of the report. When was it first proposed that such a consideration be part of the scope of the report? Who suggested that consideration and is it set out in any letter of instruction or email from NHS GGC or their solicitors that you can produce?

[4] Bundle 44, Vol 1, Document 5, page 244.

SA: I am not sure what this question is alluding to? All documentation provided to us were from the CLO on behalf of the NHS GGC, including the Case Notes Review (CNR). The documentation was added to over time and, with that, our approach to the remit we had been given also evolved. The CNR is an in-depth analysis of infections in the paediatric unit on a case by case basis. Each of us found, independently, significant causes for concern about the CNR's findings. Addressing this is fundamental to our report, as it highlights why our findings differ dramatically from those of the CNR.

PMH: I agree, for me as a microbiologist this was a critical analysis, although as mentioned in our report, the methodology of the CNR is not clear.

LD: The Case Note Review is indeed mentioned in the first paragraph of the instructions in the letter dated 21 November 2022, "All of these infections have been the subject of intensive investigations, both by NHS GCC, and by external bodies (such as HPS/ARHAI and the Case Note Review)". The purpose of the instruction as stated in the letter was "to consider the question of risk, specifically whether there is objective evidence/data that would support the proposition that since the QEUH & RHC opened in 2015 patients were exposed to a greater risk of infection than would be expected due to a widespread issue with the water and/or ventilations systems.". It is therefore logical to review and comment on documents mentioned, including the Case Note Review, as it pertains to addressing the purpose of the instruction. This is what was done and prior investigations that were made available were reviewed and commented on as appropriate. The Case Note Review was available when I started work on the report.

9) Chapter 3 of the report is entitled "Clinical significance and epidemiology of the most common groups of presumed environmental bacteria selected for inclusion by the CNR" (page 18).

a) What is the purpose of this chapter? Are you proposing that the CNR should have not considered certain bacteria in their work?

PMH: No, as the main author that is not my intention. The CNR authors have grouped a very diverse collection of species of Gram negative bacteria (GNB)

together as most likely to be derived from the environment. As an expert who has worked and researched on GNB since 1980, I could see this as an erroneous assumption. In order to inform the inquiry of the nature of these bacteria, and their variable likelihood of coming from the ward environment, I wrote this section.

SA: As a haemato-oncologist managing adults with haematological cancers, I was concerned at the assumption of the CNR of an environmental source for some of the infections. There appeared to be a lack of consideration of the patient's own gut and skin micro-organisms as the source of infections, although these sites represent the main sources for the vast majority of GNB infections.

LD: I agree – no additional comments.

b) Given the purpose and scope of the Case Notes Review as set out in Section 2.2 of the CNR Overview Report (Bundle 6, Document 38 at page 1000) how do you think the patient cohort used by the CNR been selected?

PMH: The overall cohort is as I understand it those patients with bacteremia caused by GNB in the time period of interest. What is not explained is the methodology used to, with varying degrees of certainty, categorise them as coming from the environment. For instance, the CNR highlights Stenotrophomonas maltophilia (SM) as one of the more common species causing bacteremia and attributes many of the infections to an environmental source. They have ignored the work of Aitken et al. 2021 which elegantly demonstrates that in their leukemic patients with a high rate of infection caused by SM, it was the use of carbapenem antibiotics causing oral colonisation and subsequent infection rather than discrete environmental sources. My own work [Denton et al 1998] with this bacterium in cystic fibrosis patients showed that exposure to water in the home is just as likely to result in colonisation with SM. One of the periods with increased isolation of SM coincided with an increase in the use of carbapenems (due to lack of availability of piperacillin-tazobactam experienced by many units). My own haem/oncology unit in Birmingham followed this path and soon had a

significant increase in SM infections. We restricted carbapenems and the problem resolved. There was a similar episode at that time in Glasgow, yet the CNR failed to consider this as the most likely cause.

SA: I agree.

LD: I agree.

F. The water and ventilation systems at the QEUH/RHC and the IPC response to potentially HAIs/HCAIs in the Schiehallion Unit

10) Specifically, have you been provided with or have considered any of the following documents or reports about the water or ventilation systems of the QEUH/RHC? If you have considered any of the following, please set out who supplied them to you, when you considered them, what relevance they had to the issues addressed in the Report and for what purpose they were supplied to you?

a) The DMA Canyon 2015 L8 Risk Assessment (Bundle 6, Document 29, Page 122)

This was not within the scope of our remit.

b) The DMA Canyon 2017 L8 Risk Assessment (Bundle 6, Document 30, Page 416)

This was not within the scope of our remit.

c) Minutes of the NHS GGC Water Technical Group on 13 April 2018 and 20 April 2018 (Bundle 10, Document 2, Page 9 and Document 3, Page 14)

This was not within the scope of our remit.

d) Notes of the Water Incident Debrief meeting on 15 May 2018 (Bundle 14, Volume 2, Page 211)

This was not within the scope of our remit.

e) Full Incident Management Team Report covering the IMTs from 2 March 2018 to 13 April 2018 dated 5 June 2018 (Bundle 27, Volume 5, Document 19, Page 46

This was not within the scope of our remit.

f) Legionella Control Authorising Engineer Audit – QUEH - 23 July 2018 (Bundle 18 Volume 2, Document112 at page 909)

This was not within the scope of our remit.

g) Report by Innovated Design Solutions, Feasibility Study Regarding Increasing Ventilation Air Change Rates within Ward 2B, 15 October 2018 (Bundle 6, Document 33, Page 656)

This was not within the scope of our remit.

h) Report by Innovated Design Solutions, Feasibility Study Regarding Increasing Ventilation Air Change Rates within Ward 2A, 24 October 2018 (Bundle 6, Document 34, Page 674)

This was not within the scope of our remit.

i) SBAR which was used to brief the Chair of NHS GGC, Professor Brown, on or about 13 November 2018 (Bundle 4, Document 32, Page 133)

This was not within the scope of our remit.

j) The NHS GGC Review of Issues Relating to the Hospital Water Systems' Risk Assessment (Bundle 8, Documents 34 to 40, Page 150)

This was not within the scope of our remit.

k) The HFS Water Management Issues Technical Review, March 2019 (Bundle 7, Document 4, Page 70)

This was not within the scope of our remit.

l) Legionella Control Authorising Engineer Audit – QUEH - 30 and 31 January 2020 (Bundle 18, Volume 2, Document 125, Page 1355)

This was not within the scope of our remit.

m) Legionella Control Authorising Engineer Audit – QUEH - 4 and 5 February 2021 (Bundle 18, Volume 2, Document 126, Page 1402)

This was not within the scope of our remit.

n) Legionella Control Authorising Engineer Audit – QUEH - 28 February and 1 March 2022 (Bundle 18, Volume 2, Document 124, Page 1335)

This was not within the scope of our remit.

o) Legionella Control Authorising Engineer Audit – QUEH - 11 January 2023 (Bundle 15, Document 45, Page 1226)

This was not within the scope of our remit.

p) Legionella Control Authorising Engineer Audit – QUEH - 11 January 2024 (Bundle 27, Volume 1, Document18 at page 252)

This was not within the scope of our remit.

11) Specifically, have you been provided with or have considered any of the following presentations by Dr Chaput about water testing results at the QEUH/RHC? If you have considered any of the following, please set out who supplied them to you, when you considered them and for what purpose?

a) Presentation by Dr Chaput, RHC Ward 2A/2B Water Test Results, 28 March 2023 (Bundle 18, Volume 2, Document 117, Page 1030).

Yes, we did consider this for our report to inform our understanding. This was supplied from the NHS GGC CLO.

b) Presentation by Dr Chaput, RHC Ward 2A/2B Water Test Results, 8 February 2022 (Bundle 18, Volume 2, Document 118, Page 1040).

Yes, we did consider this for our report to inform our understanding. This was supplied from the NHS GGC CLO.

c) Presentation by Dr Chaput, RHC Ward 2A/2B Water Test Results, 1 March 2023 (Bundle 18, Volume 2, Document 119, Page 1063).

Yes, we did consider this for our report to inform our understanding. This was supplied from the NHS GGC CLO.

d) Presentation by Dr Chaput, RHC Ward 2A/2B Water Test Results, 18 February 2022 (Bundle 18, Volume 2, Document 120, Page 1073).

Yes, we did consider this for our report to inform our understanding. This was supplied from the NHS GGC CLO

12) To what extent have you been provided with or have you become aware of details of the design, structure, specifications and management systems of the water

system of the QEUH/RHC as it stood at the following points of time and what were you told and when were you told it?

a) At handover on 26 January 2015?

This was not within the scope of our remit.

b) At the start of the 'Water Incident' on 1 March 2018?

This was not within the scope of our remit.

c) At the time the adult BMT patients returned to Ward 4B in the QUEH on 30 June 2018?

This was not within the scope of our remit.

d) At the time of the 'decant' from Wards 2A/2B RHC to Wards 6A/4B in the QEUH on 26 September 2018?

This was not within the scope of our remit.

e) At the point that Ward 6A was closed to new admissions in August 2019?

This was not within the scope of our remit.

13) To what extent have you been provided with or have you become aware of details of the design, structure, specifications and management systems of the ventilation system of the QEUH/RHC as it stood at the following points of time and what were you told?

a) At handover on 26 January 2015?

This was not within the scope of our remit.

b) At the start of 2018?

This was not within the scope of our remit.

c) At the time the adult BMT patients returned to Ward 4B in the QUEH on 30 June 2018?

This was not within the scope of our remit.

d) At the point that Ward 6A was closed to new admissions in August 2019?

This was not within the scope of our remit.

14) What knowledge do you have about the experience of NHS GGC haemato-oncology clinicians of potential HAIs and HCAIs in the Schiehallion Unit in Yorkhill and then RHC from 2005 to 2022?

We do not have any knowledge of the experience of clinicians in the Schiehallion Unit in Yorkhill and then RHC from 2005 to 2022.

15) What knowledge do you have about the experience of NHS GGC ICNs, ICDs and microbiologists of potential HAIs and HCAIs in the Schiehallion Unit in Yorkhill and then RHC from 2005 to 2022

We do not have any knowledge of the experience of ICNs, ICDs and microbiologists in the Schiehallion Unit in Yorkhill and then RHC from 2005 to 2022.

G. Contemporaneous Epidemiology

16) Specifically, have you been provided with or have considered any of the following documents or reports that consider the epidemiology of infections at the QEUH/RHC from 2015 to 2019? If you have considered any of the following, please set out who supplied them to you, when you considered them, what relevance you consider they have to your instructions and why they were provided to you?

a) The HPS Situational Assessment, Wards 2A/B, Royal Hospital for Children, NHS Greater Glasgow and Clyde (Bundle 7, Document 5, Page 194) and, in particular, Appendix 4 to that document (Bundle 7, Document 5, Page 205).

It was not in our instructions to review and critique the management of infection control.

b) The HPS SBAR: To support NHS GGC IMT Mycobacterium chelonae cases and the Incidence of gram-negative bacteraemia in the paediatric haemato-oncology, September 2019 (Bundle 3, Document 16, Page 127).

It was not in our instructions to review and critique the management of infection control.

c) Draft HPS Review of NHS GG&C Infection Outbreaks in the Paediatric

Haemato-oncology Data October 2019 (Bundle 7, Document 6, Page 214)

It was not in our instructions to review and critique the management of infection control.

d) HPS Review of NHS GG&C Infection Outbreaks in the Paediatric Haemato-oncology Data October 2019 - 29 November 2019 (Bundle 7, Document 7, Page 250).

It was not in our instructions to review and critique the management of infection control.

e) Presentation by Kathleen Harvey-Wood and Dr Christine Peters: Bacteraemia rates and Resistance Paediatric Haemato-oncology 2014- 2018, 30 August 2018 (Bundle 27 Volume 6, Document 9, page 107).

It was not in our instructions to review and critique the management of infection control.

f) Report by Dr Iain Kennedy: Descriptive Analysis of Trends in Bacteraemia Rates for Selected Gram-Negative Organisms, 1 October 2018 (Bundle 6, Document 27, page 95).

It was not in our instructions to review and critique the management of infection control.

g) Draft report by C Peters and K Harvey-Wood: Bacteraemia rates and resistance patterns in paediatric haematology/oncology patients 2014- 2018, 10 October 2018 (Bundle 19, Document 19, Page 143).

It was not in our instructions to review and critique the management of infection control.

h) Report by Dr Iain Kennedy: Descriptive analysis of trends in bacteraemia rates for selected gram-negative organisms, July 2019 (Bundle 6, Document 28, page 104)

It was not in our instructions to review and critique the management of infection control.

i) Presentation by Dr Iain Kennedy and Jennifer Rodgers: Paediatric Haemato-oncology RHC – Summary of Data, September 2019 - Presented at IMT

meeting of 20 September 2019 (Bundle 27, Volume 13, Document 13, Page 77)

It was not in our instructions to review and critique the management of infection control.

H. Water

17) The Inquiry has heard a large amount of evidence on the question of homogeneity or polymicrobial nature of biofilms in water in the context of WGS and to that it would assist if you can further justify your statement at the end of Section 5.3.2 that *"In our experience, when clusters of infection occur caused by potentially environmentally sourced bacteria in immune supressed patients, investigation with detailed typing very often reveals a homogeneous cluster of strains and helps tremendously in identifying the source and introducing control measures"* If you can referred to published studies that would be of great assistance.

There is an extensive literature, which will require a review to be supplied shortly by Prof Hawkey.

I. Ventilation

18) At page 51 you discuss the specifications required in HTM 03-01, Part A for "wards with neutropenic patients'. From your knowledge of the QEUH/RHC which wards in the adult and childrens' hospital can properly be described as "wards with neutropenic patients' in that context?

Wards 2A, 2B, 4B, 4C and 6A – ie, paediatric and adults wards principally caring for haemato-oncology patients.

J. Numbers of potentially significant infections amongst paediatric patients

19) Is a reader correct to understand that Tables 5A to 8 list all of the identified bacteraemia for the listed species/genera amongst all adult hospitals in NHS GGC or only in respect of patients in the care of the South, North or BMT sectors?

Data including South, North and BMT sectors were provided for analyses of adult patients. No data on adult patients was provided for other GGC sectors. See list of hospitals included in #27. Please note that Tables 5A through 8 list only bacteraemia attributed to microorganisms that were consider environmentally relevant.

20) Is a reader correct to understand that Tables 11A to 11F, 12, 13, 14 of the Report list all bacteraemia for each of the listed species/genera amongst paediatric patients between January 2005 to December 2022 and that is the broad equivalent of Tables 4.2 and 4.3 of the Case Notes Review Overview Report (Bundle 6, Document 38 at page 1028)?

"Broadly equivalent" is a very general term that is not normally used in epidemiology or scientific study. The data included in Tables 11A-11F, 12, 13, and 14 of our report include all data on bloodstream infections/bacteraemia downloaded from GGC databases for the Yorkhill and QEUH RCH between 2005 and 2022. The data contained in Tables 4.2 and 4.3 could very well be a subset of these data, but it is difficult to determine from the Case Note Review as there is not a clear indication of where the datasets came from. Additionally, it appears that there are more cases of certain organisms in the Case Note Review then in the longer time period including the Yorkhill hospital in addition to the QEUH RCH, for example with Pseudomonas putida, suggesting either a different set of data were used or a different case definition was used.

K. Background rates:

21) In respect of each of the following bacteria to what extent would you agree with the statement that "there is no background rate for these organisms" amongst the cohort of paediatric haemato-oncology patients treated by the Schiehallion Unit:

We are not clear what counsel means by "background rate".

a) Achromobacter xylosoxidans,

The statement that "there is no background rate of these organisms in the cohort of paediatric haemato-oncology patients" is unclear and imprecise, so I cannot comment on it for all organisms in question. We did observe one case of bacteraemia attributed to Achromobacter xylosoxidans in May 2010 at Yorkhill in the Schiehallion Ward based on the data provided to us.

b) Acinetobacters Iwoffi,

The statement that "there is no background rate of these organisms in the cohort of paediatric haemato-oncology patients" is unclear and imprecise, so I

cannot comment on it for all organisms in question. We did observe two cases of bacteraemia attributed to Acinetobacters Iwoffi in Feb 2005 and Sept 2006 2010 at Yorkhill in the Schiehallion Ward based on the data provided to us.

c) Burkholderia cepacia in general,

The statement that “there is no background rate of these organisms in the cohort of paediatric haemato-oncology patients” is unclear and imprecise, so I cannot comment on it for all organisms in question. There were numerous cases of bacteraemia attributed to Burkholderia cepacian in the Schiehallion Ward, Schiehallion DCU and Ward 5A between 2005 and 2014 at Yorkhill and two cases, in May 2017 and June 2018 in Ward 2A at QEUH.

d) Burkholderia cepacia (other than in Cystic Fibrosis patients),

The statement that “there is no background rate of these organisms in the cohort of paediatric haemato-oncology patients” is unclear and imprecise, so I cannot comment on it for all organisms in question. As above, there were numerous cases. Additionally, no data on the cystic fibrosis status of the patients was provided, therefore I cannot provide numbers of cases stratified by cystic fibrosis.

e) Cedecea lapagei,

The statement that “there is no background rate of these organisms in the cohort of paediatric haemato-oncology patients” is unclear and imprecise, so I cannot comment on it for all organisms in question. This organism was not reported as being isolated in any paediatric blood sample in the data provided.

f) Chryseobacterium indologenes,

The statement that “there is no background rate of these organisms in the cohort of paediatric haemato-oncology patients” is unclear and imprecise, so I cannot comment on it for all organisms in question. There were 6 cases of bacteraemia attributed to Chryseobacterium indologenes, in Yorkhill, 4 in the Schiehallion Ward, 1 in Schiehallion DCU and 1 in Ward 5A between 2005 and 2014, as well as two cases, in May 2017 and June 2018 in Ward 2A at QEUH.

g) Commamonas testosterone,

This is not a bacterium that exists. Perhaps you mean Comamonas testosteroni? There were no bacteraemia cases of Comamonas among paediatric cases in our dataset. This is not the same, however, as stating that "there is no background rate of these organisms in the cohort of paediatric haemato-oncology patients".

h) Cupriavidus gilardii,

The statement that "there is no background rate of these organisms in the cohort of paediatric haemato-oncology patients" is unclear and imprecise, so I cannot comment on it for all organisms in question. There were no cases of bacteraemia attributed to Cupriavidus gilardii, over the time period of the data.

i) Cupriavidus pauculus,

The statement that "there is no background rate of these organisms in the cohort of paediatric haemato-oncology patients" is unclear and imprecise, so I cannot comment on it for all organisms in question. There were 3 cases of bacteraemia attributed to Cupriavidus pauculus over the time period of the data. One occurred in Yorkhill in the Schiehallion DCU in Mar 2012, one in Ward 2B Day Surgery in QUEH in Sept 2017, and one in QEUH Ward 3C in Jan 2018.

j) Delftia acidovorans,

The statement that "there is no background rate of these organisms in the cohort of paediatric haemato-oncology patients" is unclear and imprecise, so I cannot comment on it for all organisms in question. In the dataset provided there was 1 case of bacteraemia attributed to Delftia acidovorans in Yorkhill in the Schiehallion DCU in Feb 2013 and 4 cases in 4 different wards at QEUH between 2017 and 2020 occurring 4 or more months apart.

k) Elizabethkingia meningospetica,

The statement that "there is no background rate of these organisms in the cohort of paediatric haemato-oncology patients" is unclear and imprecise, so I cannot comment on it for all organisms in question. Three cases of

bacteraemia attributed to Elizabethkingia meningospetica occurred in Yorkhill in 2014, one per month from May-July on the Schiehallion Ward and DCU. Three cases of bacteraemia attributed to Elizabethkingia meningospetica also occurred in QEUH over the time period of the data provided, one occurred in Sept of 2016 on Ward 1B Day Surgery and the other two occurred in Dec 2016 and Jan 2017 on Ward 2A.

l) Pantoea agglomerans,

The statement that “there is no background rate of these organisms in the cohort of paediatric haemato-oncology patients” is unclear and imprecise, so I cannot comment on it for all organisms in question. Three cases of bacteraemia attributed to Pantoea agglomerans occurred at Yorkhill, one each in Nov and Dec of 2005 on the Schiehallion Ward and OPs and one in Feb 2014 on the Schiehallion Ward.

m) Paracoccus sp,

The statement that “there is no background rate of these organisms in the cohort of paediatric haemato-oncology patients” is unclear and imprecise, so I cannot comment on it for all organisms in question. There were no cases of bacteraemia attributed to Paracoccus spp. over the time period of the data.

n) Pseudomonas chlororaphis,

The statement that “there is no background rate of these organisms in the cohort of paediatric haemato-oncology patients” is unclear and imprecise, so I cannot comment on it for all organisms in question. There were no cases of bacteraemia attributed to Pseudomonas chlororaphis over the time period of the data.

o) Pseudomonas fluorescens,

The statement that “there is no background rate of these organisms in the cohort of paediatric haemato-oncology patients” is unclear and imprecise, so I cannot comment on it for all organisms in question. There was one case of

bacteraemia attributed to Pseudomonas fluorescens at Yorkhill in the Schiehallion Ward in Oct 2007.

p) Pseudomonas oryzihabitans,

The statement that “there is no background rate of these organisms in the cohort of paediatric haemato-oncology patients” is unclear and imprecise, so I cannot comment on it for all organisms in question. There were no cases of bacteraemia attributed to Pseudomonas oryzihabitans over the time period of the data.

q) Pseudomonas putida,

The statement that “there is no background rate of these organisms in the cohort of paediatric haemato-oncology patients” is unclear and imprecise, so I cannot comment on it for all organisms in question. There were three cases of bacteraemia attributed to Pseudomonas putida in the Yorkhill Schiehallion Ward over the time period 2 in 2007 and 1 in 2013. There were 6 cases of bacteraemia attributed to Pseudomonas putida in the QEUH RCH occurring between 2015 and 2019 on Ward 2A and the Emergency Department.

r) Pseudoxanthomonas Mexicana,

The statement that “there is no background rate of these organisms in the cohort of paediatric haemato-oncology patients” is unclear and imprecise, so I cannot comment on it for all organisms in question. There were no cases of bacteraemia attributed to Pseudomonas mexicana over the time period of the data.

s) Ralstonia picketii,

The statement that “there is no background rate of these organisms in the cohort of paediatric haemato-oncology patients” is unclear and imprecise, so I cannot comment on it for all organisms in question. There was one case of bacteraemia attributed to Ralstonia pickettii in Yorkhill on the Schiehallion Ward in Oct 2007.

t) Rhizobium radiobacter,

The statement that “there is no background rate of these organisms in the cohort of paediatric haemato-oncology patients” is unclear and imprecise, so I cannot comment on it for all organisms in question. There were 8 cases of bacteraemia attributed to Rhizobium radiobacter at Yorkhill, all occurring on the Schiehallion Ward, with the exception of one occuring on Schiehallion DCU, from 2007-2014. One case of bacteraemia attributed to Rhizobium radiobacter occurred in QEUH RCH on Ward 2A in Nov 2016.

u) Serratia fonticola,

The statement that “there is no background rate of these organisms in the cohort of paediatric haemato-oncology patients” is unclear and imprecise, so I cannot comment on it for all organisms in question. There were no cases of bacteraemia attributed to Serratia fonticola over the time period of the data.

v) Shewanella puterfaciens,

The statement that “there is no background rate of these organisms in the cohort of paediatric haemato-oncology patients” is unclear and imprecise, so I cannot comment on it for all organisms in question. There were no cases of bacteraemia attributed to Shewanella puterfaciens over the time period of the data.

w) Sphingomonas species

The statement that “there is no background rate of these organisms in the cohort of paediatric haemato-oncology patients” is unclear and imprecise, so I cannot comment on it for all organisms in question. There were three cases of bacteraemia attributed to Sphingomonas spp. in the data over this time period, two at Yorkhill and one at QEUH, all in different years on different wards.

x) Stenotrophomonas maltophilia

The statement that “there is no background rate of these organisms in the cohort of paediatric haemato-oncology patients” is unclear and imprecise, so I cannot comment on it for all organisms in question. There were numerous

bacteraemias attributed to Stenotrophomonas maltophilia at both Yorkhill and QEUH, many occurring on the Schiehallion Ward. This was not surprising as this is a more commonly observed bloodstream infection in vulnerable patient populations.

L. Assessment of Clustering

22) In the parts of the report that discuss a qualitative assessment of clustering what information did you have access to about the events that surround each identified bacteraemia beyond the information contained within the relevant table and the WGS work of Professor Evans, Professor Leonord and Dr Brown?

The remit of this report was to focus on existing data and information that could provide new evidence that infections in patients at QEUH could be attributed to environmental contamination. There was some interest in trying to determine if cases clustered. The presence of two or more patients on the same ward at the same with a bacteraemia with the same microorganism is not sufficient evidence that the two infections are related. Even detecting the same species of organism in a ward provides no evidence that there is a connection between the environment and a bloodstream infection in a patient. Sequencing information is the only way to determine if two microorganisms of the same species are genetically related, and therefore potentially transmitted between people or the environment and people. We therefore asked if there were sequencing data available to help with this inquiry. Other data, such as case notes, were not used as they could not add additional objective information to determine if a cluster existed.

23) Did you have access to IMT or PAG Minutes, reports to the IPC SMT, AICC, BICC or to HPS/ARHAI or the relevant medical records from which you could draw further information about the potential for an epidemiological association between particular bacteraemia?

We were not instructed to analyse the decisions of the infection control staff.

M. Rate of infections per 1,000 bed days

24) You appear to have reported Bed Days by sector for adult patients at Table 4 of the Report (page 66). You describe in section 7.2.7 being supplied with data on bed days from Yorkhill and RHC from January 2005 to December 2022. Where

in the Report is the equivalent table to Table 4 for the paediatric patient population? If it is not in the report, please supply it.

This will be supplied as discussed on the teleconference on 28 March 2025.

25) What is your understanding of the nature of the patient cohort in each of the 'South', 'North' and 'BMT' consultant sectors for which you have reported bed days in Table 4 (page 66)? It would be of assistance if you can identify which wards in which hospitals these groups were patients in and which consultants treated each group.

For all consultant sectors, BMT, North and South, these were predominantly haemato-oncology patients. For these patients with detected bacteraemia, 31 different consultants were on the record for ordering the blood cultures and patients were on 98 different wards when the cultures were ordered. Please see Tables 1 and 2 at the bottom of this questionnaire for the consultants whose names appear on the blood culture orders and which wards the patients were on at the time of the order.

26) For clarity, to what extent do Figures 4 to 8 show bacteraemia incidence only for adult haemato-oncology patients or all patients or some other group of patients?

It is our understanding that patients in the BMT, North, and South are haemato-oncology patients. Only patients from BMT, North and South are included in the data that we analysed and therefore, figures 4 to 8 reflect this patient population.

27) What are the "Other Hospitals" that produce the red lines in Figures 4 to 8? Which hospitals or which wards or services within those hospitals are encompassed within the category of "Other Hospitals"?

The other hospitals encompass BMT, North, and South sectors and include the following hospitals: Beatson West of Scotland Cancer Center, Gartnavel General Hospital, Glasgow Royal infirmary, Inverclyde Royal Hospital, Royal Alexandra Hospital, Stobhill Hospital, Vale of Leven Hospital, New Victory Hospital and West of Glasgow Ambulatory Care Hospital. Please see Table 2 for wards from which blood samples were sent and had a bacteraemia detected.

28) Does the category "QEUH" that produces the blue lines in Figures 4 to 8 encompass the whole of the QUEH and all patients there in or is it limited to a

particular subset of patients, wards of services within the QUEH? If the latter, please provide details.

The QEUH patients are only those from BMT and South sectors when they were located at QEUH as follows: the South sector became QEUH in May 2015 and remained part of QEUH through 2023 and BMT became part of QEUH for a period of approximately one and a half months across the months of June and July in 2015 and then from June 2018 onward.

29) In section 7.2.3 on page 70 you state in respect of certain microorganisms that *"none of these organisms appeared at unexpected incidence by consultant sector or hospital"*. What is the expected incidence of Achromobacter spp., Aeromonas spp., Brevundimonas spp., Burkholderia spp., Cellulosimicrobium spp., Chryseobacterium spp., and Chryseomonas spp. amongst these patients?

Haemato-oncology patients are a very vulnerable population who frequently experience immune compromised states and are considered at high risk for bloodstream infections and bacteraemia. While we often see more cases of bacteraemia in these patients attributed to Escherichia spp., Klebsiella spp., Pseudomonas spp., Enterobacter spp., Enterococcus spp., Staphylococcus spp., Stenotrophomonas spp., Streptococcus spp., and Acinetobacter spp. among others, it is not surprising to see isolation of less common species such as Achromobacter spp., Aeromonas spp., Brevundimonas spp., Burkholderia spp., Cellulosimicrobium spp., Chryseobacterium spp., and Chryseomonas spp. and others among these patients given how susceptible to bacteraemia these patients are. Among these less common species of bacteria that are grown in blood culture, we would not be surprised to see a few cases over a prolonged period of time across multiple hospitals or wards; which is what was observed in the dataset. What would be of concern is if we observed a sufficient number over a small period of time, or even 5-10 in one year in a given setting, such as a single ward, as we expect to see these microorganisms infrequently attributable to bacteraemias.

30) The Inquiry has heard evidence of number of attempts made in 2018 and 2019 to consider the epidemiology of infections amongst the paediatric haemato-oncology patients in the RHC. Whilst noting that your category "*micro-organism species of environmental concern"* as defined in Table 1 of the Report differs to

some extent from the category "*Environmental Including Enteric (ENT) Group"* in the October 2019 HPS Review of NHS GG&C Infection Outbreaks in the Paediatric Haemato-oncology Data October 2019 (Bundle 7, Document 6 at Page 219) it seems to be the case that in that report (see Figure 6 at Page 230) the 'Rate of infections per 1,000 bed days' ranges between zero and seven infections per 1,000 bed days and yet the rate of infections shown in Figure 22 of your Report appears to range zero to seventeen infections per 1,000 bed days over a comparable period. Can you assist the Inquiry in why there might be such a difference in the rate of infections between the two reports?

There could be numerous reasons for these differences such as different data sources for the bacteraemia/bloodstream infections (numerator) or bed days (denominator); differences in case definitions; or some property of the SPC charts, which are not clearly described in the HPS Review to name a few. It is possible to determine the exact reason with discussion between those who prepared the HPS Review and us and with additional information from the CLO and those who extracted data the HPS Review on exactly what databases numerators and denominators were extracted from and how.

31) Your report does not provide the tables setting out the BSI rates per 1,000 bed days used to construct the various figures and how these were calculated by reference to numbers of BSIs and the denominator used in each case. Please provide these to the Inquiry.

We are happy to provide these and will do so in the request bundle to come on 11 April 2025, as indicated in the email from Kirsten McMillan dated 28 March 2025.

32) At a number of places within the report you discuss "spikes" or "occasional spikes" in incidence of bacteraemia (see Pages 68, 69, 80 and 82) and a number of what appear to be spikes appear at both Yorkhill and the RHC in Figure 22. To what extent is it valid to consider whether such spikes were noted by treating clinicians or members of the IPC team and if so how would they be aware of such changes in the incidence of bacteraemia at the time?

Trends in data, such as these, are very easy to observe when plotting data after it has been collected. It is much more difficult to determine what is happening in real-time, even when data are being continuously plotted. There is a huge area of research focused on detection of data anomalies in real time and numerous

algorithms have been used to determine if an increase in the number of cases of a given condition are a signal for an anomaly. This type of work is carried out by people with specialist training in very specific and complex statistical modelling and is usually led by people with a PhD with expertise specifically in this area of research. It is unfair to presume that treating physicians would or should have this skillset, and the time required to collate, clean and analyse data would not be efficient use of a physician's time. It is unlikely that physicians would notice periodic increases in number of cases of bloodstream infection or bacteraemias, especially as patient confidentiality dictates that providers focus on results from the patients who they are treating and do not review notes of patients that they are not treating unless there is a clinical reason to do so. Hospitals could employ specialists with skills to model their data to identify increased numbers of cases, but in the NHS, it would only be recommended if there was a significant cost benefit. As bacteraemia/ bloodstream infections are not transmissible in an "outbreak" sense, there may be little gain for the cost of employing someone to do this job.

N. Whole Genome Sequencing ("WGS")

33) The Report discusses the use of WGS at Section 7.3 which is entitled "*What does the available sequency show?"* and in Table 15A-15C. At page 96 reference is made to *"Report on Enterobacter Related Infection by Professor T Evans & Whole Genome Sequencing Report by Prof Leanord*". There are further references to Professor Evans at pages 76, 95, 117, 118 and yet no reports or papers by Professor Evans or Professor Leonard are listed in Chapter 10. To what extent are these references to the following reports or are you referring to other reports or papers?

a) Report by Professor Alistair Leanord and Doctor Derek Brown titled "Application of Whole Genome Sequencing to Identify Relationships..." Dated 18 January 2023 (Bundle 6, Document 40, Page 1195).

PMH: I find searching your bundles very difficult. The reports listed below have the same titles as those supplied to me by CLO. If necessary, I can send the PDFs I worked from.

b) The Report on Cupriavidus Related infections by Professor T Evans dated March 2023 (Bundle 8, Document 44, Page 223).

PMH: I find searching your bundles very difficult. The reports listed below have the same titles as those supplied to me by CLO. If necessary, I can send the PDFs I worked from

c) The Report on Enterobacter related infections by professor T Evans dated March 2023 (Bundle 8, Document 45, Page 230).

PMH: I find searching your bundles very difficult. The reports listed below have the same titles as those supplied to me by CLO. If necessary, I can send the PDFs I worked from.

d) The Report on Stenotrophomonas Infections by Professor T Evans dated March 2023 (Bundle 8, Document 46, Page 239)

PMH: I find searching your bundles very difficult. The reports listed below have the same titles as those supplied to me by CLO. If necessary, I can send the PDFs I worked from.

34) Have you had access to any other reports or data describing results of WGS carried out to samples taken from patients or the environment at the QEUH or RHC after 26 January 2015? What reports or data are these?

PMH: none

O. Comparison between hospitals

35) Your Report refers to comparison to “other hospitals” and lists infections at some other NHS GGC hospitals in Tables 5 to 8. Which hospital are these and on what basis do you consider it appropriate to compare rates of infection in adult patients in those hospitals with rates of infection in adult patients in the QEUH?

Please see question #27 for hospitals included. The comparison was considered appropriate as the patient population was the same, they were all haemato-oncology patients.

36) At the end of section 7.2.2 you explain your intention to compare rates of infection in paediatric patients at Yorkhill with rates of infection in paediatric patients at the RHC. On what basis do you consider it appropriate to compare these two hospitals in this manner?Lydia ? discuss what they are after?

Yorkhill was the primary haemato-oncology service for children in the GGC until June 2015 when the entire service moved to QEUH RHC. As this is the same service, treating the same patient population and the GGC has no other paediatric haemato-oncology service, it is the only comparator if one wants to determine if paediatric haemato-oncology patients in the GGC are experiencing a greater number of infection due to the new RHC setting. Without a comparator or regular and consistent whole genome sequencing of both the environment and microbial isolates from bloodstream infection there is no evidence that a given hospital is creating an elevated environmental risk for patient with respect to bloodstream infection.

P. Aspergillus

37) Chapter 8 of the Report is an *'analysis of infection rates and data from QEUH & RHC'.* A few questions arise:

a) Can you assist in explaining the nature of the patient cohort in each of the 'Adult South', 'Adult North' and 'Adult BMT' services and the extent to which their vulnerability or otherwise to Aspergillus infection is sufficiently similar so as to make such a comparison between them appropriate? It would be of assistance if you can identify which wards in which hospitals these groups were patients in and which consultants treated each group.

Adult BMT, Adult South and Adult North refer to the services treating haemato-oncology patients. All adult patients having a haematopoietic stem cell transplant (HSCT), were managed within the Adult BMT service. Figure 23 in chapter 8 shows the time periods when the adult BMT service was located at QEUH - the green horizontal bars at the top of the figure - and outside of these time periods, the Adult BMT service was located at the Beatson West of Scotland Cancer Centre.

As discussed in 6.1.4 of our report, those at greatest risk of *Aspergillus* infection are "… the group of patients with haematological, and other, cancers undergoing intensive chemotherapy and/or HSCT." Such patients were cared for in Adult BMT, Adult South and Adult North sectors.

b) At section 8.1.4 you explain that the variation over time between the period before and after the move to the RHC "is expected" by reference to "the

repeated relocation on the QUEH campus". The Inquiry is only aware of re-location to the RHC in June 2015, decant to Wards 6A/4B in September 2018 and a short term decant to the CDC in January 2019. What evidence do you have to support the statement that *"repeated relocation on the QUEH campus, with associated disruption, would be a risk factor of invasive aspergillosis"* in each of 2015, 2016, 2017, 2018 or 2019?

SA: I apologise if the text is confusing. I was referring to the same relocations the Inquiry is aware of – I am also unaware of any others. The movement of patients from one location to another disturbs their environment, particularly with respect to airborne particulate matter (ie, fungal spores). The movement of beds, equipment, any remedial building works, will all lead to an increased risk of infection.

The "expected" variation in rates of *Aspergillus* infection does not relate to the relocations. It seems the text has been misunderstood:

"This variation over time is expected. The repeated relocation on the QEUH campus, with the associated disruption, would be a risk factor for increased rates of invasive aspergillosis. However, there are no marked differences in case numbers by location…"

So, while the relocations would lead to increased risk of *Aspergillus* infections, this was not actually observed clinically.

c) In your Report at page 125 "*Table 20: Paediatric and adult cases with evidence of infection with Aspergillus species over time on the QEUH/RHC sites"* appears to contain no row for Ward 2A RHC or any other ward in the RHC. Why is that? What should such a row or rows show?

SA: Table 20 shows data for the periods of co-location of the paediatric and adult services – both BMT and non BMT data – during the period of co-location of services between 26/09/2018 to March 2022 on QEUH 4B and 6A. Since they were never co-located on any wards in RHC, there is no data and hence no rows corresponding to these locations. However, Table 19 shows the distribution of paediatric cases with evidence of infection with Aspergillus species by year and location in RHC (as well as QEUH).

Additional Information Considered

38) If you answered yes to question 7(c) please set out the other information you considered and the use you made of it.

Not applicable.

Inventory of Documents Provided by Dr Lydia Drumright and Dr Samir Agrawal in support of the GGC Expert (HAD) Report

This document may contain Protected Material within the terms of Restriction Order 1 made by the Chair of the Scottish Hospitals Inquiry and dated 26 August 2021. Anyone in receipt of this document should familiarise themselves with the terms of that Restriction Order as regards the use that may be made of this material. The terms of that restriction order are published on the Inquiry website.

Dr Lydia Drumright

SHI Source Identification and Supporting Workings Request Dated April 11, 2025

Requests in bold, followed by responses.

For the following pages, could you please confirm the exact spreadsheet or data source used (including the period the dataset covers), and provide the working spreadsheets, tables, and any relevant methodological details:

(1) Page 60 - Data mentioned in relation to QEUH and comparable hospitals.

Tables 1 and 2 are simple summaries of the organisms that were reported in the blood culture isolate data from two data files provided by the CLO entitled: "Final Combined GGC Paeds Onc CHI only 01.01.05 - 31.12.22" and "Adult HaemOnc 2013-31Aug23 - matched GMC". These included specimens from haemato-oncology adult patients from Beatson Cancer Center (96.5% of non-QEUH), Glasgow Royal Infirmary, Queen Elizabeth University Hospital (QEUH), Royal Alexandra Hospital, Stobhill Hospital, Vale of Leven Hospital, Victoria Infirmary, Gartnavel General Hospital between 2013 and 2023 and haemato-oncology paediatric patients from Yorkhill and Queen Elizabeth University Hospital between 2005 and 2022. Table 1 includes only microorganisms of environmental concern including potential sources of infection, this information comes from the literature including expert review by Prof Peter Hawkey. Table 2 includes all microorganisms isolated in suspected bacteraemia cases among both adult and paediatric patients as described.

A combined file of these organisms with date and differentiation between adult vs paediatric patients has been provided in an Excel file as requested labelled:
"Organisms_Isolated_Adult_Paeds_Bacteraemia_Data_GGC"

(2) Page 62 –

(a) Organism detection data differentiated by patient ID.

I have provided two separate files, one for adult and one for paediatric patients as follows:

- ADULT: "Adult_microorganism_detections_used"
- PAEDIATRIC: "Paeds_microorganism_detections_used"

(b) Data used to calculate Bed Days per month (including the period that it covers).

Please note that these data were not calculated. Bed days were provided by month and year by the CLO for both adult, by sector, and paediatric, by hospital, patients. Please see Excel spreadsheets labelled:

- ADULT: "Adult_beddays"
- PAEDIATRIC: "Paeds_beddays"

(c) Working spreadsheet(s) that demonstrate the process used to define a new case (14-day rule), monthly case counts, environmental organism classification, and calculation of incidence rates per 1,000 bed days.

This request is unclear. People with proper statistical training do not use spreadsheets to clean data. Consistent with modern gold standard statistical practice, I use Stata, R or similar analytical package to aggregate and analyze data. Cases were based on microorganism species identified in every individual patient. As patients with organisms detected in blood culture may be monitored frequently, it is not uncommon to observe multiple blood cultures very close together, therefore we decided that an incident case in the same individual with the same microorganism required a ≥15 day gap between detections. If that patient had the same microorganism detected within ≤14 days, that was considered the same bacteraemia episode. These types of automated calculations are straightforward using a statistical package such as Stata, R, SAS and others, anyone trained in statistical analysis should know how to do this. I have provided the following spreadsheets to show all microorganism detections and those that were kept for analysis and those that were not because they either were duplicate entries or were ≤14 days apparat.

- ADULT: “Adult_micro_showing_deduplicated_and14_day_drop”
- PAEDIATRIC: “Paeds_micro_showing_deduplicated_and14_day_drop”

Once individual incident cases were identified, monthly cases were aggregated based on calendar year and month. The number of cases per month was divided by bed days (provided by the CLO as described in 2b) and then multiplied by 1000 to get bed days per 1000 patients. Spread sheets by month and year of cases, including bed days and incidence per 1000 have been provided stratified by section (adult) or hospital (paediatric) and all vs organisms of environmental concern in the following files:

- ADULT: “Adult_bsi_count_beddays_rates_sector” & “Adult_bsi_count_beddays_rates_qeuh”
- PAEDIATRIC: “Paeds_bsi_count_beddays_rates”

These can easily be checked by aggregating data in the spreadsheets labelled “Adult_microorganism_detections_used” and “Paeds_microorganism_ detections_used”

As stated in the report and again in this response, organisms of environmental concern are not identified through calculation, these are based on biological knowledge and expertise and can be confirmed by thorough literature search and review of biology texts.

(3) Page 64 -

(a) Historical (2005 – May 2015) vs. current paediatric hospital data (June 2015 – 2022) - (Yorkhill vs. RHC).

The data are in the Excel spreadsheet labelled: “Paeds_bsi_count_beddays_rates”

All dates are contained within these data. “Historical data” (Yorkhill) are those data dated Jan 2005- May 2015 and label with “Yorkhill” under hospital, “current data” (QEUH) are those dated June 2015-Dec 2022 and labelled with QEUH-RHC under hospital.

Please provide additional information if this is not what you are looking for.

(b) Data used in Figures 1 and 2. (ADULT)

Data for these figures are in the following Excel files:

- Figure 1: “Figure 1 data”
- Figure 2: “Figure 2 data”

(4) Page 68 – Data used in Figure 4, please also clarify if it is fair to assume that references to ‘other hospitals’ prior to page 69, do indeed refer, and always refer to the combined data from Beatson and SGH?

In the dataset provided by the CLO, there was data on blood cultures from 11 different GGC hospitals including Queen Elizabeth University Hospital (QEUH) corresponding to consultant sectors: BMT, North and South. Among the hospitals classified as “other’, i.e. not QEUH, 96.5% of blood cultures came from the Beatson Cancer Center while the remainder came from Glasgow Royal Infirmary, Lightburn Hospital, Lorn and Island Hospital, Matie Curie Huntershill, Royal Alexandra Hospital, Stobhill Hospital, Vale of Leven Hospital, Victoria Infirmary, and Gartnavel General Hospital; of which, organisms grew from patients located at Beatson Cancer Center, Glasgow Royal Infirmary, Royal Alexandra Hospital, Stobhill Hospital, Vale of Leven Hospital, Victoria Infirmary, and Gartnavel General Hospital.

Data for Figure 4 can be found in the Excel file labelled: “Figure 4 data”

(5) Page 65 –If available, please also provide the tables and workings for Figures 4–22.

I am not sure what “workings” refer to, but the data tables are provided at the end of this document and the raw data have been provided based on the other questions in this document, as well as by the CLO as stated in [redacted] email dated 22 April 2025.

(6) Pages 64–69: Data source(s) for references to “other hospitals in NHS GGC” and related figures.

See question number 4. I was provided with two datasets for adult haemato-oncology patients. One with all blood-related samples sent to microbiology for growth and results including dates, unique IDs, consultant sectors, wards and hospitals and the other containing bed days by month and year for the sectors, BMT, North and South for the time periods outlined in the report and above. As I understood it, these data were extracted from the GGC NHS database systems.

Terminology Clarifications

(7) Page 60: Please provide an explanation of what the 'ticks' and 'crosses' along the Adult and Paediatric columns in Table 1 and 2, in order to clarify the intent.

A check mark specifies that that species or organism was detected and an "X" indicates that it was not in that patient group.

(8) Pages 64–69: Please confirm whether "other hospitals in NHS GGC" consistently refers to Beatson and SGH across the report.

See number 4.

Figure Labels and Consistency

(9) Page 65: Could you confirm whether Figures 1 through 22 represent incidence rates (cases per activity/time point) as opposed to incidence (cases per time point)?

Incidence rates per month per 1,000 bed days.

(10) As many figures currently lack data labels, the provision of numerical tables would significantly aid in replicating and verifying your findings.

See question number 5.

(11) If the data you have drawn upon appears in the documents contained within Bundle 44 Vol 1, please refer to them as Bundle X and Page Y. If the sources are different or are not clearly identifiable within that bundle, we would be grateful if you could supply the specific spreadsheet(s), workings, and documentation as requested.

Data sources in the bundles are not clear.

The CLO, confirmed by [redacted] in an email dated 22 April 2025, that the council has received the same datasets that I was provided with. I have shared those data in this request.

If you could please share with me (1) raw data files used in Bundle 44 vol1 and (2) the code used for analyses, so that I can double check that we are indeed working with the same data. I will also be better able to answer queries about any differences. Please note if the code are in R, Stata or Python, I can take code in that format. If code are in SAS, SPSS or another statistical package, please provide code in a document file as I can read it, but do not have a software license for these.

Data Tables for Figures 4-22

Per request data tables for all figures have been provided below as supplemental tables to the report.

Supplemental Table 1: Data table for Figure 1 providing incidence rates per 1,000 bed days of all bacteraemia by month and year by consultant sector (rounded to the nearest hundredths place; greyed out cells indicate no data available, last 2 months of 2023 appeared to have incomplete data and therefore not included)

Notes to my calculations regarding cases of invasive aspergillosis

The data-set

In chapter 8 of our report, "Expert Report for the Scottish Hospitals Inquiry on the evidence of risk of infection from the water and ventilation systems at the Queen Elizabeth University Hospital and Royal Hospital for Children, Glasgow," there is a detailed explanation of how the parameters used to obtain the raw data from the Central Legal Office, on behalf of Greater Glasgow Health Board (NHSGGC).

For ease, this copied here:

Laboratory data

The NHS GGC laboratory services take samples from other health boards and primary care, so data was filtered based on allocation to either a haematology/haemato-oncology consultant or location.

All microbiological data that could indicate infection due to *A. spp*. were analysed. As *A. spp*. are never (with only vanishingly rare exceptions) cultured form blood, we looked at data from sputum and BAL with any *A. spp*. growth detected. In addition, three biomarkers that can indicate the presence of *A. spp*. were analysed:

- Galactomannan (GM), which is specific for *A. spp*.
- PCR for *A. spp*, which is also specific for *A. spp*.
- Beta-D-glucan (BDG), which can support a diagnosis of invasive aspergillosis, even though it is not *A. spp*. specific, but is a pan-fungal marker.

Time period

Results were available from 2013 to 2023 for the adult haemato-oncology service and from 2005 to 2022 for the paediatric service.

De-duplication

Where the same patient had multiple positive tests for the same admission episode, this was classified as one case.

Case definitions

In chapter 8, there is a detailed explanation of my definitions to define a case of invasive aspergillosis.

For ease, this is copied here:

Case definitions for this report

In this patient population, Proven cases of aspergillosis are exceptionally rare (as obtaining sterile tissue for diagnosis requires invasive procedures in an unwell patient). Outside of Proven cases, objective evidence for invasive aspergillosis comes from mycological data - culture or biomarkers – which is part of the Probable case definition but not Possible. Also, if BDG is the only mycological criterion, this is not indicative of an invasive aspergillosis as it is a pan-fungal marker.

Given these challenges of case definition, for the purposes of this evaluation, *any evidence of infection with A. spp. was counted as a suspected case (regardless of host and imaging factors)*. This approach may inflate the number of cases as mycological data alone is not regarded as a case by the EORTC/MSGERC criteria. On the other hand, Possible cases will be lost, as this category is based on host plus imaging criteria, but as explained above, Possibles lack any objective evidence of infection with an *A. spp*.

Data analysis

The file, "Cases over time_protected_updated_190624" shows the data I extracted from the original data-set of any case with any positive data based on the case definitions used.

Data is presented per sector, with each line a case and all relevant results for that case recorded.

I have made notes indicating where there was doubt about classification and why cases were accepted or rejected.

Date	Sample	Culture	GM	BDG	PCR	UPN	Year	Cases

4.6 Comparison of the overall rates of infection with other institutions 39
5. Chapter 5: Water 42
5.1 Are hospital water systems sterile? 42
5.2 What constitutes a contaminated water system? 42
5.3 What if there was ‘widespread contamination of the hospital water system? 45
5.4 If patients were at an increased risk of infection as a result…? 48
6. Chapter 6: Ventilation 51
7. Chapter 7: Water – Analysis Of Infection Rates and Data from QEUH & RHC 52
7.1 Learning from water testing for *P.aeruginosa* 52
7.2 BSI incidence rates and the likelihood of clustering 54

7.3 What does the available sequencing data show? 77
8. Chapter 8: Ventilation – Analysis of Infection Rates and Data from QEUH & RHC 86
Acknowledgements 87

1. PREFACE:

As a result of continuing problems arising from patient infection incidents on the QEUH campus, in November 2019, the Scottish Government's Health and Social Care Management Board escalated NHS GGC to 'Stage 4' of its escalation ladder. As a result, an Oversight Board under the chair of the then Chief Nursing Officer, Professor Fiona McQueen, was established to address issues concerned.

As part of the work of the Oversight Board, the Cabinet Secretary for Health and Sport set out plans for a Case Note Review in a Parliamentary statement on 28 January 2020. We were commissioned to form the Independent Expert Panel for that Case Note Review with the charge that we would review the case notes of Paediatric Haemato-Oncology patients at the RHC and QEUH who, from 2015 to 2019, had experienced a Gram-negative environmental pathogen bacteraemia (and selected other organisms).

We commenced our work at the end of February 2020 and published the Case Note Review Overview Report in March 2021. We completed our work in July 2021 having communicated our findings to the families of all children and young people involved.

We gave evidence to the Scottish Hospitals Inquiry in October 2024 (Glasgow III hearing) but in March 2025 were requested to provide a written response to the Inquiry of an additional independent report, instructed by the Central Legal Office on behalf of NHS Greater Glasgow and Clyde, published in July 2024 and authored by Professor Hawkey, Dr Agrawal and Dr Drumright.

We have worked together to provide this rebuttal of the evidence presented in that report, and of the conclusions reached by its authors. Despite the criticisms made of our work by Hawkey et al., we remain confident that the conclusions reached and presented in the CNR Overview Report stand.

For simplicity, in places in our text we have informally referred to the report by Hawkey et al. as the 'HAD report'.

2. CHAPTER 1: INTRODUCTION

This chapter commences with a short statement about the instruction given for the report and sets out its intent as follows:

"The purpose of this instruction is to consider the question of risk, specifically whether there is objective evidence/data that would support the proposition that since the QEUH and RHC opened in 2015 patients were exposed to a greater risk of infection than would be expected due to a widespread issue with the water and ventilations systems".

There then follows a discourse on the nature of infection risk and on the authors' planned approach to its investigation in the context given.

We identified a number of themes within this short chapter (also with reference to the Executive Summary) which are reiterated and developed elsewhere in the overall report but on which we make the following observations here.

1.1 Infection Prevention and Control (IPC)

Hawkey et al. state *"Infection risk is multifactorial and varies depending on: a micro-organisms ability to cause disease (pathogenicity), its natural habitat (source), ability to spread (mode of transmission), susceptibility of the host to infection (opportunity). If an increase in infection rates is observed, this is not necessarily attributable to the built environment given this complexity."*

There is a key omission here. As in much of the report, the effectiveness of infection prevention & control (IPC) measures is neither considered nor recognised. IPC measures are crucial to minimise the risk of infection, especially in vulnerable populations such as patients with haematological, and other, cancers undergoing intensive chemotherapy and/or haematopoietic stem cell transplants. IPC measures are also relevant in minimising the risks of acquiring exogenous microorganisms, including those from the environment.

Indeed, in the entirety of the HAD report, the terms IPC, infection prevention and control, infection prevention or infection control are infrequently mentioned, outside of

the chapter on ventilation. When infection control is mentioned, the context is sometimes confusing, as in the following example in Chapter 7, Page 97:

"Indeed, the most common source of Klebsiella pneumoniae infection in healthcare settings is person to person transmission, followed by contaminated intraven[e]ous catheters, which point to infection control practices rather than environmental concerns; improved infection control may be why we have seen a reduction in cases at QEUH compared Yorkhill."

The suggestion made by Hawkey et al of benefit from improved IPC practice is entirely contrary to the observations made in the Case Note Review (CNR) Overview Report about deficiencies in IPC process and practice at NHS GGC – a point to which we refer again in Chapter 2.

1.2 Source of Blood Stream Infections (BSIs) and routes of transmission

The Executive Summary (Page 1) includes this statement:

"6. The primary source for bacteria causing bloodstream infection (BSI) in neutropenic patients is the patient's own gut, particularly for Gram-negative bacteria."

Whilst this is true, it does not address the source of the bacteria in 'the patient's own gut'. So, where do Gram-negative bacteria come from? Are they truly the patient's own (endogenous) bacteria, and as such were they present when the patient entered the hospital, or were they bacteria acquired in the hospital? Bacteria causing BSIs may be acquired from the environment directly or via the hands of the patient, healthcare workers, visitors and/or other patients. These bacteria may colonise the intravascular catheters that form a mainstay of treatment (e.g. for administering drugs and blood products) in haematology/oncology patients, subsequently they may then enter the blood, typically whilst the catheters are manipulated. Alternatively, bacteria may colonise the gastrointestinal tract of these patients with the potential to transit the mucosa of the gut, damaged by chemotherapy, into the blood stream.

It is almost never established with certainty which routes of transmission have occurred in an individual patient. Nevertheless, in our critique of the HAD report, we

discuss how the epidemiology (clustering) of the BSIs seen in the CNR supports the possibility of exogenous / hospital-acquired infection.

The Executive Summary (Page 2) also includes the following statement:

"12 Attributing the source of a BSI pathogen to the built environment of the hospital can only be shown if: the strains identified are indistinguishable, a source is present, and a route of transmission and a portal of entry are identified."

This dogmatic statement is not true. In fact, it is well appreciated by IPC and infection epidemiology experts that molecular proof, as suggested by Hawkey et al. later in their report, is often not forthcoming. One can very reasonably attribute the origin of an infection to a source/sources if the available data/epidemiology are consistent with such a hypothesis.

Hawkey et al. place significant weight on the results of Whole Genome Sequencing (WGS) analysis (principally discussed in Chapter 7 but also referred to elsewhere) and in response we have set out in detail how sampling of the water environment and, the identification (typing) of the strains recovered from patients and water source were both incomplete.

In fact, in Chapter 2, Section 2.2, Hawkey et al., in discussing the definition of an outbreak, make this concession *"Practically, precise genetic subtyping of microorganisms rarely identifies the outbreak as it is a relatively slow and complicated process and therefore typically carried out retrospectively."*

1.3 Comparative incidence and Clusters

Hawkey et al. write *"As the hospital environment is not sterile, it will always pose a certain level of risk of infection. If the built environment poses an increased risk of infection, then this would manifest in an increased rate of infection."*

Whilst this statement may seem intuitively correct, as we discuss in Chapter 7, Section 7.2, there are many other factors that moderate infection rates and which challenge the use of whole population analyses to decide, as stated by Hawkey et al. (Page 12) *"…if there is no increase in infection rates then it can be concluded that there is no increased level of risk from the built environment or other potential factors".*

This is not true and there remains the necessity to look in detail at individual patient factors where epidemiological data suggest the possibility of a cluster of the same infection, as was done in the CNR. We reject the assertion made by Hawkey et al. that the CNR was not of assistance in relation to the question of whether the built environment at the QEUH and RHC posed an increased risk of infection to those in the cohort we were asked to assess in the CNR.

It must be emphasised that an increased risk of infection to an individual is not the same as an increased rate of infection in the population from which they come.

If the BSIs identified in the CNR were most likely endogenously acquired, for this to have been true, the clusters of infections we identified would need to have been independent events, i.e. were not related. Basic infection control analysis clearly showed clustering of some types of infections in time and place. The occurrence of repeated, unrelated infections with the same microorganism is very unlikely. What is the chance that clusters, occurring in time, of children managed in the same wards all developed BSIs caused by bacteria of the same species that had no common source(s)? It is implausible that, on repeated occasions, patients who developed a BSI were the source of BSIs in other patients. It is more likely that there were common sources of the bacteria involved that either colonised (and then infected) or directly infected the children.

3. CHAPTER 2: MICRO-ORGANISMS

Chapter 2 of the HAD report, entitled Micro-organisms, begins with an historical review of the standard classification of bacteria. It emphasises the normality of bacteria within our usual habitat and social environments whilst highlighting their potential as a cause for disease, particularly in immunocompromised individuals. The second part addresses the meaning and use of the term 'outbreak'.

in this chapter, we are critical of the authors' approach in three key areas:

- In their section on Naming and Classification of bacteria, we found much of the content is not directly relevant to the work and findings of the CNR; and the authors add little understanding to the real impact of Health Care Acquired Infection within the environment in which immunocompromised patients are managed.
- The discussion about 'What is meant by an outbreak?' does not utilise a standard definition as was used for the purposes of the CNR.
- The authors' failure to recognise the value of an investigation of the individual patient in terms of the origin of the infection.

2.1 How bacteria are named

Bundle 44 vol 1,Page 13, Section 2.1

It is difficult to understand the authors' intent in including this section in their report. Whilst it may be relevant in providing a textbook description of the historical evolution of bacterial characteristics and classification, it has no direct relevance to the HAD report's criticism of the CNR. Nor does it reference the impact of the organisms named within a clinical environment, and only superficially draws on infections that could particularly manifest in immunocompromised patients.

Perhaps Hawkey et al. could have linked their description of environmental bacterial exposure more directly to the fact that infections and outbreaks of infection occur in patients in hospital, and to a description of how such infections occur. This possibility applies not only to patients who are immunocompromised, although they are at especial risk. It may occur where there is a portal of entry and where infection prevention and control (IPC) practices are suboptimal; where there is contamination

of a medical device, such as an intravenous line, or of the patient environment; or cross infection from patient to patient. An investigative response to determine the possible source and mode of transmission is critical to reduce the risk for further cases of infection.

Standard precautions referenced in the National IPC Manual[1], describe measures that should be in place to mitigate for opportunistic pathogenic organisms and reduce the bioburden for patients. We identified suboptimal IPC practice at NHS GGC in the CNR Overview Report[2].

Section 2.1 of the HAD report mentions a number of Gram negative bacteria excluded from the CNR. Reference to Escherichia coli is also made in Chapter 4 of the report on which we comment further. It is nevertheless worth reiterating here that E.coli bacteraemia, the most prolific blood steam infection acquired in hospital with the potential for endogenous infection, was excluded from the CNR review.

2.2 What is meant by an outbreak?

Bundle 44 vol 1, Page 15, Section 2.2, Paragraph 1

The published definition of a health care associated infection outbreak is clearly stated in section 3.1 of the Health Protection Scotland National IPC Manual[3] as *"Two or more linked cases with the same infectious agent associated with the same healthcare setting over a specified time period, or a higher-than-expected number of cases of HAI in a given healthcare area over a specified time period".* This was the definition we accepted for our work in the CNR. However, the first definition of outbreak given in this Section of the HAD report is not the same and refers to infection *"…caused by genetically indistinct micro-organisms"*. We assert that this is aspirational and not the reality with which infection prevention and control practitioners work daily - a fact Hawkey et al. appear to acknowledge later in the same paragraph where they discuss

[1] Bundle 19, Document 24, Page 440.

[2] Bundle 6, Document 38, Page 1039, Section 5.3.4

[3] Bundle 19, Document 24, Page 458, Section 3.1.

the importance of recognising an increase beyond the normally expected numbers of a specific infection.

An apparent increase in numbers of cases of the same infection linked by time, place, and person (i.e. those in proximity such as within the same ward), should trigger an investigation, using defined outbreak management principles, to identify any potential commonality between cases as well as to consider suboptimal aspects of IPC practice that may have led to cross infection and/or the identification of a potential source.

In practice, even with contemporaneous investigation, it is not always possible to identify the source of an outbreak until later in an investigation, or if at all. The investigation is also dependent on the investigating team taking the most appropriate samples from locations or people and requesting the most appropriate testing to either confirm or exclude linked cases.

Whilst Hawkey et al. place great emphasis on the identification of genetically similar micro-organisms, in practice mutations are possible and there remains the potential for genetically very similar but not exact matches to be linked. We discuss this further in our critique of Section 7.3 of the HAD report.

In the latter part of Section 2.2, the authors' focus on the role of the gut as a site of endogenous spread for blood stream infections (BSI) in immunocompromised patients. This possibility is one to which we explicitly referred in the CNR and took into consideration, as far as was possible, when considering if there was the possibility of the origin of a blood stream infection from the hospital environment[4].

The final reference in this section is to the reality that environmental bacteria will be found in the general environment.

Hawkey et al. illustrate this with reference to a study which identified *Cupriavidus spp* and *Burkholderia spp* in domestic water supplies[5]. Apart from the obvious longer term implications for public health from findings of this kind, the identification of some bacterial species which may cause human disease in this way, and more especially in those who are immunocompromised, serves to underline the importance of IPC

[4] Bundle 6, Document 38, Page 1018, Section 3.6.6.

[5] Khan, S., Knapp, C.W. & Beattie, T.K. Antibiotic Resistant Bacteria Found in Municipal Drinking Water. *Environ. Process.* **3**, 541–552 (2016). https://doi.org/10.1007/s40710-016-0149-z

precautions in the environments in which such patients are managed. It is striking that Hawkey et al. do not reflect on this or on the critical relevance of methodologies available for reducing risk in water supply to the built environment[6].

2.3 Investigation of the individual patient

Bundle 44 vol 1, Page 17, Paragraph 2

Hawkey et al. make two important statements early in their report, the first at this point in Chapter 1 which states: *"A significant reliance appears to have been placed on the Queen Elizabeth University Hospital and Royal Hospital for Children Case Note Review Overview Report (Stevens, Evans and Wilcox, 2021) (CNR) in relation to whether the built environment at the QEUH and RHC posed an increased risk of infection. However, we do not consider that the CNR is of assistance in determining this for the reasons set out below."*

Bundle 44 vol 1, Page 13, Paragraph 2

At the beginning of Chapter 2, they write *"In order to be able to identify the sources of particular micro-organism that can cause infection, a number of factors need to be understood including, the natural habitats of that microorganism, the route of transmission by which micro-organisms get to the patient and enter the body. The identification of micro-organisms and what constitutes an outbreak must also be understood."*

It is therefore very strange that the authors seem both to recognise the complexity of attempts needed to determine how patients develop infection but at the same time imply that individual patient review, as undertaken by the CNR, is not helpful.

A prime requirement in determining the root cause of an infection is to consider, in detail, the clinical circumstances of the individual experiencing the infection, in addition to the microbiological and environmental factors involved. It is worth re-emphasising that the use of Root Cause Analysis was not introduced for the investigation of infection in paediatric haematology oncology patients at NHS GGC until late 2019,

[6] Bundle 1, Document 6, Page 287.

long after concerns about the pattern and frequency of gram-negative environmental BSI had been raised as a matter of concern[7].

In conducting the CNR we followed conventional IPC practice when attempting to determine the aetiology of the BSIs in the children we studied, and when categorising the likelihood that these might in some way be related to the hospital environment. We set out our approach in considerable detail in Chapter 3 of the Overview Report[8]. Furthermore, we invited the families of the children concerned to contribute their own observations about the circumstances of their child's infection in case this offered insights additional to our own deliberations. We maintain this to be the correct approach.

[7] Bundle 6, Document 38, Page 1064, Section 8.2.2.2.

[8] Bundle 6, Document 38, Page 1007, Chapter 3.

4. CHAPTER 3: CLINICAL SIGNIFICANCE AND EPIDEMIOLOGY OF THE MOST COMMON GROUPS OF PRESUMED ENVIRONMENTAL BACTERIA SELECTED FOR INCLUSION BY THE CNR

This chapter offers commentary on the *"particular bacterial species"* considered by the CNR. We largely address its content in the sequence in which it is presented but as our comments focus only on certain areas of the data provided in Chapter 3 of the HAD report, the sections in our chapter follow that sequence but are not necessarily named the same.

3.1 Klebsiella

Bundle 44 vol 1, Page 23, Section 3.1.1

After an introduction to the wider group (Enterobacterales) to which Klebsiella belongs, and a review of its characteristics in health care settings, Hawkey et al. make this general statement *"It is important to maintain a balanced view, as just because bacteria of the same species can be found in those sites they are not necessarily the source of infection."*

It is good to see this statement as that is the position we took in our approach to the CNR but we believe that the clustering epidemiology, which we discuss in Chapter 7, Section 7.2, supports the possibility of a common source(s).

At the end of this section, Hawkey et al. conclude, *"To summarise, Klebsiella are important nosocomial pathogens, the most common sources are the community colonised patients admitted to hospital and a colonised hospital patient with transfer to colonise other patients via contact with contaminated surfaces, hands of medical/nursing staff and sometimes food. On occasions wet sources such as sink traps, drains, medical equipment and cleaning cloths can act as primary sources for infection having been contaminated by material from colonised patients."*

It seems, therefore, they agree that the hospital environment could be a source of infection with these Gram-negative bacilli and we highlight next just a few of many reports in the published literature that confirm this to be the case.

In this UK publication[9], a sampling strategy was used to investigation the hospital water environment. It is notable that the level of stringency of environmental testing was typically absent when GGC investigated its clusters of BSIs in children. Three units (acute admissions, adult critical care, adult general medicine) within a single hospital (John Radcliffe Hospital, Oxford, UK) were screened four times on rotation every 3 weeks over 3 months, March–May 2017. Units were chosen to capture different patient populations, admission turnaround times and wastewater plumbing infrastructure. The haematology ward (on a separate hospital site) was also sampled on a single day (12 May 2017) subsequent to a small cluster of patient cases of three *OXA-48* carbapenemase-associated Enterobacterales bloodstream infections described and published previously[10].

The authors concluded: *"In this study, we have demonstrated that hospital sink drains are widely—and in many cases abundantly—contaminated with key Enterobacterales species causing healthcare-associated infections, and are potential reservoirs of multiple resistance genes encoding resistance to important clinical antimicrobials….."* and

"In conclusion, without conditioning on the presence of resistance markers, we have demonstrated that colonization of ward sink drains with diverse and abundant populations of Enterobacterales, including drug-resistant lineages, is common and persistent. The evidence linking contaminated, unmitigated wastewater reservoirs (including sink drains) in healthcare settings with outbreaks of colonization/disease with drug-resistant Gram-negative bacilli in patients seems clear but no study to our knowledge has focused on the potential risk posed by Enterobacterales in sinks in general. Screening of sinks is not carried out in the absence of observed outbreaks, making it difficult to quantify wider patient-associated risk from the studies available. We demonstrate that contaminated sinks may be contributing to a proportion of healthcare-associated infections caused by Enterobacterales, and further work to

[10] Chau K. WGS investigation of three OXA-48 carbapenemase bacteraemia and sink colonisation on a haematology unit. Poster presentation 2018.

investigate how to reduce the risk posed by this hospital environmental reservoir is warranted." [We have omitted the inclusion of references quoted in the relevant excerpts.]

Next, we highlight a pertinent paragraph in a publication from the Netherlands concerning the role of the environment in the transmission of Gram-negative bacteria in two consecutive outbreaks in a haematology-oncology department[11].

"In recent years, many studies have demonstrated that sink drains, shower drains and toilets in hospitals can serve as a reservoir of Gram-negative bacterial infections in patients. These bacteria reside in biofilms in and on water related devices, which are refractory to disinfection. Bacteria in the biofilm of drainage systems are under a prolonged antibiotic selective pressure, because antibiotics in faeces and urine of patients are absorbed by the biofilm. Within these biofilms, containing several bacterial species, acquired mobile resistance elements are frequently transferred, resulting in highly resistant microorganisms, such as extended-spectrum β-lactamase and carbapenemase-producing Enterobacterales and Pseudomonas species". [We have again omitted the inclusion of references quoted in the relevant excerpts.]

These authors ended: *"In conclusion, the drainage system of the hospital is an important reservoir of MDR bacteria, threatening the admitted patients."*

Finally, we also draw attention to the recommendations of a Joint Working Party that reported on the prevention and control of multi-drug-resistant Gram-negative bacteria; Professor Hawkey is a co-author of this report[12]. The following are direct quotes from that report:

[11] van der Zwet WC, Nijsen IEJ, Jamin C, van Alphen LB, von Wintersdorff CJH, Demandt AMP, Savelkoul PHM. Role of the environment in transmission of Gram-negative bacteria in two consecutive outbreaks in a haematology-oncology department. Infect Prev Pract. 2022 Feb 25;4(2):100209. https://doi.org/10.1016/j.infpip.2022.100209

[12] Wilson AP, Livermore DM, Otter JA, Warren RE, Jenks P, Enoch DA, Newsholme W, Oppenheim B, Leanord A, McNulty C, Tanner G, Bennett S, Cann M, Bostock J, Collins E, Peckitt S, Ritchie L, Fry C, Hawkey P. Prevention and control of multi-drug-resistant Gram-negative bacteria: recommendations from a Joint Working Party. J Hosp Infect. 2016 Jan;92 Suppl 1:S1-44. https://doi.org/10.1016/j.jhin.2015.08.007

"Environmental screening should be considered where there is unexplained transmission of MDR Gram-negative organisms or a possible common source for an outbreak".

"Transmission from patient to patient is believed to be mainly via hands of staff, although common environmental sources have occasionally been described and should be sought where no other plausible vectors can be found (e.g. ventilator equipment or water supply)".

"Several studies have found that environmental contamination with resistant K. pneumoniae is more common than contamination with resistant E. coli".

"Transmission of MDR Gram-negative bacteria, particularly non-fermenters, has been associated with contamination of the environment, water systems or equipment".

Returning to the HAD report, and with specific regard to *Klebsiella* spp, Hawkey et al. write:

"These careful early studies of the epidemiology of Klebsiella are often forgotten and the importance of the colonised patient is underestimated. Careful investigation of outbreaks of infection nowadays can reveal lapses in hand hygiene which probably represents the most common route of transmission in hospital wards."

No references are provided here to support this assertion.

The authors go on to discuss possible water-related sources of Klebsiella infections, and indeed highlight here *"Sink traps (U bends or P traps) which always contain water and therefore large bacterial populations, usually in a biofilm, are sometimes seen as the most important source of Gram-negative infections in wards with vulnerable patients (e.g. haematology/oncology, intensive care units, burns units etc.)."*

We have referenced, above, reports that emphasise the importance of water related nosocomial infections caused by *Klebsiella* spp. and other Gram-negative bacteria. Below, using a citation made by Hawkey et al in the HAD report, we provide further evidence of the importance of the hospital environment as a source of hospital-acquired infections.

When discussing the sources of nosocomial Klebsiella infections, Hawkey et al refer to a 2017 systematic review by Kizny Gordon et al. published in 2017[13]. To be clear, the conclusions of this review are applicable not just to carbapenem resistant bacteria; as Hawkey et al. themselves state *"the basic bacterial epidemiology is unaffected by the antibiotic resistance genes carried."*

Hawkey et al. concluded by quoting from Kizny Gordon et al. as follows: "*Pseudomonas spp. and Acinetobacter spp. are environmental colonisers surviving in low nutrient conditions whereas the Enterobacteriales are predominantly of human origin and their concentration in drains may represent a different ecosystem and inoculation from human waste."* Notably, however, the next sentence by Kizny Gordon et al. is omitted by Hawkey et al. This reads: *"However, all these organisms are capable of colonizing water system biofilms".*

The Kizny-Gordon et al. review also contains other important conclusions not mentioned by Hawkey et al. For example:

"Seventy-two percent of studies reported controlling outbreaks, of which just more than one-third eliminated the organism from the water environment. A combination of interventions seems to be most successful, including reinforcement of general infection control measures, alongside chemical disinfection."

"Within the hospital there are numerous opportunities for patient exposure to water and drainage reservoirs Transmission may result from direct or indirect water contact, or from droplets created during water activities, highlighting the importance of water delivery and wastewater design to minimize these risks. Seven studies recognized that poor design or use of sinks, drains, and sluice areas may have contributed to institutional outbreaks."

It is relevant to mention here is that the taps installed in the paediatric haematology oncology wards at NHS GGC were not of approved design. In the CNR Overview Report, we drew attention to our inability to find an evaluation of the implementation of recommendations that impacted the risk of infection to patients; for example, the

[13] Kizny Gordon AE, Mathers AJ, Cheong EYL, Gottlieb T, Kotay S, Walker AS, Peto TEA, Crook DW, Stoesser N. The Hospital Water Environment as a Reservoir for Carbapenem-Resistant Organisms Causing Hospital-Acquired Infections-A Systematic Review of the Literature. Clin Infect Dis. 2017 May 15;64(10):1435-1444. https://doi.org/10.1093/cid/cix132

installation of point of use water filters to taps and linking these to the results of water testing[14].

Two of the seven institutional outbreaks cited by Kizny Gordon et al. involved *Klebsiella* spp[15] [16] but we contribute other examples include the following references[17] [18], the latter not referenced by the systematic review. In addition, multiple other potential water system related nosocomial outbreaks caused by Klebsiella are cited by Kizny Gordon et al., with the following sobering statement:

"General limitations of our study include potential publication bias and the language and literature source restrictions used in this review. Healthcare water environments are probably often neglected in outbreak assessments, which may result in an underestimation of the problem."

We have rehearsed the data for Klebsiella in significantly more detail than that for the other important types of GNE bacteria discussed in this chapter but this literature illustrates many of the general points that guided our understanding of potential risk to patients in the CNR that could have arisen from the hospital environment.

3.2 Enterobacter

Bundle 44 vol 1, Page 26 (Section 3.1.2

Next, Hawkey et al. address the potential for environmental sources of hospital-acquired infections due to *Enterobacter* spp. Although they may seem to play down this risk, it is notable that five studies highlighting a role for *Enterobacter* spp. in hospital-acquired infections are included in the Kizny Gordon review, relating to water sources (drains, taps, showers, sinks).

Hawkey et al. write "*When outbreaks of Enterobacter cloac[e]ae involving environmental sources occur molecular typing using WGS usually demonstrates a clear cluster of a specific strain type.*"

This statement is unhelpful and misleading for two reasons. First, it presumes that only one strain type is causing an outbreak rather than multiple types as could happen if a water/wastewater system was contaminated with multiple bacteria as is normally found. Second, there is an assumption that sufficient samples have been obtained to enable a robust comparison to be made of bacteria present in water sources with those causing infections. Notably, in a study cited by Hawkey et al. in which Enterobacter infections were linked to the hospital water system[19], the authors state the following:

"To determine whether showering was the most likely route of acquisition, we performed a shower test in six bathrooms in which OXA-48-positive E. cloacae had been detected in the shower drains 48 h prior to testing. In two experiments, E. cloacae was detected on the sedimentation plates placed on the shower tap, on a soap dish, and on the rim of a sink. In the other four experiments, we did not detect any E. cloacae in the sedimentation plates by culture. Other water-carrying systems such as sinks, toilets, and shower heads were screened prior to the shower tests to exclude existing reservoirs." and:

Genomic Investigation and Successful Containment of an Intermittent Common Source Outbreak of OXA-48-Producing Enterobacter cloacae Related to Hospital Shower Drains. Microbiol Spectr. 2021 Dec 22;9(3): e0138021. https://doi.org/10.1128%2FSpectrum.01380-21

"Wastewater from toilets and shower drains was collected at defined intervals, weekly during the peak of the outbreak and otherwise monthly, from all patient rooms of the three affected wards"

Again, it is clear that extensive sampling is required to find possible sources of infection and, in that context, we refer again to the deficiencies in the data from WGS investigation provided to the CNR[20].

3.3 Pseudomonas

Bundle 44 vol 1, Page 23, Section 3.2.1

Here Hawkey et al. discuss *Pseudomonas* spp., implicated as being potentially linked to the hospital environment in the CNR (defined as being in 'Strong Possible', 'Probable' & 'Strong Probable' groups)[21]. They comment:

"It is the most important bacterium when considering colonisation of hospital water systems which then can lead to infection in susceptible patients."

We agree. The authors say nothing here to refute our findings.

3.4 Acinetobacter

Bundle 44 vol, Page 30, Section 3.2.2

Hawkey et al. discuss *Acinetobacter* spp., which was also implicated as being potentially linked to the hospital environment in the CNR. They comment that: *"The epidemiology of Acinetobacter is therefore rather different to Pseudomonas and Klebsiella in that although there are reports of contamination of wet medical equipment together with isolates from sink traps as outbreak sources, surface contamination and resistance to drying is the most important source (Cruz- Lopez 2022)."*

[20] Bundle 6, Document 38, Page 1076, Section 8.3.1.

[21] Bundle 6, Document 38, Page 1044, Section 5.6, Table 5.4.

We agree but note that the authors say nothing here to refute our CNR findings and we are aware of published examples of water associated hospital outbreaks of infection caused by *Acinetobacter* spp.[22] [23].

Front Public Health. 2024 Oct 9;12:1468521. https://doi.org/10.3389/fpubh.2024.1468521

3.5 Stenotrophomonas

Bundle 44 vol 1, Page 30, Section 3.2.3

In this section, Hawkey et al. discuss *Stenotrophomonas maltophilia*, also implicated as being potentially linked to the hospital environment in the CNR. They comment that: *"This emphasises the fact that S. maltophilia can be found very widely in the hospital environment but comparatively rarely causes infections, even in the immune-compromised and careful strain typing is needed to identify any actual environmental source."*

Their comment *"comparatively rarely cause infections"* belies the fact that *S. maltophilia* is widely recognised as an increasingly important pathogen, especially in immunocompromised patients. In writing this response, we undertook a simple literature search via PubMed® using the terms 'stenotrophomonas, infection, immunocompromised': this provided 252 publications. There are multiple reports implicating environmental/water sources in hospital outbreaks caused by *S. maltophilia*, for example.[24] [25] [26]

3.6 Other GNE organisms

The remaining sections in Chapter 3 (Sections 3.1.3, 3.1.4 and 3.3.1 – 3.4.10) briefly describe a range of other Gram-negative bacteria that caused BSIs in the CNR.

Hawkey et al. discuss *Serratia* spp.(Section 3.1.3) and *Citrobacter* spp.(Section3.1.4). *Serratia* spp. were less frequently implicated as being potentially linked to the hospital environment in the CNR (defined as being in 'Strong Possible', 'Probable' & 'Strong Probable' groups)[27]. No *Citrobacter* spp. were found in these groups. Whilst we do

[27] Bundle 6, Document 38, Page 1043, Section 5.6, Table 5.4.

not comment in detail here on these sections, these do not refute the possibility of an environmental source for infections cause by *Serratia* spp. or other rarer BSIs. Indeed, for one of these, *Cupriavidus* spp., NHS GGC told us that, in 2016, it had been possible to definitively link the environment to one Cupriavidus BSI. Although this case was not included in our review, it is referred to in our report[28].

3.7 Mycobacterium chelonae

Finally, we are surprised that Chapter 3 makes no mention of this organism despite it being the source of infection in 3 patients in the CNR. *M. chelonae* is ubiquitous in the environment and is found in soil, water, and aquatic animals. It is commonly associated with skin and soft tissue infection and also causes catheter-related infections and post-surgical infections after implants, transplants, and injections. Notably, NHS GGC told us that it was possible to definitively link the environment to infection by *M. chelonae* in a case that was included in the CNR but as we did not see the confirmatory data, we were unable to record this as definitely related to the environment in our report[29].

We maintain our position that it remains entirely plausible, supported by the epidemiology of the infections seen in the CNR, that there could have been an environmental source(s) for some of the BSIs identified.

[28] Bundle 6, Document 38, Page 1071, Section 8.3.1.

[29] Bundle 6, Document 38, Page 1044, Footnote 66.

5. CHAPTER 4: CASE NOTE REVIEW

4.1 Introductory comments

Chapter 4 of the HAD report, entitled Case Note Review, seeks to challenge aspects of the methodology used in the CNR and the validity of its conclusions. We are, however, critical of the authors' approach to their critique in the following key areas:

- Discussing the patient as a source of infection, with consequent risks of patient cross contamination, without acknowledging our own recognition of the possibility of endogenous infection and observations of less than adequate Infection Prevention Control (IPC) measures.
- Proposing a theory of infection selection in patients (relating specifically to the occurrence of *S. maltophilia*) from the use of specific antibiotics of the carbapenem group (notably Meropenem) without fairly representing the strength of the evidence on which this observation is based.
- Appearing to misunderstand the selection of bacteria chosen for study in the CNR and ignoring, without explanation, one specific group of infections included within it (*M. chelonae*).
- Criticism of our approach to the use of Whole Genome Sequencing (WGS) data in defining clusters but failing to recognise the limitations on the data made available to us by NHS GGC at the time.
- Criticising a lack of comparison of the overall rates of infection with other similar institutions without discussion of the data available from studies made by Health Protection Scotland in 2019, to which we referred in our report.

As references to some of these themes reappear at different points within this Chapter, we have taken the points on which we wish to comment as they first arise within the text, providing Page and Paragraph/line references to relevant text in the HAD report itself.

4.2 The patient as a source of infection and patient to patient colonisation

Bundle 44 vol 1, Page 40

The HAD report states that patients spend long periods at home (during treatment) when there is ample opportunity for colonisation by environmental bacteria.

The references offered in the HAD report were not all published at the time we undertook our work, and we suggest that those chosen to support the risk of bacterial colonisation in the home environment are selective and neither specific to the population of patients included in the CNR *(Denton et al. 1998)*[30] nor obviously relevant *(Tavares et al. 2020)*[31]. Nevertheless, we do not disagree that this is a possibility and one which we carefully considered in own deliberations[32]. Indeed, we specifically identified one patient in the CNR who almost certainly acquired his repeated blood stream infections from the home environment[33].

We wish to point out that, certainly in paediatric practice (and we note that none of the HAD report authors has experience in paediatric haematology oncology), the opportunity to maximise time for patients to spend out of hospital during treatment still requires frequent and recurrent exposures to the hospital environment, whether this is in an outpatient clinic, day care unit or during inpatient admission. We believe the frequency of a patient's separate encounters with the hospital environment may be as relevant as, for example, the duration of a single inpatient stay[34]. We also point out that the desire to maximise time for the patient to be at home is not merely for reasons of social benefit or family cohesion, important as these factors are, but also because of the recognised risk of hospital acquired infection.

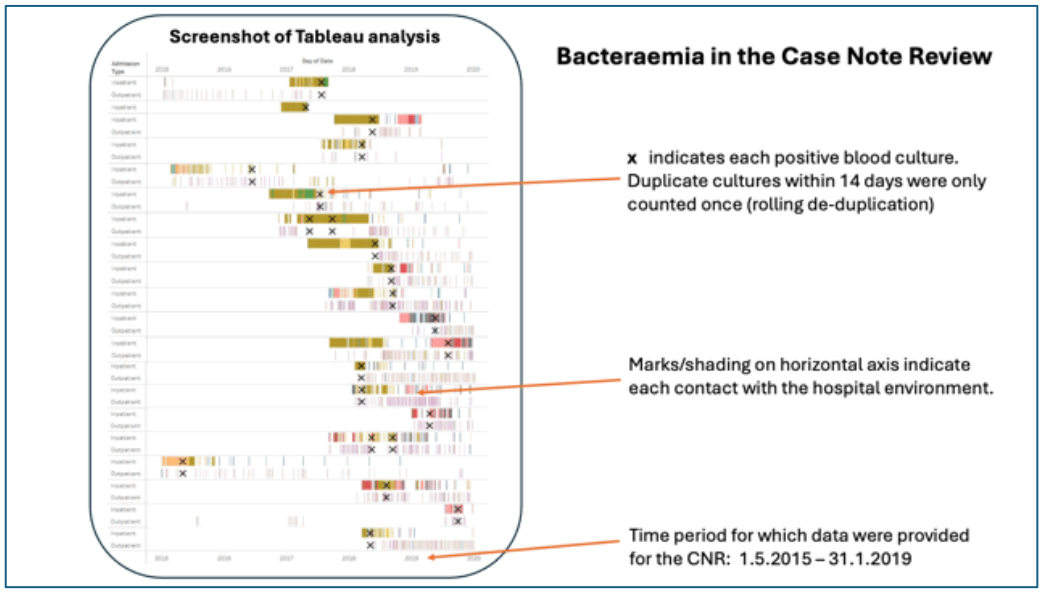
[34] Glasgow 3 - Prof Mike Stevens, Transcript, Transcript - Professor Mike Stevens - 30.10.2024 | Hospitals Inquiry, page 65.

We had access, via Tableau data visualisation software, to each coded point of contact with the QEUH/RHC environment for every patient in the CNR. This included outpatient, day care and inpatient episodes which could be interrogated by date and location[35].

The relevant question posed of the CNR was whether it was possible to associate the infections identified within the CNR with the environment of the RHC and the QEUH. In order to address this, we took the dates, pattern and frequency of each patient's interaction with the hospital environment into consideration alongside details of clinical history and the proximity (by date and location) of the same infection arising in other patients. Figure 4.1 illustrates the complexity and utility of the location data available.

Figure 4.1: Screenshot of tableau analysis showing a selection of data illustrating bacteraemia in relation to contacts with the hospital environment



Bundle 44 vol 1, Page 40, line 11

Having raised the question of bacterial colonisation from the home environment and noting the conclusion drawn in the CNR that 34% of infectious episodes were categorised as 'most likely' to be derived from the hospital environment, Hawkey et al. suggest that a lower figure (20% or less) would be reasonable. This estimate still

[35] Bundle 6, Document 38, Page 1011, Section 3.3.3.

appears to us to be significantly high, particularly as we were describing bacteraemia and not merely evidence of colonisation. Their suggestion appears to be supported by reference to publications which compared bacterial isolates from patients with those obtained from the environment using Whole Genome Sequencing (WGS) and with a prospective approach to environmental sampling.

Whilst WGS will be discussed further in Section 4.5 of this Chapter and in more detail in our response to Section 7.3 of the HAD report, we wish to be clear that, in addition to transmission from the hospital environment, we considered the possibility of environmental origin outside the hospital site as well as the possibility of patient to patient spread. We agree that sequencing information, as provided by WGS, is the only way to determine if two microorganisms of the same species are genetically related, and therefore potentially transmitted between patients or the environment and patients. Yet during the era in which patients considered within the CNR were being treated, and up to the date of submission of our report, WGS data at NHS GGC were limited. Nor was there evidence of a systematic approach to prospective environmental microbiological surveillance.

We consider patient to patient infection to be a failure of protection within the hospital environment and we are surprised that the authors do not reference the importance of Infection Prevention Control (IPC) measures in reducing the risk of patient to patient and environment to patient transmission. The absence of comment on this point is particularly relevant as we described less than optimal IPC measures in the environment in which care was delivered at QEUH/RHC[36]. Our concerns included poor quality data and lack of governance and assurance relating to improvements to IPC based on audit submissions.

[36] Bundle 6, Document 38, Page 1036, Section 5.3.

4.3 The Meropenem theory

Bundle 44 vol 1, Page 40, line 26

The authors move from a discussion of the risk of the home environment to consider the impact of broad spectrum antibiotic use and its risk for the development of multi-resistant Gram-negative bacteria.

We agree that broad spectrum antibiotic use has the potential for dominant colonisation of the microbiological environment of the gastrointestinal tract in patients being treated for cancer and similar conditions.

The HAD report pays particular attention to *Stenotrophomonas maltophilia* and we agree *that S. maltophilia* is a bacteria of rising concern that has been reported as a cause of healthcare-associated infection with significant morbidity and mortality. It is a non-fermentative, aerobic, Gram-negative bacillus usually isolated from humid places such as water, soil and sewage. It can form biofilms and colonise surfaces of medical devices.

Hawkey et al. present data from a study in adult patients with acute myeloid leukaemia [Aitken et al. 2021][37]. This is an aggressive malignancy also seen in children and adolescents although significantly less frequently than the more typical form of acute lymphoblastic leukaemia found in the paediatric age group.

The authors use the Aitken study to highlight the theory that prior administration of carbopenem antibiotics (typically, meropenem) may drive the risk of patient colonisation with *S. maltophilia* and with it, the risk of subsequent blood stream infection. There are, however, weaknesses in the Aitken study which the study authors themselves identify, notably that: the study was small (only 8/90 patients studied developed *S.maltophilia*); it was based in a single treatment centre; and it lacked the power to permit a full multivariate analysis. Indeed, the impact of prior meropenem exposure was found not to be significant in the exploratory multivariate analysis the authors report. In addition, Aitken et al. referenced at least three other studies that had not identified meropenem exposure as a risk factor for *S. maltophilia* colonisation or

[37] Bundle 27 Volume 18, Document 4, page 32.

blood stream infection. These authors concluded that their own results should be viewed as '*hypothesis generating'*.

Bundle 44 vol 1, , 45, Paragraph 2, line 5

In contrast, Hawkey et al. suggest that the work reported by Aitken et al. offers a *"highly plausible explanation for the apparent increase in S. maltophilia BSI …"*. This might seem a premature and over-optimistic assessment of a risk which cannot be considered as proven at this stage. However, as we recognise an increased interest in this arena and we have reviewed more recent literature (from 2022) to further illuminate the hypothesis.

We identified 5 studies of patients with *S. maltophilia* BSI published since that time which appear to be of relevance. Two are relatively large adult studies and two are from paediatric populations. We also identified one systematic review although this addressed *S. maltophilia* pneumonia rather than BSI.

These publications are briefly summarised here:

Kanchanasuwan et al.[38]. This retrospective study, from Thailand characterised the previous antibiotic exposure and outcome of 117 adult patients with *S. maltophilia* blood stream infections (BSI) of whom 112 (96%) had received prior carbapenem antibiotics. The authors concluded that *S. maltophilia* mostly affects patients with a history of the prior use of antibiotics, especially carbapenem, reflecting the widespread but potentially problematic use of carbapenem in hospitalized patients. Unfortunately, they did not study a parallel population of equivalently ill patients without *S. maltophilia* infections to determine if prior use of carbapenem was equally prevalent. This study cannot be considered informative to the matter in question.

Chung Yi Koh et al.[39]. A retrospective study of adults from Singapore reported a total of 349 distinct encounters (from 322 unique patients, one third of whom were in

38 Kanchanasuwan S, Rongmuang J, Sirapaitoon P et al. Clinical Characteristics, Outcomes, and Risk Factors for Mortality in Patients with Stenotrophomonas maltophilia Bacteremia. J Clin Med. 2022;11(11):3085. https://doi.org/10.3390/jcm11113085

[39] Koh Mcy, Ngiam Jn, Chew Kl et al., Clinical Presentation And Outcomes Of Bloodstream Infection With Intrinsically Carbapenem-Resistant Non-Fermenting Gram-Negative organisms:*Stenotrophomonas maltophilia*, *Elizabethkingia* spp. and *Chryseobacterium spp*. in Singapore, from 2012 to 2024. BMC Infect Dis. 2025;25(1):273. https://doi.org/10.1186/s12879-025-10636-9

intensive care) with a BSI over a 12 year period. *S. maltophilia* was the commonest (56.4%), followed by *Elizabethkingia spp*. (36.4%) and *Chryseobacterium spp*. (7.2%). Prior carbapenem exposure (defined as within 1 month prior to infection) was observed in 59.9% of all cases but with no significant differences observed among the three pathogens.

Franco et al.[40]. This is a retrospective matched case-control study from a neonatal intensive care unit in New York, published this year. It reported a total of 15 cases with *S. maltophilia* cultured from any site, and 35 controls. This was a small study and it was not restricted to BSI; it could therefore include patients who were colonised rather than with established infection. Nevertheless, significant risk factors identified for the culture of *S. maltophilia* included days of any prior antibiotics (median 24 vs. 18, *p = 0.036*) and days of all broad-spectrum antibiotics (median 19 vs. 12 days, *p = 0.027*), as well as duration of meropenem exposure (median 9 vs. 6 days, *p = 0.018)* and of any meropenem exposure (100% vs. 22%, *p = 0.005*). There was no multivariate analysis to allow for confounding variables in the analysis.

Bilen et al.[41]. This was a retrospective observational study from a tertiary children's hospital in Turkey, performed between January 2014 and December 2021. All patients aged under 18 years with *S. maltophilia* (n= 73) and *P. aeruginosa* (n=80) BSI were included in the study. Over 30% of patients in each group were being treated for haematology oncology conditions. 81% of *S. maltophilia* and 95% of *P. aeruginosa* infections were nosocomial in origin (identified after 48 hours in hospital).

Prior glycopeptide (teicoplanin or vancomycin) and carbapenem (meropenem, ertapenem or imipenem) antibiotic use was significantly higher in patients both with *S. maltophilia* BSI (41% vs. 21.2%; OR, 2.544; 95% CI: 1.250–5.180; *p= 0.009* for glycopeptide exposure, and 52% vs. 23.7%; OR, 3.429; 95% CI: 1.719–6.840; *p= 0.001* for carbapenem exposure). Multivariate analysis showed that only prior

Risk Factors for Infection and Mortality Associated With Stenotrophomonas maltophilia Bloodstream Infections in Children; Comparison With Pseudomonas aeruginosa Bloodstream Infections. Pediatr Infect Dis J. 2023 May 1;42(5):374-380. https://doi.org/10.1097/INF.0000000000003845

carbapenem use was associated with *S. maltophilia* BSI (adjusted odds ratio [AOR], 2.710; 95% CI: 1.225–5.992; *p= 0.014*). Further multivariate analysis showed PICU admission because of BSI and prior glycopeptide use were independently associated with mortality in patients with *S. maltophilia* BSI (AOR, 19.155; 95% CI: 2.337–157.018; *p = 0.006* and AOR, 9.629; 95% CI: 1.053–88.013; *p= 0.045*, respectively) but not prior carbapenem exposure.

Wang N et al.[42] This meta-analysis, the only recently published study using this methodology that we were able to identify, included a total of eight studies with a sample size of 2,320 cases. Meta-analysis of prior antibiotic exposure showed that β-Lactamase inhibitors (OR = 9.98, 95% CI: 1.51 ~ 65.96), aminoglycosides (OR = 4.01, 95% CI: 2.06 ~ 7.80), carbapenems (OR = 2.82, 95% CI: 1.49 ~ 5.31), and quinolones (OR = 2.17, 95% CI: 1.21 ~ 3.89) were all significant risk factors for ICU-acquired *S. maltophilia* pneumonia. It is unclear whether this result can translate to a similar analysis of patients with BSI but the study serves to illustrate that other antibiotic exposure, not just carbapenem, may represent risk.

Whilst the meropenem hypothesis cannot be dismissed, nor is it proven and the published experience remains inconsistent. However, given the emphasis placed by Hawkey et al. on 'meropenem risk' (our terminology) regarding *S. maltophilia,* we have undertaken a) a review of antibiotic policy for treating haematology oncology patients at RHC during the era of the CNR and b) looked again at data available on the use of antibiotics in the CNR.

We had access to all versions of the policy guiding the use of antibiotics for febrile neutropenia[43] (fever in occurrence with low white cell count, a state which carries a significant risk of serious infection in immunocompromised patients) in paediatric haematology oncology patients issued from August 2010 to March 2020, i.e. encompassing the era of the CNR. There was no significant change across the four versions of the policy issued during this time. Each specified Tazocin (piperacillin-

[42] Wang N, Tang C, Wang L. Risk Factors for Acquired *Stenotrophomonas maltophilia* Pneumonia in Intensive Care Unit: A Systematic Review and Meta-Analysis. Front Med (Lausanne). 2022;8:808391. https://doi.org/10.3389/fmed.2021.808391

[43] Bundle 44 Volume 1, Documents 33, 34, 35, 36, Pages 597 – 634.

tazobactam) and Gentamicin as first line antibiotic therapy for suspected infection, with the addition of Vancomycin or Teicoplanin if there was concern about infection of the central venous line. Meropenem was to be substituted for Tazocin (continuing also with Gentamicin) if there was persistent fever at 72 hours. This guidance could be (and was) modified by microbiological advice and the reporting of antibiotic sensitivities from proven positive cultures.

Hawkey et al. refer to a worldwide shortage of piperacillin-tazobactam in 2017-2018 and suggest that this sometimes required the substitution of meropenem. They provide no evidence that this occurred at NHS GGC. They also state that *"This resulted in an increase usage of meropenem around the time of the increase(d) occurrence of S maltophilia"* before referring again to the work of Aitken et al.

No evidence is provided for this assertion.

Although we collected data on antibiotic usage in our clinical summaries of each patient prior to and during the treatment of each infection in the CNR, we do not have a fully comprehensive dataset across the whole CNR for the entire duration of the period under study. This would be necessary to identify any change in meropenem use with time.

Nevertheless, we have undertaken an analysis of meropenem exposure in periods of 30 and 60 days prior to infection in patients in the CNR who experienced *S. maltophilia* BSI.

We used patients in the CNR who experienced Enterobacter cloacae infections as a similar sized comparator group.

The analysis shows no difference. (Table 4.1).

Table 4.1 The use of meropenem within periods of 30 and 60 days prior to the occurrence of infections with *Stenotrophomonas maltophilia* and *Enterobacteria cloacae* in the CNR

Organism	Patients with informative	Meropenem use documented within 30 days prior to infection	Patients with informative	Meropenem use documented within 60 days prior to infection

	records* (Total)	Yes	No	records* (Total)	Yes	No
S. maltophilia	18 (23)	5	13	14 (23)	5	9
E. cloacae	22 (24)	4	18	12 (24)	5	7
Uncorrected χ^2		0.523			0.097	
p (2 tail)		0.50 (not significant)			0.76 (not significant)	

*The term 'Informative Records' implies that these patients had hospital contact records spanning periods of 30 or 60 days prior to infection *and* adequate clinical information about antibiotic use in these periods from data extracted for the CNR.

4.4 Defining the population within the CNR

Bundle 44 vol, Page 41, Paragraph 2

Hawkey et al. claim that they were not clear exactly how many BSI occurred in the period studied, and what the causative bacteria were. We this this statement may refer to data for all types of BSI in patients included over the entire period of the CNR, as data describing the infections included in the CNR are provided in the Overview Report[44].

Their concern also appears to relate to whether some bacterial species regarded as having an environmental origin were included or not, and yet we believe our report to be quite clear on this point[45] . We worked to a pre-defined protocol[46]; the HAD team say this was not available to them although it could have been requested.

It is of note that the infections selected for the CNR included three patients with infections caused by acid fast environmental organisms (*Mycobacterium chelonae)*. It is interesting to note that Hawkey et al. do not address these infections in their report at all. We understood that NHS GGC established a direct link to the hospital environment in one of these patients – a point to which we referred in the CNR Overview Report[47]. However, as we were not provided with direct evidence for this link during our work, we were unable to classify this case as 'definitely' linked to the hospital environment as would otherwise have been the case.

Bundle 44 vol 1, Page 44, Paragraph 2

Hawkey et al. question the exclusion of *E coli* from the CNR but *E coli* was described as a Gram negative, non-environmental organism in the databases used to define the cases selected[48]. The HAD report refers to one study *(Woodford et al. 2007)*[49] which

[44] Bundle 6, Document 38, Page 1028, Section 4.3, Tables 4.2 and 4.3 *and* Page 1105, Appendix B.

[48] To be Bundled - A53008955 - Case Note Review - Paediatric Haemato-Oncology Patients RHC, NHSGGC - Epidemiological & Clinical Outcomes Protocol - April 2020 v1.

[49] Woodford N, Kaufmann ME, Karisik E, Hartley JW. Molecular epidemiology of multiresistant Escherichia coli isolates from community-onset urinary tract infections in Cornwall, England. J Antimicrob Chemother. 2007;59(1):106-9. https://doi.org/10.1093/jac/dkl435

suggests that a strain of *E coli* may have caused a cluster of infections on a ward in one hospital over a period of several months. However, detailed reading of this publication reveals that only one isolate was available for testing and we believe this, and the very small size of the study, is insufficient to challenge the more commonly held view that *E coli* causes systemic infection by translocation from gut colonisation.

4.5 Defining clusters and WGS

Bundle 44 vol 1, Page 41, Paragraph 3

The HAD report discusses the terminology of a 'cluster' and makes the following statement: *"We do not think it appropriate to group different species of bacteria as a cluster despite the CNR panel suggesting that the putative environmental sources had multiple types of many different species…."*. We can confirm that we separately distinguished different species of the same bacteria in our considerations of possible clustering.

Bundle 44 vol1, Page 41, Paragraph 4

This leads on towards a discussion of the relevance of WGS, both in this paragraph and in the next, as well as in Chapter 7. We will respond to this more fully in our critique of their Section 7.3.

Initially, however, Hawkey et al. discuss the importance of other factors in determining the likelihood of clustering. Whilst they suggest the identification of a species of bacteria from an environmental site in spatial and temporal association with a patient who has a similar bacteraemia does not unequivocally establish it as a source, we assert that it substantially raises the possibility that this may be the case.

The authors suggest that a route of transmission and portal of entry need also to be identified but do not specify how a specific route of transmission or a specific portal of entry might be determined with any certainty except by undertaking a detailed root cause analysis.

It is self-evident that patients such as those in the CNR receive care in an environment in which there are multiple opportunities for exposure to water supply, water and drainage, including taps, sinks, lavatories, drains and all surfaces that might be wet from cleaning or splashing. All these represent opportunities for transmission of bacteria. Furthermore, virtually all patients have interventions on multiple occasions involving venous access, sometimes at multiple sites and most often via central venous catheters, as well as other invasive procedures, all of which would have afforded potential portals of entry.

Defining a specific route of transmission or a specific portal of entry may therefore be less relevant than the recognition that the nature of the patient's diagnosis and treatment raise these as a strong possibility.

All that said, it is of interest in this context that the HAD report does not comment on our observations about the frequency of environmental repairs to both ventilation and plumbing in the clinical environment[50]; the lack of proactive action following IMT meetings regarding investigation of potential outbreaks of infection[51]; or the failure to update the ICNet system to provide additional alerts which would have ensured greater engagement by IPC nurses with their investigation[52]. We also commented on the surprisingly late agreement (in the latter part of 2019) that Root Cause Analysis (RCA) should form the basis for future IMT investigation[53].

Bundle 44 vol1, Page 42, Paragraph 1

At the end of this Paragraph the authors describe the CNR's method of defining outbreaks/clusters as *"unusual, suboptimal and a limited method of investigation"*. They go on to suggest that we did not wish to consider WGS strain typing and, in doing so, reference Section 8.3.1 in the CNR report[54]. We will consider this further in our critique of Section 7.3 of the HAD report. Their prior suggestion is, however, incorrect:

[50] Bundle 6, Document 38, Page 1035, Section 5.2.

[51] Bundle 6, Document 38, Page 1066, Section 8.2.2.3 and Example 8.5.

[52] Bundle 6, Document 38, Page 1071, Section 8.4.2 and Page 97, Example 8.7

[53] Bundle 6, Document 38, Page 1064, Section 8.2.2.2.

[54] Bundle 6, Document 38, Page 1069, Section 8.3.1.

we would have been pleased to utilise more data about WGS had this been available to us.

Hawkey et al. fail to acknowledge our description of the inadequacy of the data with which we were provided. We referenced this both with regard to environmental sampling[55], and to data about WGS[56]. We made the point that not only were there limited data on patient isolates, the number of environmental samples available for analysis was particularly small. We highlighted, for example, in Section 8.3.1 of our report, that only 6 water samples were included in the database provided to us for environmental isolates in 2019, of which only 3 could be successfully analysed by WGS. Furthermore, 140 other samples from the total of 550 samples in the database for that year had incomplete location information, so any results that might have been obtained could not be accurately related to sites of patient care.

We also described our general concerns about the quality of data we had received from NHS GGC[57]. In the Executive Summary[58] we made a statement about data from WGS analysis which included these words "*…despite over 5 years of experience in investigation of outbreaks of GNE bacteria and concerns about the hospital environment, NHS GGC had not established an electronic database of microbiological typing results…. and consequently had no ability to easily relate potentially linked bacterial isolates".* We also went on to comment on *"an inconsistent approach to environmental sampling…".*

We stand by these criticisms and reiterate that it is important to understand the approach we took to address the second of the key objectives for the CNR, namely, 'Is it possible to associate these infections with the environment of the RHC and QEUH?'. Our deliberations and final decisions were based on all the information available to us at the time including that describing the clinical circumstances of the patient prior to and at the time of the infection; the temporal relationship between

infections of the same bacterial species; and the overall frequency and pattern of GNE infections within the period of the CNR.

Bundle 44 vol 1, Page 44, Paragraph 4

Hawkey et al. revisit the issue of WGS in this Paragraph (and in Paragraph 2 on Page 40). We will address this again in our response to Section 7.3 of their report.

They also repeat their conclusions about the publication [Aitken et al., 2021] which they suggest supports a theory of 'meropenem risk' and reiterate the unsubstantiated suggestion that meropenem usage increased within NHS GGC because of a shortage of piperacillin-tazobactam. These points are further rehearsed in Paragraph 3 on Page 40 of the HAD report and have already been addressed in Section 4.3 of this Chapter.

4.6 Comparison of the overall rates of infection with other institutions

Bundle 44 vol 1, Page 45, Paragraph 4

Hawkey et al. suggest that a comparison with overall rates of infection in other similar institutions should have been undertaken as part of the work for the CNR.

Although this was not directly within the Terms of Reference for our review, we had access to relevant work undertaken by Health Protection Scotland (HPS), published in November 2019[59] (although this document is still dated October 2019 which is when, we believe, a first draft was published).

This work had previously informed the protocol for the CNR (see Section 4.4 above) and was referenced in the CNR Overview Report[60]. It includes an analysis of rates of infection at NHS GGC during the era of the CNR compared with similar data from the two other paediatric haematology oncology units in Scotland (Edinburgh and Aberdeen) over the same period of time. It included the following as one of its recommendations:

[59] Bundle 7, Document 7, Page 250.

[60] Bundle 6, Document 38, Page 1009, Section 3.2.1 and Page 1068, Section 8.2.3.

"NHS GG&C should consider current control measures around restriction on services for newly diagnosed patients as there is no evidence from the HPS review of the data that supports the continued restriction of services".

However, our own conclusion about the data presented in this report and included in the CNR Overview Report read as follows[61]:

"We do not see that this report would have provided any clear message of either reassurance or concern about past events. Nor do we see that it offered a clearly interpretable and favourable comparison with other Scottish children's hospitals (not least because of the size of the paediatric haematology oncology services in these three hospitals varies substantially – NHS GGC being easily the largest)".

It is interesting to note that this final version of the HPS report (published in November 2019) was redacted in parts for reasons we do not know. We requested an unredacted copy of the report (which we believe to have been first distributed in October 2019 [62]) in preparation for giving evidence to the Glasgow III hearings in October 2024. The text of the same recommendation simply reads *"NHS GG&C should consider current control measures around restriction on services for newly diagnosed patients".* We are unclear why the additional assurance was added to the redacted version and do not believe the data supports this addition.

The redacted version of the 2019 HPS report[63] is still publicly available and would have been accessible to Hawkey et al., but it is not referred to in their own report despite their assertion that such a comparison would have been important for the CNR. Nor did they undertake a similar comparison themselves, relying instead on an analysis of data comparing rates of infection at RHC during and beyond the era of the CNR, with those at Yorkhill (the previous home of RHC). We will address the findings relating to this analysis in our critique of Section 7.2 of the HAD report.

A comparison of incidence data for infections at NHS GGC with that at other Scottish paediatric haematology oncology units was also included in another document,

[61] Bundle 6, Document 38, Page 1068, Section 8.2.3.

[62] Bundle 7, Document 6, Page 214.

[63] Bundle 7, Document 7, Page 250

published earlier in 2019[64]. This was not referred to in the CNR Overview report but shows that the rate of environmental bacteria cultures was significantly higher at Yorkhill and RHC (combined) than at the other Scottish paediatric hospitals over the 5 years from 2014-2018. Reasonably, in our view, the report advises that the comparison with the paediatric hospitals in other health boards should be interpreted with caution as differences in the patient population may introduce bias to the comparison.

In conclusion, Hawkey et al. assert that comparative studies with other institutions would have been important for our work but although we did not undertake such comparisons ourselves, such data do exist. This position was also elaborated with reference to Mr Mookerjee's expert witness report[65], as part of Professor Stevens evidence to the Inquiry in October 2024[66].

Our view remains that comparisons of populations from different units offer limited assistance in responding to the question asked of the CNR – "Is it possible to associate these infections with the environment of the RHC and QEUH?"

6. CHAPTER 5: WATER

We highlight below specific points and shortcomings in this chapter. In doing so, we note that it contains multiple examples of important observations that reinforce the plausibility for the hospital environment providing potential sources of infections in hospital patients, particularly in immunocompromised individuals.

5.1 Are hospital water systems sterile?

Bundle 44 vol 1, Page 47

This offers a brief introduction to the reality that hospital water systems are not sterile and that high quality supply is typically only supplied to specialist areas and now to augmented care areas, particularly with respect to *P. aeruginosa*.

We have no comments to offer.

5.2 What constitutes a contaminated water system?

Bundle 44 vol 1, Page 47

After a general discussion of bacteria in water, Hawkey et al. turn towards the clinical setting and state:

"Probably the most common method of the regression type of contamination occurs when the tap outlet is contaminated by immersion in water containing human derived material (e.g. wash water from a patient which may contain small amounts of urine, faeces, or worse, infected urine being emptied into a sink). Hospitals have strict rules on the disposal of such waste to prevent colonisation of water outlets in clinical areas, but under pressure they may not always be followed. The bacteria encountered in this setting are gut bacteria and sometimes skin bacteria although skin bacteria such as Staphylococcus aureus do not survive well in the environment whereas E. coli, Klebsiella spp. and other such organisms may survive as transient colonisers of the biofilm on the tap nozzle. The significance of this is that the tap in turn can act as a source to contaminate water that is drawn from the tap for use on patients or staff hands during hand washing."

We note and agree with this statement and highlight the admission by Hawkey *et al.*. about Gram-negative bacteria such a *Klebsiella* spp. having a potential environmental source(s) for transmission to patients e.g. via the contaminated hands of healthcare workers, and suboptimal IPC and environmental cleaning practice.

A little further on the same page, we encounter a more contentious statement:

"Furthermore, taps in domestic premises and non-clinical areas of hospitals are usually colonised. However, some groups of patients (such as those with neutropenia, immunosuppression, long term indwelling intravascular cannulas, respiratory tract intubation with mechanical ventilation, etc.) can infrequently become infected from these sources. It should be remembered that though one can find a source in a hospital environment of potentially pathogenic bacteria, without a route of transmission and a portal of entry into the patient these sources are of little consequence."

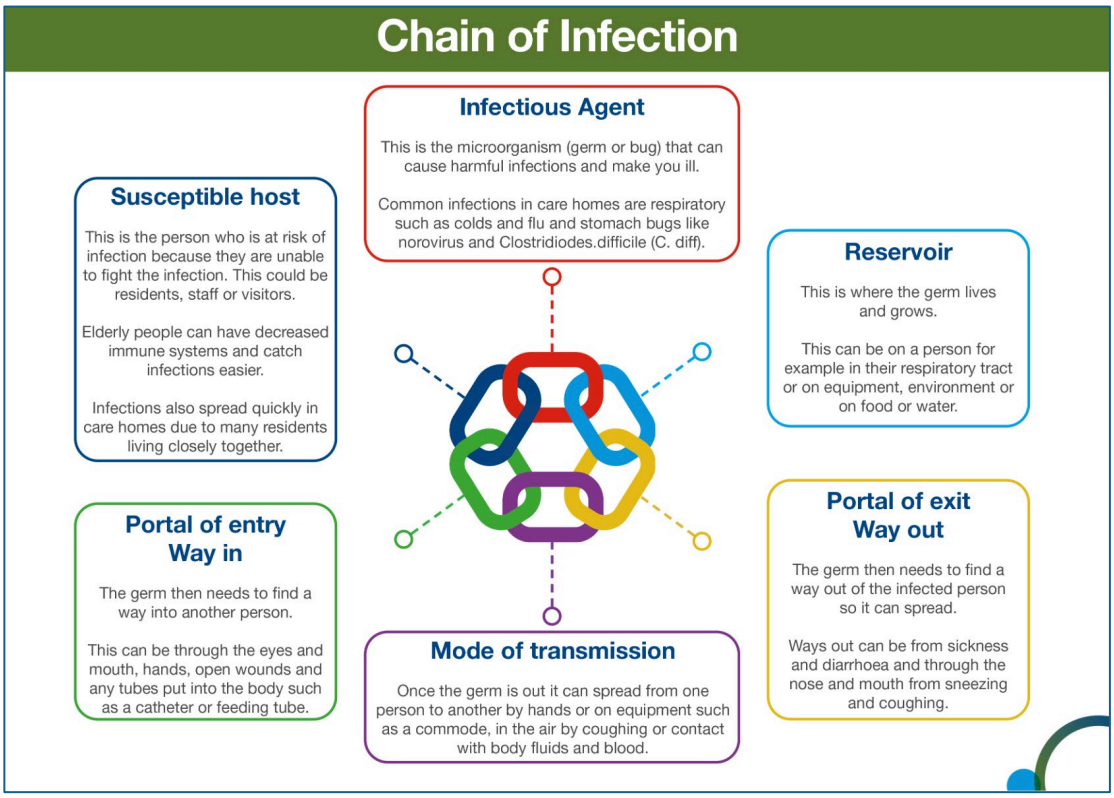
Whilst we note and agree with the first section of this paragraph, particularly that immunocompromised patients in hospitals can become infected from contaminated taps, the last part of this statement is odd. There are multiple potential ways in which bacteria may be transmitted to immunocompromised patients in hospitals and then cause infection.

Most strikingly, these patients typically have intravascular catheters for much of their hospital stay and these provide direct access into the bloodstream for drugs, blood products, fluids and (unwittingly) for microbes that can be encountered in the environment and on the hands of patients, healthcare workers and visitors.

The image below (Figure 5.1) from the NIPCM[67], originally designed for use in care home settings, is helpful in explaining the link:

[67] National Infection Prevention and Control Manual. Chain of infection https://www.nipcm.scot.nhs.uk/care-home-infection-prevention-and-control-manual-ch-ipcm/print?section=2820

Figure 5.1: The Chain of Infection



Hawkey et al.'s focus on determining the route of transmission and portal of entry is something also discussed in Chapter 4 of our rebuttal (Section 4.5).

Bundle 44 vol, Page 48

At the end of Section 5.2, Hawkey et al. conclude *"In summary, although sink traps have a diverse and sometimes profuse bacterial population which is enriched sometimes by human derived materials and consequently bacteria associated with human colonisation or infection, they are not the dominant source of bloodstream infection when compared to gut and or oral microbiomes of immune compromised patients themselves."*

We did not claim this to be the case. However, as Hawkey et al. state, and many reports have shown, sinks are clear potential sources of bacteria that can cause infections in patients. Gram-negative bacteria that are found either predominantly in the environment, e.g. in water systems, and/or in humans and which contaminate sinks via discarded fluids, are the key microbes found in sinks/sink traps.

The epidemiological clustering of BSIs identified in the CNR, noting how we categorised the likelihood of each infection being linked to the hospital environment, could certainly be linked to sink contamination.

Characterisation using WGS methodology is the tool with which links between patient and environment can be determined. We comment elsewhere in this report (Chapter 7, Section 7.3) about the interpretation of the WGS data available from NHS GGC and the sporadic and inconsistent sampling and storage of isolates from environmental sites when looking for such links.

5.3 What if there was 'widespread contamination of the hospital water system?

Bundle 44 vol 1, Page 48

In Section 5.3 of their report, which deals with questions that would be pertinent if there was indeed widespread contamination of the water system, Hawkey et al. make the following statement

"In our experience significant problems of increased rates of infection caused by bacteria capable of coming from an environmental source are identified when intensive testing of water is undertaken when an outbreak is suspected, rather than from routine or prospective testing.'

We agree and believe that NHS GGC clearly suspected that the hospital environment, and specifically the water system, could be linked to infections in children. They subsequently took mitigating action in treating the water system and taking the major decision to remove patients from the paediatric haematology oncology unit (Wards 2a and 2b) to permit environmental improvements. Yet, as we have detailed in the CNR Overview Report[68] [69] and in our critique elsewhere in this rebuttal (Chapter 7, Section 7.3), the short-comings of the environmental sampling and WGS investigations that were carried out at the time, and since, to determine if an environmental source(s) could explain the clusters of BSIs investigated in the CNR, are significant.

[68] Bundle 6, Document 38, Page 1041, Section 5.5.2

[69] Bundle 6, Document 38, Page 1042, Example 5.2

When discussing the possibility that a water system is a source of environmental contamination, Hawkey et al. return to the theme of WGS investigation:

"*The definitive evidence for linkage is to demonstrate that the DNA sequences (or part thereof - see below) of a micro-organism causing a BSI in a patient is indistinguishable to that of the same species of micro-organism found in the built microenvironment. This is not only essential for the understanding/identifying of an environmental source of risk to patients but also for ensuring there is not an overreaction to these possible sources of infection."*

We agree that DNA based typing can indeed provide definitive evidence linking infections in patients with the built environment. However, it is important to acknowledge two key issues here. Firstly, the 'needle in a haystack' analogy may apply, given the numerous opportunities for microbial contamination of a water system and the very many different bacteria that can be found which will vary in time and place. Secondly, especially if coupled with low frequency, sporadic and/or missed opportunities to establish linkages (see further our comments Chapter 7, Section 7.3), establishing DNA based matches between bacteria in patients with those in the environment may not be achieved.

Earlier in their report (Chapter 3), Hawkey et al. cite an authoritative systematic review published by Kizny Gordon et al.[70], and do so again here. This was a review of published studies investigating the hospital water environment as a source for antibiotic-resistant organisms causing hospital-acquired infections. Despite placing significant weight on the findings of this review, Hawkey et al. did not include the following statements from this publication:

"Screening of patients and the environment varied widely with regard to the methods used, frequency, and site".

"Differences in environmental sampling, such as collecting water samples before or after tap flushing and use of varying water volumes, may affect sampling sensitivity. Microbiological methods differed between studies, and although the use of selective

[70] Kizny Gordon AE, Mathers AJ, Cheong EYL, Gottlieb T, Kotay S, Walker AS, Peto TEA, Crook DW, Stoesser N. The Hospital Water Environment as a Reservoir for Carbapenem-Resistant Organisms Causing Hospital-Acquired Infections-A Systematic Review of the Literature. Clin Infect Dis. 2017 May 15;64(10):1435-1444. https://doi.org/10.1093/cid/cix132

culture media may have improved detection, organisms with near-breakpoint minimum inhibitory concentrations could have been missed, underestimating the true prevalence and extent of environmental contamination. Molecular tests may increase sensitivity."

Experience from the literature also suggests that published studies will tend to have more complete information and, by contrast, unpublished investigation of links between the hospital environment and patient infections can be expected to have more gaps in data, increasing the chances that linkages will occur but go unrecognised

We concur with the caveat implied in the quotations from Kizny Gordon et al. (above) and believe that, put simply, the absence of DNA based typing links between microbes in the hospital environment and those causing patient infections does not exclude the possibility that the former is a source of the latter.

Conventional IPC practice, when there is a suspected source of infection, is to eliminate or modify the source. For this reason, Kizny Gordon et al. noted the following: *"Seventy-two percent of studies reported controlling outbreaks, of which just more than one-third eliminated the organism from the water environment. A combination of interventions seems to be most successful, including reinforcement of general infection control measures, alongside chemical disinfection."*

In interesting contrast, Hawkey et al. comment that *"In our experience, when clusters of infection occur caused by potentially environmentally sourced bacteria in immune supressed patients, investigation with detailed typing very often reveals a homogeneous cluster of strains and helps tremendously in identifying the source and introducing control measures."*

This unreferenced statement downplays the realities of such investigations. Interestingly, we note the following published investigation[71] of which Professor Hawkey was a co-author. This reports the use of intensive sampling to investigate the water systems in four UK hospitals as the source of infections in patients.

[71] Halstead FD, Quick J, Niebel M, Garvey M, Cumley N, Smith R, Neal T, Roberts P, Hardy K, Shabir S, Walker JT, Hawkey P, Loman NJ. Pseudomonas aeruginosa infection in augmented care: the molecular ecology and transmission dynamics in four large UK hospitals. J Hosp Infect. 2021 May;111:162-168. DOI:10.1016/j.jhin.2021.01.020

The authors noted that *"In order to understand the extent and dynamics of the colonization of ICU tap water outlets, a prospective longitudinal study is required. Only one such study has been published …"* and concluded *"The overall findings suggest that water outlets are the most likely source of P. aeruginosa nosocomial infections in some settings, and that widespread introduction of control measures would have a substantial impact on infections."*

Thus, intensive sampling to an extent that is infrequently practiced in routine settings is needed to identify hospital water systems as a source of infection in patients.

5.4 If patients were at an increased risk of infection as a result…?

Sections 5.4.1 and 5.4.2 add little to earlier to data in sections of Chapter 3, on which we have commented in detail.

Bundle 44 vol 1, Page 52, Section 4.3

Here Hawkey et al. use a study by Kampmeier et al.[72] to attempt to refute that the clusters of cases of *S. maltophilia* BSIs we described in the CNR could have had an environmental source. Notably this study examined a single cluster of 4 cases of BSI over a 6 month period using WGS and concluded that their assumed cluster of cases did not constitute 'an outbreak'.

This scenario differs somewhat from the findings of the CNR in which 21 *S. maltophilia* BSIs occurred in 19 children. There were 12 episodes of *S. maltophilia* bacteraemia in 11 children during 2018, but none after September 2018 (when Ward 2A closed in September and patients were transferred to Ward 6A), until the first of 4 episodes in 4 children between April - September 2019 [we acknowledge that there is an error in Section 4.3.2 of the CNR – there were 4, not 5, cases of *S.maltophilia* BSI between April – September 2019].

Referencing this one report has no particularly useful bearing on the scenario we investigated in the CNR. In fact, Kampmeier et al. indicated that while the 4 isolates

[72] Kampmeier S, Pillukat MH, Pettke A, Kossow A, Idelevich EA, Mellmann A. Evaluation of a *Stenotrophomonas maltophilia* bacteremia cluster in hematopoietic stem cell transplantation recipients using whole genome sequencing. Antimicrob Resist Infect Control. 2017 Nov 13;6:115. DOI:10.1186/s13756-017-0276-y

causing BSIs were not genetically related to each other, this clearly did not remove the possibility of an environmental source(s) for these infections. Indeed, they found that one environmental isolate from a shower outlet was closely related (by WGS) to a single patient's isolate. They concluded:

"WGS analysis can be used to precisely refute an outbreak of S. maltophilia. Additionally, WGS- based typing documented sanitary installations in HSCT units to be an actual source or result of transmission between environmental and human habitats. Hence, in addition to classical infection control strategies, monitoring of aqueous habitats has to be established within the rooms of HSCT recipients in order to prevent transmission of these multidrug resistant organisms, as recently also shown for P. aeruginosa."

Bundle 44 vol, Page 53

Towards the end of this chapter, Hawkey et al. make a statement with which we don't disagree *"The important lesson here is that not all clusters of S. maltophilia infections in immunocompromised patients are necessarily spread from an environmental source."* and go on to say *"It also demonstrates the power of WGS typing to identify highly related clusters of organisms coming from single sources*." with which it is also possible to agree but, as we argue repeatedly in this rebuttal, WGS can only do so when sampling of both patient and environment is adequate.

With regard to their specific attention to the study by Kampmeier, we suggest that they inappropriately compare the larger clusters in time and place that we identified in the CNR, and the possibility/probability of them having an environmental source(s), with one small cluster of cases in a hospital in Germany, and whether a cluster of BSIs was caused by a single bacterial strain. Clusters of cases may be caused by one or more strains of a particular bacterial species, noting that the environment can contain multiple different strains of that species, especially over weeks/months.

This chapter ends with a return to the 'Meropenem theory' placing particular emphasis on the study by Aitken et al.[73], the findings of which even the authors expressed

[73] Aitken SL, Sahasrabhojane PV, Kontoyiannis DP, Savidge TC, Arias CA, Ajami NJ, Shelburne SA, Galloway-Peña JR. Alterations of the Oral Microbiome and Cumulative Carbapenem Exposure Are Associated With Stenotrophomonas maltophilia Infection in Patients With Acute Myeloid Leukemia

caution. We have addressed this issue in some detail in Chapter 4 and do not believe the case to be proven.

Receiving Chemotherapy. Clin Infect Dis. 2021 May 4;72(9):1507-1513.

7. CHAPTER 6: VENTILATION

We did not evaluate the involvement of the hospital ventilation systems or the airborne transmission of pathogens in the CNR but offer a few observations.

In an introduction to Chapter 5 in the Case Note Review Overview Report[74] we mentioned 'chilled beam' systems (a type of radiation/convection heating, ventilation, and air conditioning system designed to heat and cool buildings) in passing only.

We also cited the findings of a 2020 Independent Review,[75] which highlighted deficits in the hospital environment that included (but were not limited to) issues such as: the design and maintenance of the water system; lower than required air exchange in patient rooms and inadequate positive pressure protection of patient rooms; the lack of provision of particulate (HEPA) filtration in some higher risk patient areas; and uncertainties around the appropriate utilisation of chilled beams for temperature control in rooms used for immunocompromised patients[76].

We referred further to chilled beams when reviewing the built environment and its maintenance[77], describing problems with *"….maintenance of chilled beams following reports about leaks or condensation, or both, and where additional cleaning was required for control of dust".*

We note that Hawkey et al. do not reference the 2020 Independent Review and nor are chilled beams mentioned.

We have no further comments to offer on this chapter.

[77] Bundle 6, Document 38, Page 1036, Section 5.2

8. CHAPTER 7: WATER – ANALYSIS OF INFECTION RATES AND DATA FROM QEUH & RHC

Despite the title of this chapter, its three sections deal with quite different issues. Section 7.1 examines the issue of water testing for one bacterium, *P. aeruginosa*, and what can be inferred from such results; Section 2, despite its title, is devoted to a detailed epidemiological review of bacteraemia from available NHS GGC data for both adults and children; and Section 3 focuses on Whole Genome Sequencing.

We address our comments to each of these sections in turn, providing Page and Section/Paragraph references to relevant text in the HAD report itself.

7.1 Learning from water testing for *P.aeruginosa*

Bundle 44 vol 1, Page 62

Hawkey et al. state: "*Inspection of water testing results for Pseudomonas aeruginosa should give a good indication as to whether there was extensive contamination of the hospital water system and particularly in the high risk areas which includes the paediatric haematology-oncology wards."*

No robust evidence is provided to support this claim, especially the assertion that results for one bacterium give 'a good indication' about contamination levels in general. In fact, Hawkey et al. admit that: *"In trying to assess whether there is widespread contamination of the water system we are faced with the problem that all water systems have a bacterial load and there is no published and accepted threshold value for contamination that correlates with the development of an outbreak."* The levels of *P. aeruginosa* in water tell us about one bacterium and not about others.

Having claimed that water testing results for *P. aeruginosa* can be used as a proxy to determine if extensive contamination of the hospital water system occurred, they then point out that for much of the period covering the CNR only low-level testing for *P. aeruginosa* occurred: *"At the QEUH, low level (frequency) testing for Pseudomonas aeruginosa of approximately an average of 20 samples per month was undertaken over the whole time only in the high risk areas. There was intensive sampling in*

December 2015 to March 2016 with 450 samples taken." Higher rates and wider sampling were introduced in November 2018.

The NHS England Health Technical Memorandum (HTM)[78] provides guidance on the legal requirements, design applications, maintenance and operation of hot and cold water supply, storage and distribution systems in all types of healthcare premises. Importantly, the following statement is made on page 25 of the HTM:

"**When water treatment and control programmes are effectively maintained to control Legionella, there will be less likelihood of colonisation of other opportunistic microorganisms. However, in the case of P. aeruginosa, where the origin may be due to retrograde contamination from patients and/or staff, other local management control measures and monitoring will be necessary.**"

Scottish guidance[79] notes that total bacterial burden in water, as opposed to levels of *P. aeruginosa*, can be indicative of levels of specific bacterial pathogens.

"Levels of TVC organisms in water samples give an indication of the effectiveness of residual disinfection and consequently the likelihood of finding potentially pathogenic micro-organisms."

The Gram-negative bacteria causing BSIs in patients in the CNR clearly can also enter water systems via 'retrograde contamination' from patients and/or staff. Thus, sampling and testing for one bacterium, i.e. *P. aeruginosa*, neither tells whether other bacteria were present nor how prevalent they were.

In the CNR Overview Report we commented on the confusion we identified at NHS GGC regarding water testing in general and for *P. aeruginosa* specifically. We stated[80]:

"There did not appear to be a systematic water sampling process in place, or a consistent water system related response to clusters of infections caused by (often

[78] A48115612 - NHS England. Health Technical Memorandum 04-01: Safe water in healthcare premises. Document first published: 20 May 2016. Page updated: 27 August 2024. [79] Bundle 25, Document 56.3, Page 787

[80] Bundle 6, Document 38, Page 1042

unusual/uncommon) GNE bacteria. We are not assured that there was adequate communication about what sampling and testing occurred and the results obtained. We have been told that some key staff involved in IPC at NHS GGC were denied access to water sampling/testing information despite multiple requests. As the concerns increased about whether the bacteraemias occurring in children on the Haematology Oncology wards at NHS GGC might be related to environmental/water contamination, the lack of a clear step change in the organisation's approach to water sampling, testing, reporting and strategy is of concern."

We stand by this statement. We also conclude that the levels of *P. aeruginosa* reported by Hawkey et al. have little or no bearing on the likelihood of water contamination by other Gram-negative bacteria relevant to our case series.

7.2 BSI incidence rates and the likelihood of clustering

This section of Chapter 7 does not directly address the question identified in its title. It largely consists of analyses of BSI incidence rates at NHS GCC and an examination of the likelihood that clustering, defined in time and space (described by Hawkey et al. as epidemiological clustering), occurred in haematology oncology patients, including those from the paediatric service.

Bundle 44 vol 1, Page 64. Comparing infection rates

At the start of this section, Hawkey et al. write *"It is difficult, and often inappropriate, to compare numbers of cases of a possible healthcare associated infections (HCAI) between different hospitals, locations and/or wards without taking into account the volume of activity in a given hospital/location/ward."*

We were not asked to, and did not compare infection rates at NHS GGC with levels elsewhere. We agree with the statement above and would have argued as such had we been asked to do so. In Chapter 4, Section 4.6 of this rebuttal, we have already addressed the suggestion made by Hawkey et al. that we should have undertaken such an analysis and critiqued the data that were available to us when we wrote the our report from the work undertaken by HPS in 2019[81].

[81] Bundle 7, Document 7, Page 250.

It is also the case that inter-institution comparison could lead to 'normalisation' of higher than desirable rates if the comparison offers similar or better results than elsewhere, whereas the focus should be on searching for ways to reduce rates to the minimum and identify any source.

There are many reasons why comparison of apparent infection rates between hospitals, and especially between units/wards can be flawed, and indeed misleading. The ways in which infections are diagnosed vary as does the intensity of sampling and testing patients. The types of patients, including their underlying diseases and severities of conditions, the way they are managed, including the use of anti-infectives to prevent or treat infections, may vary considerably. Routine surveillance to compare infection rates across hospitals for target bacteria, such as MRSA and *C. difficile*, has occurred for over a decade. However, hospital level results may also hide/mask the infection rates seen within individual units/specialties/wards in those hospitals.

Hawkey et al. argue that bed days are the most appropriate denominator for calculating incidence rates for HCAIs but go on to discuss the many other factors that may affect the risk and detection of infection within a hospital population (including those we describe above) and which will influence comparative incidence rates.

We suggest that a further factor to be considered is the frequency with which patients attend the hospital environment. This is discussed in Chapter 4, Section 4.2 of this rebuttal and visually illustrated in Figure 4.1. Are, for example, 20 day case attendances the same as 20 inpatient days in terms of the risk of environmental exposure? This point was addressed in evidence given by Professor Stevens as part of the Glasgow III hearings[82]. We do not claim to know how this pattern of care affects environmental risk but argue that this is another factor that also needs to be taken into consideration when assessing the utility of incidence analysis across a whole population without also considering the specific circumstances of an individual patient and the infection concerned. This latter approach being, we believe, the strength of the CNR process.

Bundle 44 vol 1, Page 66. Selection of micro-organisms

[82] Glasgow 3 - Prof Mike Stevens, Transcript, Transcript - Professor Mike Stevens - 30.10.2024 | Hospitals Inquiry, page 126.

Hawkey et al. here set out their approach to a review of *"all potential bacteraemia in adult and paediatric settings in the NHS GGC for Queen Elizabeth University Hospital (QEUH) and comparable hospitals"*. Their aim was to examine bacterial incidence and compare any difference in trends.

Tables 1 and 2 set out the micro-organisms grown in blood samples between 2008 and 2023 for adult and paediatric patients at NHS GGC hospitals that either could be, or are not usually, environmentally transmitted respectively.

We note some differences from the list in Table 1 when compared with the protocol used to select patients for the CNR[83], notably the absence of *Mycobacterium chelonae* and, less importantly, *Herbaspirillum spp*. The absence of any consideration given within the HAD report to the patients with *M. chelonae* infections is unclear and represents a serious omission. Table 1 also includes a number of bacteria that were not included in the CNR protocol, perhaps most notably *Proteus spp*. Interestingly, Table 2 (non-environmental BSI) includes *Escherichia spp*. which seems inconsistent with the criticism made by Hawkey et al. for the exclusion of *E. coli* from within the CNR cohort. This is discussed in Chapter 4, Section 4.4. of our rebuttal.

Bundle 44 vol 1, Page 67. Methodology

In Section 7.2.2, Hawkey et al. describe methodology for analysing their bacteraemia data. There is a lack of detail in the text which we observe as follows:

Nowhere is it explicit that the populations studied in the analyses provided are exclusively haematology oncology patients: we have assumed this to be the case.

It is likely the patient records were extracted by consultant name and/or ward. In our experience, hospital coding by consultant name can be inaccurate and we reported inaccurate patient location coding by NHS GGC in the CNR Overview Report[84].

No definition is provided for the selection of the paediatric population: we assume this is likely to have been based on location of care and / or consultant name rather than

[83] To be Bundled - A53008955 - Case Note Review - Paediatric Haemato-Oncology Patients RHC, NHSGGC - Epidemiological & Clinical Outcomes Protocol - April 2020 v1.

[84] Bundle 6, Document 38, Page 1075, Section 8.5

by age; but, if age has been a criteria, it is important to note that Teenage/Young Adult (TYA) patients are also under the care of the paediatric service.

There is no definition of how bacteraemias were classified: the protocol agreed for the CNR defined this as follows: Hospital associated infection (HAI) – a positive blood culture in a patient who has been hospitalised for at least 48 hours; and Healthcare associated infection (HCAI) – a positive blood culture in a patient within 48 hours of admission but who has had specified healthcare contact or intervention in the prior 30 days. It is not clear if the same rules guided the inclusion of patients and infections in the populations studied by Hawkey et al.

Finally, Table 1 and 2 in this section state that data included in the analyses were collected from 2008 – 2023, a substantially longer period than that we considered in the CNR. There is no discussion why these dates were chosen or any consideration given to changes in the nature of the relevant clinical services over that period of time, apart from reference to geographical re-location. Confusingly, later in this chapter, graphs provided in Section 7.2.3, addressing adult patients, show that the period of data collection extended from 2013 – 2023; and in Section 7.2.7, dealing with paediatric patients, that data collection was from 2005 to the end of 2022.

This lack of precision and the observed deficits in explanation given to the description of how the cohorts were established for these studies is surprising.

Bundle 44 vol 1, Page 67. Definition of Clustering:

Hawkey et al. explain that they examined epidemiological clusters in the list of organisms with the potential to be environmentally transmitted (Table 1) by bacterial species, dates and locations. They go on to provide definitions for different levels of likelihood of clustering which they summarise in Table 3.

We agree with their observation that a ‘probable’ epidemiological cluster is a ‘qualitative definition’ that can only be definitively confirmed with the molecular evidence that the microorganisms concerned are closely genetically related. They go on to suggest that these epidemiological clusters are those *“we would recommend investigating”* in this way. They fail at this point to acknowledge that this is what the CNR attempted to do, but that only limited data from molecular studies were available and there was very little evidence of systematic/robust environmental sampling that

could provide the parallel assessment required to identify a likely source. We discuss the issue of Whole Genome Sequencing later in our review of Section 7.3.

Hawkey et al. further develop their approach to the analysis of clustering and we agree that it would be reasonable to look at the number in each clustering category (Probable, Possible etc. as per Table 3) by location over a period of time (years) but question the validity of expressing the data as 'rate per clustering type per hospital'. We also question the use of a cumulative scoring system.

The approach taken by the HAD report fails to recognise that important clusters in a small number of patients (which might in time and with appropriate investigation be shown to be related to the environment) could be obscured by the 'noise' generated by much larger amounts of non-informative data.

Bundle 44 vol 1, Page 69. Adult patient data:

We reviewed data provided for adult patients in Sections 7.2.3 to 7.2.6 with interest but concluded that the principal focus of our rebuttal should remain with the paediatric population (Sections 7.2.7 to 7.2.9) as these data are of direct interest to the findings of the CNR. Moreover, we have no knowledge of the nature and delivery of adult haematology oncology services in NHS GGC. There are, however, some general points of comparison between the adult and paediatric analyses that are worth considering.

Hawkey et al. provide no data on the size of the patient populations from which their incidence data derive but, based on the age distribution of the general population and the rapidly increasing frequency of malignant disease with age, it is certain that the number of adults in the adult dataset would be substantially larger than the number of children and young people contributing to the paediatric dataset. This is apparent when comparing, for example, Figure 1 (adult) and Figure 17 (children). Similarly, the number of bed days of exposure will be substantially different.

It was therefore of interest to us that the number of BSI caused by selected environmentally relevant bacteria in the paediatric group compare with the adult group as follows (Table 7.1):

Table 7.1: Number of environmentally relevant bacteria in the HAD report adult and paediatric series, with added comparison to data from the CNR[85].

	HAD report Adult data (Data from 2013-2023)	HAD report Paediatric data (Data extracted only for the CNR era 2015-219)	Data from CNR Overview Report
Acinetobacter baumanni	0	5	6
Acinetobacter ursingii	13	5	6
Klebsiella oxytoca	27	8	9
Klebsiella pneumoniae	No data given	22	21
Klebsiella oxytoca	27	8	9
Pseudomonas aeruginosa	32	8	9
Enterobacter cloacae	36	24	25
Stenotrophomonas maltophilia	45	22	23

Apart from small discrepancies between the numbers of cases identified in the CNR and those identified within the same date range as the CNR from the HAD report paediatric database, it is striking that the relative number of BSI caused by, in particular, *E. cloacae and S. maltophilia* are disproportionately far greater in the paediatric setting than would be expected. This, of itself, would have been a useful observation for Hawkey et al to have discerned and explored.

Bundle 44 vol 1, Page 9. Paediatric patient data:

The relevant sections relating to the HAD paediatric dataset commence with Section 7.2.7. It is our assumption that Hawkey et al. chose to collect data from the Yorkhill

[85] Bundle 6, Document 38, Page 1029, Table 4.3

site from 2005 as this offered 10 years of patient observation prior to the move of the RHC to the QEUH site, but this is not explicit.

Figure 17 shows a plot of the incidence of all bacteraemia per 1,000 bed days [we note that the Y axis is incorrectly labelled] over their entire study period (2005-2022). The authors comment that this shows an obvious decrease in incidence rate from early 2018 onwards. They attribute this to changes in IPC practice and to antimicrobial or other policy change.

We have two important observations about this graph. First, there was indeed a concerted effort to reduce CLABSI (Central Line Associated Bacterial Infections) in the paediatric haematology oncology unit at NHS GGC during the era of the CNR. This work derived from a Quality Improvement Group established in 2017 and there was subsequent evidence of a significant reduction in CLABSI rates from a previously very high level to that of 0.77/1000 line days at the time of the writing of the CNR report. This is an impressive achievement, and we highlighted this as good practice in our report[86]. Nevertheless, we caution that, although good central line care can reduce the incidence of Gram-negative BSI, its principal benefit is in driving down the frequency of staphylococcal line site infections and infected line site associated BSI. Without access to data on changes in the incidence of line associated BSI we cannot assess the impact this had on overall BSI rate, but it is likely to have been considerable.

Second, the X axis of Figure 17 extends for a period of 18 years whilst the era of the CNR was 4.5 years (June 2015-December 2019). Were the data in Figure 17 to be plotted only to show those years, we suggest the visual interpretation would be different. It is more likely that it would conclude a rise in incidence after the move from Yorkhill, peaking in 2017-2018, followed by a decline. It was at this time that concern about the water system reached a critical point, mitigating measures were taken and wards 2a and 2b were closed for substantial alterations.

Moreover, comparing the pattern of BSI from bacteria of environmental concern in Figure 18 [we note that the legend for the X axis is incorrect], we suggest it is even less likely that one could state with certainty that there was a reduction in incidence

[86] Bundle 6, Document 38, Page 1085, Section 9.4

rate over the era of the CNR, as this is somewhat obscured by a very obvious peak in incidence during 2018.

These changes in perspective challenges the strength of the conclusion reached by Hawkey et al. when they state *"This suggests that whatever factors are influencing bacteraemia incidence overall are also having an impact on bacteraemia attributable to environmentally relevant pathogens".*

Bundle 44 vol 1, Page 95, Section 7.2.8. Environmentally relevant BSI:

The preliminary observations described above on the overall incidence of BSI lead on to a more detailed analysis of the type of bacterial species identified and the possible clustering of BSIs in the paediatric dataset.

As we have already pointed out, Hawkey et al. chose to present and analyse data from a much wider range of years than those covered by the CNR. This creates two problems. First, as we have argued in section 7.2 of this rebuttal, comparison of incidence rates across different sites is not straightforward. Second, the inclusion of data beyond the years studied in the CNR may obscure or dilute trends of significance within a shorter period. Crucially, clusters of infection occurring over shorter time periods can clearly be obscured/missed by such analysis.

Much of section 7.2.8 is a narrative description of species identified, but it includes informative tables (11a, b, c, d, e, f; 12; 13; & 14) which include assessments of clustering probability.

In response, we have re-visited our original data to reassess the likelihood of epidemiological clustering using the criteria established by Hawkey et al. themselves (Table 3 of their report). We also compared this with the final decisions we took in the CNR about the likelihood of a relationship to the environment.

In presenting these data, we wish to reiterate that the methodology used by the CNR not only took into consideration evidence for epidemiological clustering but also the clinical and other data with which we had been supplied. This included a small amount of WGS data and we address this more specifically in relation to the extended WGS dataset provided to Hawkey et al. for their work.

Table 7.2 summarises our application of the criteria used by Hawkey et al.

Table 7.2: Clustering criteria and score coding used in Table 3 to 7

CLUSTERING CRITERIA & SCORE CODING (derived from HAD report Table 3)		
Coding against HAD definition: same hospital, **and same wards**	PROBABLE	2 or more cases 0-30 days apart
	POSSIBLE	2 or more cases 31-120 days apart
	UNLIKELY	2 or more cases 121-365 days apart
	NOT CLUSTERED	2 or more cases more than 365 days apart
Coding against HAD definition: same hospital, **but different wards**	PROBABLE	2 or more cases 0-30 days apart
	POSSIBLE	2 or more cases 31-60 days apart
	UNLIKELY	2 or more cases 61-365 days apart
	NOT CLUSTERED	2 or more cases more than 365 days apart

The following Tables 7.3 to 7.7 show data from the CNR for the following micro-organisms: *Klebsiella oxytoca*; *Klebsiella pneumoniae*; *Pseudomonas aeruginosa*; *Enterobacter cloacae*; and *Stenotrophomonas maltophilia*. The time interval (in days) was calculated between BSIs of the same bacterial species and the criteria shown in Table 7.2 were applied to determine the likelihood of a cluster with either a preceding or succeeding BSI. These data are shown alongside the final decisions of the CNR, for the same BSI, expressing the likelihood of a relationship to the environment.

Notes:

1. Clustering at room level is rarely identified and only possible where complete data were available. Bed spaces were not coded in day care areas (Ward 2b and Ward 4b). We also encountered mis-coding where clinical activity was coded to Ward 2b after it's closure. In our experience there is considerable and frequent movement of patients, carers and staff within and between inpatient and day care settings.

2. Numbers in red in the columns showing days of separation between BSIs highlight the shortest intervals and indicate a Probable cluster.

3. One patient with multiple GNE infections was included in the CNR dataset but the child's parents did not consent for the clinical analysis. Infection dates were included for clustering purposes but no clinical data was reviewed and no assessment made of

likely linkages to the environment. These BSIs are excluded from Tables 7.4, 7.6 & 7.7.

Table 7.3: Clustering analysis for BSI with Klebsiella oxytoca

Klebsiella oxytoca clustering analysis							
Location at time of culture or at last hospital attendance (Ward / Bed)	**Clustering by ward and room with another BSI of the same species within 90 days**	**Days from preceding infection**	**Days from succeeding infectione**	**Likelihood of clustering by interval from preceding infection using HAD report clustering criteria**	**Likelihood of clustering by interval from succeeding infection using HAD report clustering criteria**	**Highest likelihood of clustering - interval from either preceding or succeeding infection using HAD report clustering criteria**	**Final CNR decision (whether the BSI was likely to be related to the hospital environment)**
2a/7	no	n/a	104	n/a	POSSIBLE	POSSIBLE	POSSIBLE

We then reviewed the clustering status for these five groups of micro-organisms, comparing results from the HAD data (taken from their Tables 11 c, d & e, 12, 13 & 14 but extracting data for BSI *only* within the era of the CNR) with our own data from the CNR, coded according to the HAD criteria, and with the final decisions taken by the CNR for the same BSI episodes (Table 7.8).

In considering the data in Table 7.8, it should be emphasised that a comparison of the data for epidemiological clustering with that for the final decisions reached by the CNR is not a directly equivalent relationship. The final decisions provided, and discussed in the CNR Overview Report reflected our integrated view of the likelihood that a BSI was linked to the hospital environment; these decisions were not simply a statement of the likelihood of clustering based on time and space.

Table 7.8: Clustering probabilities determined as Possible or Probable comparing CNR data with that from the HAD database and with the final CNR decision for the five principal environmentally relevant micro-organisms over the era of the CNR (June 2015-December 2019)

	CNR data scored by HAD criteria				HAD data				CNR final decision			
	Total BSI	Possibly cluster (&)	Probably cluster (&)	Total Probably + Possibly (%)	Total BSI	Possibly cluster (%)	Probably cluster (%)	Total Probably + Possibly (%)	Total BSI	Possibly related (%)	Probably related (%)	Total Probably + Possibly (%)
K. oxytoca	8	2 (25%)	3 (37%)	5 (62%)	8	2 (25%)	4 (50%)	6 (75%)	8	5 (62%)	3 (37%)	8 (100%)
K. pneumoniae	21	10 (48%)	9 (43%)	19 (90%)	22	9 (41%)	11 (50%)	20 (91%)	19 (2 excluded from assessment)	11 (58%)	5 (26%)	16 (84%)
P. aeruginosa	9	1 (11%)	7 (78%)	8 (89%)	8	4 (50%)	3 (37%)	7 (87%)	9	6 (67%)	3 (33%)	9 (100%)
E. cloacae	24	5 (21%)	19 (79%)	24 (100%)	24	12 (50%)	12 (50%)	24 (100%)	23 (1 excluded from assessment)	16 (69%)	6 (26%)	22 (96%)
S. maltophilia	23	6 (26%)	16 (69%)	22 (96%)	22	15 (68%)	6 (27%)	21 (95%)	21 (2 excluded from assessment)	9 (43%)	12 (57%)	21 (100%)

Interpreting these data is not straightforward and variation is likely attributable to the numbers in some individual categories being very small.

There are some minor discrepancies between the total numbers in the CNR and HAD data groups and some of the BSI were excluded from assessment in the CNR final decision process (as also shown in Tables 7.4, 7.6 & 7.7). However, some general observations can be offered.

Overall, when considering the combined total of those Possibly and Probably clustered, there is little distinction between the HAD data and the CNR data scored by the HAD criteria, with substantial alignment of both with the final decisions from the CNR. In particular, the data for *E. cloacae* and *S. maltophilia* are all very close. These are the two largest groups. The total (Possibly + Probably) for *K. pneumonia* varies to a greater extent, but differences are still small and the lesser degree of alignment with the final outcomes from the CNR may reflect a tendency for us to have been more conservative in assigning the probability of a link with the environment to BSI with this organism.

There is some inconsistency in the assignation of 'Probably' clustered when comparing the HAD data and the CNR data scored by the HAD criteria. This is particularly obvious for *S. maltophilia* (27% vs 69%) and to a lesser extent for *E. cloacae* (50% vs 79%). This is difficult to explain without more specific data from the HAD database to calculate time separation in days. This is, of course, unless Hawkey et al moderated the data shown in their Tables 11 c, d & e, 12, 13 & 14 with the results of the available WGS data (shown in their Tables 15a, b and c) but this is not made clear in their text.

There is a tendency for the final CNR decisions to be rated Probably (linked to the environment) less frequently than the CNR data, scored by the HAD. Visually, this can be seen more obviously in Tables 7.3 to 7.7 where the colour coding assists in highlighting the differences between the penultimate column (highest likelihood of clustering) and the final column (final CNR decision). This would be in line with a moderating effect of other factors taken into consideration when we undertook our final assessment, in which we considered each case in detail, reviewing all available risk factors for each individual infection and patient.

Overall, however, the finding of 100% Probable + Possible environmental clustering for *E. cloacae;* ≥95% for *S. maltophilia;* ≥90% for *K. pneumoniae;* ≥87% for *P. aeruginosa* ; and ≥62% for *K. oxytoca,* in data looking at the same infections in the CNR and HAD datasets, together with a very close alignment to the final decisions made by the CNR, is hard to dismiss as circumstantial. This strongly supports the potential for an environmental link in the origin of at least some of these BSI.

It is also worth making a specific comment about Table 16 in the HAD report. This shows a statistical analysis of data for epidemiological clustering between BSI at Yorkhill and at RHC/QEUH. We have already indicated our general caution about comparisons between different hospitals, especially so over a period of 18 years when many other influencing factors will have changed, not least the mitigations put in place to the water supply by NHS GGC at the QEUH site from late 2018. We believe these influences challenge the validity of the statistical comparison being made.

Furthermore, looking carefully at Figure 19 [not specifically referenced in the text by Hawkey et al. and in which the X axis is incorrectly labelled] and Figure 20, showing an analysis of BSI incidence per 1,000 bed days across the 18 years of HAD data, it is difficult to be convinced that there is any diminution in the incidence of environmental BSI before the end of 2019, when the CNR ended. The most obvious feature of the section of the chart relating to the CNR era is what appears to be a clear increase in incidence from the time that the Children's Hospital relocated until at least the latter part of 2017.

In assessing the trend line fitted to the data shown in Figure 22, we visually compared the patterns of spikes and troughs with those shown in Figure 19, both apparently using the same data for environmentally relevant microorganisms. There appear to be some differences, the most obvious being that the highest peaks in incidence shown in 2014, 2018 and 2019 are all higher in Figure 22 than in Figure 19. This merits review by Hawkey et al but, even with these differences, the trend line fitted to the data in Figure 22, purporting to show a declining incidence of environmental BSI from mid 2015, is almost certainly affected by the inclusion of data after the end of 2019.

We therefore challenge the conclusions drawn from Figure 22 and, even with any needed corrections to the presentation of the data, suggest that a similar analysis for the specific period of the CNR would not be interpreted in the same way.

We are aware that Hawkey et al. had the opportunity to review more WGS data than was available to us and our comments on this aspect of their analyses (their Tables 15a, b & c) are further elaborated in Section 7.3.

In conclusion, we disagree with the conclusion made by Hawkey et al. that *"There have been large reductions in incident BSI overall and by microorganisms [with] environmental attribution at QEUH overtime, suggesting overall increasing effective prevention strategies*" in so far as this might apply to the period of the CNR.

We remain firm in our belief that the conclusions of the CNR Overview Report stand.

7.3 What does the available sequencing data show?

Bundle 44 vol 1, Page 119

Hawkey et al. refer to reports by Professor Tom Evans on multiple occasions in this chapter of their report but do not formally cite these and do not provide source data for conclusions made by Prof. Evans. They repeatedly draw from the *"detailed reports by Professor Tom Evans"* to assert that the WGS investigations undertaken at NHS GGC do not support environmental sources for the BSIs investigated in the CNR.

For example, they write

"The detailed reports by Professor Tom Evans do[es] not identify any matching isolates between the environment and patients for Stenotrophomonas. In the case of Enterobacter spp. all 29 blood culture isolates were typed together with 60 environmental isolates. The only paired indistinguishable isolates in the clinical collection were from isolates obtained at different times from the same patient. This confirms the sensitivity and specificity of WGS SNP typing. No patients shared indistinguishable strains which is what would be expected if a common environmental source was potentially responsible."

We identified the Evans' reports in evidence given to the Glasgow II hearings in June 2023. They consist of four documents - three reports on Cupriavidus[87], Enterobacter[88] and Stenotrophomonas[89] respectively, and a Technical Appendix[90] to these reports. The contents describe what was found when WGS was carried out on a range of bacteria obtained from humans and the environment.

As we were concerned to understand more fully the importance of the reports, we have reviewed each to understand what was done, and notably what was not included, so as to be able to comment on the robustness of these investigations. Our critique follows for each microorganism in turn.

Cupriavidus

We shall not comment in detail on Evans' report on Cupriavidus as there were only 2 BSIs with this microorganism in the CNR. We found the report difficult to unravel and we also reviewed a parallel report from Leanord and Brown[91]. We believe there are important caveats that suggest a lack of robustness of the WGS investigation and its conclusions. In summary, we note specifically that:

- It is not clear from the report how many isolates in total were examined in the WGS investigation, (sections 3.1-3.3, page 225 of his report).
- The report does not set out whether isolates from children were included.
- While the report by Leonard & Brown does specify that isolates from children were included in the WGS investigation, when showing the relationships of these isolates (e.g. page 1208, Figure 6 of their report) 'human' isolates are not distinguishable as to whether they were from children or adults.
- The numbers in the separate reports on *Cupriavidus* spp. by Evans and by Leonard & Brown do not tally. For example, Evans states (page 225 of his report) *"8 isolates were from human blood cultures. Of the 8 human samples, there were duplicate*

[87] Bundle 8, Document 44, Pages 223-229

[88] Bundle 8, Document 45, Pages 230-238

[89] Bundle 8, Document 46, Pages 239-246

[90] Bundle 8, Document 47, Pages 247-248

[91] Bundle 6, Document 40, Pages 1195-1235

sets of samples from 2 patients on the same occasion. Accounting for these duplicates gives a total of 6 human isolates." Leonard & Brown (page 1207 of their report) indicate that *"A total of 9 human clinical isolates were also sequenced. These included two isolates from the original human case described by Inkster et al. (2021), and 7 other human isolates from different hospitals in NHS GG&C, isolated between 2016 and 2021"*

- It is clear that no environmental *Cupriavidus* spp. isolates prior to March 2018 were included in the WGS investigation.
- One of the two *Cupriavidus* spp. BSIs in the CNR occurred in September 2017, the other in January 2018. Thus, both BSIs occurred before the dates when any of environmental isolates included in the WGS investigation were obtained.

We conclude therefore that the WGS investigation of *Cupriavidus* spp. lacks sufficient robustness to exclude the possibility of matches between isolates from the hospital environment and the BSIs found in the CNR.

Enterobacter

In his report on Enterobacter infection, Evans makes statements that show the lack of robustness of the WGS investigation and its conclusions. For example, on Page 223 of his report he says:

"As outlined in the separate report on water sampling, between 2015 and 2020 10,311 water samples were tested by the Environmental laboratory (not counting those tested only for Legionella). 6 of these samples contained a species of Enterobacter and they were not analysed further. Enterobacter spp. are not one of the alert organisms specified by the National Infection Prevention and Control Manual Appendix 13."

This statement confirms that none of the isolates from water samples during 2015-2020 that were identified as showing *Enterobacter* spp. were included in the WGS investigation. Furthermore, it is highly probable that there were other isolates of *Enterobacter* spp. recovered from water samples during this period but, as pointed out by Evans, these are not one of the alert organisms specified by the National Infection Prevention and Control Manual Appendix 13, and the laboratory would typically not routinely aim to identify *Enterobacter* spp. in water samples.

On the same page, Evans also reveals that:

"In addition to water testing, some environmental sampling was carried out in the QEUH and RHC, including swabs of sinks, drains, and other surfaces. This was not performed in a standardised or structured fashion. Samples were processed in the routine microbiological laboratories and in accordance with standard practice were not necessarily subsequently stored."

We conclude therefore that many of the *Enterobacter* spp. in samples from sinks, drains, and other surfaces would also not have been available for the WGS investigation. Indeed, from the table on page 233-4 of his report, we can see that there was a total of 59 *Enterobacter* spp. isolates. Again, depending on how and why the various samples from sinks, drains, and other surfaces were processed, and the bacteria grown were/were not identified, it is highly probable that the actual total number of *Enterobacter* spp. isolates from these environmental sites was much higher than this.

These findings about environmental sampling are entirely consistent with the observations we made in the Case Note Review Oversight Report in which we stated:

"There did not appear to be a systematic sampling process in place or a consistent water system related response to clusters of infections caused by (often unusual/uncommon) GNE bacteria" [92] and *"We conclude these data do not support a systematic approach to water sampling (i.e. frequent, repeated sample collection) certainly for wards 2A and 2B and in the context of concern regarding possible environmental sources of bacteraemias."* [93]

Thus, the sporadic nature of sampling means that any such isolates are, at best, a narrow snapshot of the true prevalence of *Enterobacter* spp. in the hospital environment.

Using the numbers in Evans' report, even if we were to assume that the total of *Enterobacter* spp. isolates from water samples (n=6) and sinks, drains, and other surfaces (n=59) was therefore 65, the report states on page 234 that: *"6 isolates of*

[92] Bundle 6, Document 38, Page 1042

[93] Bundle 6, Document 38, Page 1042, Example 5.2

Enterobacter from environmental samples were serendipitously retained and whole genome sequences obtained." It seems, therefore, that approximately 90% of the *Enterobacter* spp. isolates recovered from the hospital environment were not included in the WGS investigation of these bacteria.

Furthermore, Evans also states on page 234 of his report that: *"Over this period, 29 patient samples were identified from blood cultures from patients within the QEUH/RHC. These were subjected to whole genome analysis. The species identified were E. hormaechei (14), E. asburiae (5), E. roggenkampii (4), E. kobei (2), E. chengduensis (1), E. genomosp. O (2), and E. ludwigii (1)."*

Almost all of the *Enterobacter* spp. in the CNR (n=27) were *E* cloacae, which is not described in Evans list, and only 2 were *E. hormaechei*, one from 2017 and one from 2019. At best, we conclude only these 2 patients could have been included in this WGS investigation.

It is inconceivable, therefore, that Evans' statement (on page 236 of his report) *"On that basis, I conclude on balance of probabilities that the human infections from these Enterobacter species were not acquired from environmental sources within the QEUH/RHC."* could apply to the CNR.

We disagree with his conclusion and suggest that the WGS investigation falls substantially short of being an analysis robust enough to define the true relatedness of *Enterobacter* spp. recovered from patients with BSIs and/or from the hospital environment.

<u>Stenotrophomonas</u>

Finally, and similarly, in his report on Stenotrophomonas infection, Evans makes statements that illustrate the lack of robustness of the WGS investigation and its conclusions.

For example, Page 242 of his report states: *"Out of this total, 76 isolates of S. maltophilia were found. The number of isolates of this organism versus the number of water samples in each year were: 2015, 0/127 samples; 2016, 1/286 samples; 2017, 0/383 samples; 2018, 26/2490 samples; 2019, 8/2147 samples; and 2020, 41/4878 samples. Of these 10,311 water samples, 6,183 looked specifically for Gram negative organisms including S. maltophilia, of which 71 (1.1%) were positive for this species.*

40 isolates of S. maltophilia were isolated from other environmental sources such as drains. Although as outlined, different locations and extents of testing were carried out, there is no reason to suppose that this level of the presence of S. maltophilia in water samples is not representative. Over this time period, there were 23 isolates of clinical relevance isolated from blood cultures."

So, we see that, despite Evans assertion that *"there is no reason to suppose that this level of the presence of S. maltophilia in water samples is not representative"*, approximately 40% of the water samples referred to were not specifically examined for the presence of Gram-negative bacteria such as *S. maltophilia*. We disagree with his statement, as it is clear that the sampling of water, sinks, drains and other sites was sporadic/not systematic, and the degree of scrutiny to which these samples were subjected to look specifically for *Stenotrophomonas* spp. will have been variable.

Next, Evans describes (on page 242 of his report) that *"We were able to carry out a detailed analysis of the genomes of 84 these organisms and related them to available epidemiological data, notably time and place of isolation. 79 of these sequences were from samples at the QEUH campus (including the Royal Children's Hospital). Of these, 23 of the isolates were from blood cultures, and 56 from isolates of water samples and environmental samples taken from drains from a variety of outlet points (which represents 48% (56/116) of the total water/environmental S. maltophilia isolated at the QEUH campus). The human samples were collected between 2015-2020, the water and environmental samples from 2018-2020. For the purposes of this report, the term "environmental" is used below to include isolates obtained from the water supply or from other environmental sources."*

From this statement we see that:

- only some of the (sporadically sought/obtained) *Stenotrophomonas* spp. isolates from environmental samples were included in the investigation;
- the environmental isolates in the investigation did not cover the period 2015-early 2018; approximately one third of the *Stenotrophomonas* spp. BSIs in the CNR occurred before the period when environmental isolates were included in the WGS investigation.

- there is a lack of detail provided on precisely how many of the blood culture isolates from children in the CNR were included; 23 *S. maltophilia* BSIs were reported in our case series. We suggest again, from the numbers provided and the whole hospital approach to the inclusion of blood culture isolates here, that it is likely, at best, that only a few such isolates from the CNR will have been included in the WGS investigation.

In an attempt to obtain greater clarity, we also reviewed the report provided by Leanord & Brown. Specifically, we looked at *'Figure 15: Maximum Likelihood Tree of Stenotrophomonas maltophilia isolates generated from SNP analysis'*. On face value, these appear to be the results of the WGS analysis discussed by Evans in his report – both cover 84 bacteria – here, 25 are from humans, whereas Evans refers to 23 from blood cultures. No dates for the human isolates are provided in Figure 15, which hampers our understanding of its relevance to the CNR. It is possible that some were from other children at the RHC but not in the CNR. We also see that a total of 11 hospital ward drain isolates were included; 8/11 were from the children's wards relevant to the CNR. However, none of these were obtained in 2018, which was the peak year for *S. maltophilia* BSIs in the CNR (n=12). This further challenges the value of the WGS investigation in relation to the conclusions of our work in the CNR.

Evans concludes (Page 245 of his report) that *"Overall, therefore, in my opinion, on balance of probability, none of the clinical cases of infections with S. maltophilia originated from water systems within the QEUH/RHC."*

We do not agree with this assertion and alternatively conclude the WGS investigation of *Stenotrophomonas* spp. isolates has important shortcomings that mean it lacks sufficient robustness to exclude the possibility of a match between isolates from the hospital environment with some of the BSIs in the CNR.

Conclusions

Based on our in-depth analysis of how these investigations were conducted, we do not agree with assertions made by Hawkey et al. that the WGS data do not support environmental sources for BSIs, including those included in the CNR. Instead, we assert that these investigations were flawed and cannot be relied on to refute matches

between isolates present in the hospital environment and those causing infections patients.

Searching for matches between bacteria in the hospital environment with those causing infections in patients is fraught with challenges, analogous to looking for a needle in a haystack. Noting the protracted period represented by our case series, to increase the odds of finding evidence to link source(s) in the environment to patient infections requires systematic searching, i.e. both in sampling and in the laboratory investigations of those samples.

Systematic sampling of the environment did not happen, and isolates recovered between 2015 and early 2018 were not even included in the WGS investigations. Similarly, and surprisingly, some bacteria causing BSIs in children were not included in the WGS investigations, yet it is routine practice to store blood culture isolates for years. Given the heightened concerns emerging about infections in children on the haematology oncology unit from 2015-2019, we do not understand why the bacteria causing the BSIs were not stored, and as a result important gaps were created in the WGS investigations subsequently undertaken.

To conclude, in their own commentary on the Evans' reports, Hawkey et al. acknowledge their recognition that not all clinical and environmental isolates were subjected to WGS strain typing but present a view that disagrees with our position that inconsistent and incomplete inclusion of both patient and environmental isolates in these studies is a significant shortcoming.

Interestingly, however, after stating *"We do not believe in the face of the published experience and the levels of infection with marker organisms seen at QEUH that the environment was a significant source of infection"* they go on to insert an important concession *"We conclude that whilst some infections may have been acquired from the hospital environment,* [our underlining] *acquisition of colonisation in other settings can be considered as the probable cause for many of the infections encountered."*

Perhaps, therefore, the disagreement rests not on the principle but on the quantum – how many of the infections in the CNR were related to the environment?

We are clear that the WGS data available do not provide the answer, and that it remains difficult to dismiss the very marked epidemiological clustering described in Section 7.2, with its close relationship to the final decisions reported by the CNR.

9. CHAPTER 8: VENTILATION – ANALYSIS OF INFECTION RATES AND DATA FROM QEUH & RHC

As stated in Chapter 6, we did not evaluate the involvement of the hospital ventilation systems or airborne transmission of pathogens in the CNR.

We have no comments to make on this chapter

10. ACKNOWLEDGEMENTS

We would like to thank:

Marie Brown, Head of Public Inquiries and Scrutiny, Strategic Planning Service Transformation Directorate, NHS National Services Scotland, and formerly Programme Manager for the Case Note Review, for her help in accessing documents used in the Case Note Review from archive within the Scottish Government.

Dr Fiona Murdoch, Lead Healthcare Scientist, National ARHAI Scotland for facilitating our reconnection with the Tableau timelines used in the Case Note Review.

Abstract Multidrug resistant bacteria in water supply systems have been emerging as a growing public health concern. Many factors affect the source and fate of these bacteria. However, conditions in the plumbing systems may contribute to the dispersion of resistance genes among bacterial populations. Through the process of lateral gene transfer, resistance genetic material can be exchanged between species in the microbial population, intensifying the problem of resistance genes. The main aim of this study was to investigate the diversity of microorganisms in tap water in Glasgow, Scotland, and the occurrence of certain antibiotic resistance genes and gene-transfer mechanisms. Results show that antibiotic resistant bacteria exist at the consumers' end of the distribution system, some of which also contain integrase genes, which can aid in the dispersion of resistance genes. Presence of such microorganisms indicates that further investigations should be taken to assess the risks to public health.

Keywords Antimicrobial resistance · Water distribution system · *intI* · *qac* · *sul*

1 Introduction

Supply of safe drinking water to the global population remains one of the major concerns for public health. Many factors impact this provision, including increasing world population, limited freshwater resources, and pollution. Contemporary issues affecting supply include

Highlights • Plumbing systems contain antibiotic resistance bacteria
• *sul*1 and *sul*2 genes are found in bacteria which show resistance against sulfonamides drugs
• The presence of integrons suggests that resistance traits can be transferred to other bacteria

contamination with chemical compounds, e.g. pharmaceutical and personal care products, and biological agents, which can contribute to increased antimicrobial resistance in bacteria (Batt et al. 2006; Larsson et al. 2007; Fick et al. 2009; Pruden et al. 2013; Hartmann et al. 2014). The use of these chemicals has been increased to a point that propagation of antimicrobial resistance has become unavoidable, and it is now considered an emerging contaminant of concern in the environment (Pruden et al. 2006). In urban areas, water treatment plants utilise multiple technologies to remove many pollutants (Xu et al. 2007), while integrated constructed wetlands are used in rural areas for removal of pollutants and resistance genes (Chen et al. 2015a), however, these systems are never entirely effective (Xu et al. 2007).

Various processes in the treatment plants (Armstrong et al. 1981), and the physical and chemical nature of the long distribution systems, facilitate the enrichment of bacteria and their genes. Attachment to particulates, capsule formation and increased tolerance of bacteria to chemical disinfectants help in the survival and spread of resistant organisms in water supply systems (Ridgway and Olson 1982; LeChevallier et al. 1984; LeChevallier et al. 1988; Bridier et al. 2011, Wingender and Flemming 2011).

The presence of antimicrobial resistant bacteria and their genes in water bodies is not limited to under-developed countries (Khan et al. 2013; Ahammad et al. 2014); they have been found in developed nations including Australia, Germany and the United Kingdom (Stoll et al. 2012). Many enteric bacteria with multiple drug resistance (MDR), e.g., *Escherichia*, *Enterobacter*, *Klebsiella*, *Salmonella* and *Shigella* species, have been found in drinking and recreational water resources (Kumar et al. 2013). Previously, both Gram-positive and Gram-negative bacteria, including *Staphylococcus*, *Alcaligenes*, and *Acinetobacter* species, have been reported in drinking-water distribution systems (Armstrong et al. 1981). Antibiotic resistant *Pseudomonas* species have also been isolated from drinking water (Vaz-Moreira et al. 2012; Ribeiro et al. 2014). The presence of MDR in the clinical environment makes the treatment of diseases difficult (Ashbolt et al. 2013); their presence in water bodies, and increased exposure risk, may necessitate enhanced water treatment and increase expense.

Bacteria isolated from drinking water may not only contain antibiotic resistance, they may also express resistance to commonly used disinfectants, including chlorine and monochloramine (Ridgway and Olson 1982; Chiao et al. 2014, Khan et al. 2016). These disinfectants are indispensable in water treatment plants to eradicate bacteria and minimise the growth of bacteria in the distribution system. Resistance develops upon exposure to sub-inhibitory concentrations over time, and a number of bacterial species with monochloramine resistance have been reported in drinking water, including: *Coxiella*, *Desulfuromonas*, *Desulfomonile*, *Escherichia*, *Geobacter*, *Legionella*, *Mycobacterium*, and *Sphingomonas* species (Chiao et al. 2014).

Besides physical and chemical processes, genetic factors contribute to the dispersion of resistance genes in drinking water distribution systems. Horizontal gene transfer (HGT) mechanisms move resistance genes from resistant to susceptible populations on mobile genetic elements like integrons (Mazel 2006; Gillings et al. 2008; Stalder et al. 2012; Jechalke et al. 2013). HGT spreads genetic elements and their genes among dissimilar groups of bacteria (Gaze et al. 2011), rapidly transferring antibiotic and disinfectant resistance genes (Boucher et al. 2007; Stokes and Gillings 2011; Mokracka et al. 2012). Integrons have a recombination system, which captures genes and serves as a reservoir of resistance genes (Stokes and Hall 1989; Demarre et al.

2007; Xu et al. 2011). The transfer of multiple genes on integrons via HGT intensifies the problem of resistance in bacterial communities, as it can link resistance traits between environmental bacteria and human pathogens in drinking water systems (Ribeiro et al. 2014).

Among multidrug resistance bacteria, class 1 integrons are most common (Shearer and Summers 2009), and they are related to the presence of resistance to quaternary ammonium compounds (QACs), *qac*EΔ1 genes and sulphonamide resistance *sul*1 determinants (Kucken et al. 2000). Almost half of the class 1 integrons contain a *qac* resistance genes cassette (Gillings et al. 2009), and the prevalence of class 1 integrons in bacteria having previous exposure to QACs is greater than those without previous exposure (Gaze et al. 2005). Moreover, bacteria that possess or acquired plasmids, transposons or integrons, have greater QACs resistance than those which do not have any of these genetic elements (Bjorland et al. 2003). Bacteria often show cross resistance for QACs and antibiotics (Morente et al. 2013), including the use of efflux-pump systems to generate resistance to unrelated broad-range antimicrobials (Buffet-Bataillon et al. 2012). Enzyme based mechanisms of antibiotic resistance is also found in bacteria. In the presence of antibiotics, bacteria may acquire genes encoding enzymes which can destroy the antibiotic before reaching the target, resulting in the development of resistant bacteria (Tenover 2006).

This study aimed to determine the prevalence of bacteria and resistance genes in drinking water. Assays included genes responsible for resistance to a wide variety of quaternary ammonium compounds (*qac* genes) and sulphonamide antibiotics (*sul*1 and *sul*2 genes), as these genes commonly co-occur. Mobile genetic integrons were detected via their integrase gene *intI*1 and *intI*2. The co-occurrence of *sul* and *qac* genes in bacteria from the water distribution system was also examined.

2 Materials and Methods

2.1 Sampling and Processing

Tap-water samples were collected from residences in Glasgow in sterile screw capped bottles, and were processed within 2–4 h of collection. One hundred millilitres water samples were vacuum-filtered through 0.22 μm pore size cellulose nitrate gridded membranes (Millipore, UK), which were then aseptically placed on Standard Plate Count Agar APHA (Oxoid, UK). The plates were incubated for 48 h at 37 ± 2 °C. Selected bacterial isolates from the resultant growth were streaked on Nutrient Agar (Oxoid, UK) plates to isolate colonies; 4–5 colonies of each strain were preserved in glycerol using a Bacterial Beads Preservation Kit (Cryo vials TS/71-MX, Technical Service Consultants Ltd., UK) and stored at −80 °C.

2.2 DNA Extraction and PCR Amplification

DNA of the bacterial isolates were thermally extracted by mixing strains with 100 μL of PBS (pH 7.4) and undergoing a series of freeze thaw cycles at −80 and 70 °C with continuous shaking between each cycle. The contents were centrifuged at 10,000 rpm for 5 min at the end of the fourth thermal cycle, and DNA from the supernatant was stored at −80 °C.

PCR reactions were performed with a Bio-Rad iQ5 Real-Time PCR Detection System for the presence of 16S-rRNA, *intI*1, *intI*2, *sul*1, *sul*2 and *qac* genes using previously described primers (Table 1; Pei et al. 2006; Luo et al. 2010; Caporaso et al. 2011; Jechalke et al. 2013). Twenty microliter PCR reactions consisted of 10 μL of MegaMix-Blue-PCR Mastermix with dye (Microzone Limited, UK), 1 μL of each primer (500 ηM final concentration; Sigma-Aldrich Life Science, UK), 6 μL of nuclease-free water, and 3 μL of DNA sample. Each PCR run consisted of initial denaturation at 95 °C for 3 min; this was followed by 40 cycles of denaturation at 95 °C for 30 s, annealing for 30 s at annealing temperature (Table 1), extension at 72 °C for 30 s, and then a final extension at 72 °C for 10 min. PCR products were further verified with 2 % agarose gel in 1× Tris Acetate-EDTA buffer; the size of amplified products was determined against a 50-bp incrementing DNA ladder (Fisher BioReagent, UK).

2.3 DNA Purification and Sequencing

PCR products from 16S-rRNA gene amplification were purified using the QIAquick PCR Purification Kit (Qiagen, UK) according to the manufacturer's instructions. Purified and cleaned amplicon concentration was determined by the EPOCH™ Microplate spectrophotometer system (BioTek, UK). Amplicon was mixed with 5 μM forward primer solution used in PCR in a 1:1 ratio in a total volume of 10 μL and sent to LightRun Sequencing Service (GACT Biotech Ltd, London, UK) for sequencing. Bacteria were identified by comparing the sequences using the BLAST program through the National Centre for Biotechnology Information (NCBI).

3 Results

3.1 Identification of Bacteria by16S-rRNA Sequencing: Bacterial Community Structure

Bacteria were isolated from tap water by a membrane filtration method ($n = 148$) and 87 colonies were identified up to genus level by sequencing the V4 region of 16S-ribosomal RNA gene. The water distribution system harboured three phyla of bacteria: Proteobacteria, Actinobacteria and Firmicutes. Among them, 54 (62.1 %) belonged to the phylum Proteobacteria. Sub grouping of this phylum indicated the presence of 10 alpha-proteobacteria (11.5 %), 38 beta-proteobacteria (43.7 %), 5 gamma-proteobacteria (5.7 %) and 1 epsilon-proteobacterium (1.2 %). Firmicutes were the second largest phyla found in drinking water and 18 (20.7 %) bacteria belonged to this group, while 15 (17.2 %) bacteria were from Actinobacteria.

The presence of both Gram-negative and Gram-positive bacteria was confirmed in the tap water; among them some of the bacteria can be pathogenic. Species of *Bacillus*, *Paenibacillus*, *Brevibacillus*, *Kocuria*, *Staphylococcus*, *Arthrobacter*, *Comamonas*, *Acidovorax*, *Blastomonas*, *Variovorax*, *Escherichia* and pathogenic *Burkholderia* were found in the water distribution system.

3.2 Presence of Antibiotic Resistance Genes

Detection of the *sul*1 and *sul*2 genes specific for sulfonamide resistance was performed on 148 isolates and these genes were detected in 12 (8.1 %) isolates, thus confirming the presence of antibiotic resistant bacteria in the water distribution system; none contained both genes. *Sul*1 genes were detected in 8 (5.4 %) bacteria, while *sul*2 genes were present in 4 (2.7 %) isolates (Table 2). In two (1.4 %) isolates, these genes were also positive for integrons, while in 10 (6.8 %) isolates they were found singly without integrase genes indicating that *sul* genes did not always correspond to *intI* genes as expected. This suggests that the *sul* genes in these bacteria might either be present on chromosome, or associated with other genetic elements (Gundogdu et al. 2011) other than *intI* genes. The distribution of bacteria containing antibiotic resistance genes (ARGs) was widespread among organisms including *Bacillus*, *Cupriavidus*, *Variovorax*, *Kocuria*, *Ralstonia*, *Dermacoccus*, *Micrococcus* and *Staphylococcus* species from the samples.

3.3 Presence of Disinfectant Resistance Genes

Disinfectant resistance genes *qac* were not found in any of the isolates. *Qac* genes associated with class 1 integrons have a high occurrence rate in the environment both in Gram-positive and Gram-negative bacteria (Jaglic and Cervinkova 2012); in this study, the presence of *qac* genes was not detected.

3.4 Presence of Transferable Markers

PCR amplification analyses indicated that class-1 integrons existed in eight bacteria (9.2 %), while *intI*2 genes were not detected in any isolate. In this study, *Dermacoccus* sp. had both *sul*1 and *intI*1 genes, while *Micrococcus* sp. had *sul*2 and *intI*1 genes simultaneously. Presence

A53210128

of *intI*1 genes confirms the presence of transferable genetic element integrons in the bacteria of the water supply system which could involve in the dispersion of antibiotic and disinfectant resistance genes in the environment.

4 Discussion

The presence of antibiotic resistant bacteria and their genes in water is a major public health concern and a global challenge (Pruden et al. 2012; Pruden et al. 2013). They are a major contributing factor in water pollution, found in natural water bodies (Ahammad et al. 2014), treated drinking water (Pruden et al. 2006), and drinking water distribution systems (Xi et al. 2009), can cause infectious diseases (Pruden et al. 2012), and are difficult to treat (Levy 2002). Currently, waterborne diseases are not only related to the presence of faecal bacteria, but also the occurrence of opportunistic pathogens in water systems (Wang et al. 2013). Around 30 different bacterial genera have been isolated from drinking water in different studies including genera of *Pseudomonas*, *Klebsiella*, *Enterobacter*, *Escherichia* and *Proteus* (Norton and LeChevallier 2000; Allen et al. 2004; Gallego et al. 2005, Chiao et al. 2014). In developed countries, outbreaks of waterborne infections due to the drinking water have been reported (Kilvington et al. 2004; Brunkard et al. 2011). Antibiotic resistant infections are also not uncommon in these countries. In the USA, two million people suffered from antibiotic resistant infections every year and among them 23,000 died (CDC 2013). Drinking water distribution systems host a variety of microorganisms (Simoes et al. 2010), and bacteria having antibiotic resistance can find their way into drinking water in these systems. From drinking water, they can colonize the gastrointestinal tract and serve as a potential health risk for the population, especially immune-compromise individuals (Lee et al. 2010).

Isolation of bacteria by membrane filtration demonstrates the presence of viable organisms, so it is a good indicator of the presence of living bacteria in the water environment, which can be actively involved in gene transfer among bacteria and spread of disease in humans. 16S-rRNA gene information is generally used for the identification of bacteria from different environments (Chakravorty et al. 2007). While a useful housekeeping genetic marker to classify bacteria, 1–14 % of organisms remain unidentified as it has low phylogenetic power at species level and cannot discriminate some genera properly (Drancourt et al. 2000; Woo et al. 2003; Mignard and Flandrois 2006; Janda and Abbott 2007). In this study, we identified 87 % of bacteria from the tap water, while 13 % of bacteria were not characterized as no significant similarity was found. These bacteria belong to 22 genera (Table 2), and also included *Burkholderia*, some species of which are waterborne pathogens and may cause melioidosis in humans (Howard and Inglis 2003). The isolation and identification of multiple types of bacteria at the point of use indicates that the distribution network or plumbing systems might be playing some role in the existence of these bacteria, and the ecology of the system could be a contributing factor in their incidence (Hong et al. 2010).

A well-recognized factor which could contribute to the existence of antibiotic resistance bacteria at the consumer end is the presence of biofilms in the distribution system or plumbing system of the buildings from where water samples have been taken. Prevalence of antibiotic resistant bacteria in a water supply system, even in the presence of disinfectant, could be exacerbated by aging infrastructure, in which

biofilms have formed on surfaces (Abe et al. 2012). The multiple layers of microorganisms in these biofilms decrease the residual disinfectant levels to the inner layers; further, bacteria in these layers could develop and transfer resistance traits against antimicrobials to other susceptible populations present in these biofilms (Molin and Tolker-Nielsen 2003; Bridier et al. 2011). Water storage in tanks and cisterns also causes a decrease in the amount of residual disinfectant as water retention time increases, thus allowing bacteria to grow in water. Disinfection itself could concentrate the antibiotic resistant bacteria and their genes in drinking water, as was found in the work of Shi et al. (2013), where chlorination caused the enrichment of *tet*, *amp* and *erm* genes.

The emergence of antibiotic resistance in the environment is not only due to physiological factors, but also depends on genetic factors like horizontal gene transfer (HGT) rate (Andersson and Hughes 2010). Co-selection of two different antibiotic resistance genes occurs through HGT due to the genetic linkage of these genes. For example, sulfonamide resistance genes are plasmid borne and often linked with other antibiotic resistance genes. It has also been found that *sul* and *intI* genes co-exist in water, which might be due to the presence of *sul*1 genes on the class 1 integrons (Chen et al. 2015b). This contributes to the reason that sulphonamide resistance has not declined even when the use of the antibiotics has been reduced (Enne et al. 2004).

Quaternary ammonium compounds resistant genes are also present on mobile genetic elements, such as class 1 integrons (Chapman 2003). Bacterial strains, which acquire genetic units like plasmids, transposons or integrons, show a higher resistance to QACs (Bjorland et al. 2003). The selective pressure by quaternary ammonium compounds (Stalder et al. 2012) disperses *qac* genes and antibiotic resistance genes associated with the integrons (Paulsen et al. 1993; Paulsen et al. 1996; Jeong et al. 2009). This indicates that cross resistance for QACs and antibiotics is possible (Morente et al. 2013). Other mechanisms like a multidrug efflux pump and modification of the cell wall also induce resistance in bacteria (Jaglic and Cervinkova 2012), which allow them to survive in the presence of disinfectant. This could be a reason that in the current study, *qac* genes were not detected in any of the bacteria despite the fact that *intI*1 genes were present with antibiotic resistance genes. This suggests that in the absence of disinfectant resistant genes, other mechanisms of resistance might help bacteria persist in the water distribution system.

5 Conclusions

Isolation of antibiotic resistant bacteria from drinking water demonstrates a need for greater awareness of ecological interactions in drinking water and increased monitoring of distribution systems and plumbing. Presence of those genera, some species of which could cause human diseases, indicates that water quality could not be guaranteed at the consumer end, and future studies should focus on treatment considerations at point of use to guarantee safety.

Acknowledgments PhD work of SK is supported by the "Faculty for the Future" grant scheme from Schlumberger Foundation.

An initial version of this paper has been presented at the 9th World Congress of the European Water Resources Association (EWRA) "*Water Resources Management in a Changing World*: *Challenges and Opportunities*", Istanbul, Turkey, June 10–13, 2015.

Case Note Review

Paediatric Haemato-Oncology Patients

Royal Hospital for Children

NHS Greater Glasgow and Clyde

Epidemiological & Clinical Outcomes Protocol

April 2020 v1.0

Introduction

National Antimicrobial Resistance & Healthcare Associated Infection (ARHAI) Scotland (formally Health Protection Scotland) has been supporting NHS Greater Glasgow and Clyde in the investigation of a suspected increase in the number of cases of patients with unusual environmentally associated Gram-negative bacteria blood cultures.

Previous epidemiological investigations have focused on microbiological laboratory data. These investigations recommended that systematic collection of clinical and epidemiological information on cases be carried out allowing the cases to be described in the context of risk including, where possible, in the context of environmental risks and incidents.

In January 2020, the Scottish Government announced that a case note review would be undertaken to include all children with Gram negative environmental bacteraemia and selected other infections between May 2015 and December 2019. An internationally validated Paediatric Trigger Tool (PTT) has been selected to provide data to the independent review team. In addition to the PTT review, a supplementary epidemiological review of the cases is required to collect patient, outcome and risk data systematically using agreed definitions and for the findings to support the incident investigation.

The objectives of this epidemiological investigation are to:

- Determine a timeline for each of the cases
- Characterise the cases in terms of time, place and person
    - Time: describe the episodes of bloodstream infection over time and create a timeline for outbreak, including plotting of control measures against number of cases
    - Place: describe the location of patients (hospital, ward, bed/bay) and describe their movements in the hospital
    - Person: characterise the patients with infection in terms of intrinsic and extrinsic risk factors; outcomes; antimicrobial prophylaxis and treatment; and individual infection prevention and control measures in place.
- Describe the cases in the context of environmental risks and incidents including use environmental microbiological data and HAI-SCRIBE/other estates data (where possible)

Methods

Study design

This protocol describes the methodology for a retrospective review of cases using patient cases notes. The epidemiological study design is descriptive rather than analytical and no control group will be selected to make comparisons between patients with and without infection to determine risk (at this time).

The study population includes all cases that meet one of the following definitions:

- A patient being cared for in the paediatric haematology or oncology specialty in the Royal Hospital for Children, NHS GGC with:
    - at least one positive blood culture of a Gram negative organism associated with the environment* between May 2015 and December 2019 OR
    - at least one positive culture of an atypical Mycobacterium (Acid Fast Environmental bacteria, see Appendix 1) between May 2015 and December 2019

Note: The expert panel agreed to a flexible approach to inclusion of patients in the review. There may be instances when there is a request to review the case notes of a patient who does not meet the above inclusion criteria. There may also be instances where parents request that their child is not included in the review. Both these circumstances will need to be considered during the analysis and when the final report is being prepared.

A number of datasets were available from previous epidemiological review of the microbiology data. Assessment of these datasets indicated that, whilst there were overlaps, it was necessary for optimal case ascertainment to combine the datasets and create a list of patients that appear in one or more of the datasets. These datasets were two extracts from NHS GGC's LIMS system, a central line associated bloodstream infection surveillance dataset and the Electronic Communication of Surveillance in Scotland (ECOSS).

* Details of the organisms in each of the datasets are provided in Appendix 1.

Data collection methods

A team of 3-4 epidemiologists from National ARHAI Scotland will undertake the case note review using all available patient information in the GGC Clinical Portal. It is expected that this will include:

- Nursing notes
- Medical notes
- Temperature charts
- Paediatric early warning scores
- Drug charts
- Surgery/operation notes
- Laboratory report e.g. microbiology results
- Other relevant charts e.g. wound charts, stool charts, care plans.

Clinical Portal holds all of the patient notes with the exception of those held in Critical Care. Admission and movement data are captured in the GGC Trakcare system and an extract will be provided for ease of processing the data.

Further information relating to each of these categories is provided in supplementary document “Expert Panel Dataset V1.0”.

Linkage to the Paediatric Trigger Tool Review (PTT)

The epidemiological review will be undertaken in collaboration with the clinical team undertaking the PTT review (‘ground team’) thus ensuring that the clinical expertise available provides support to the epidemiological and clinical outcomes review. The PTT will assess admissions associated with the infections that are included in the review.

Data handling

All data will be linked by the patient’s CHI number and a timeline will be created for each case. All data will be collected in a bespoke relational database from which data can be extracted into a template for use by the Expert Review Panel.

Appendix 2: Origin of Infection (mandatory enhanced surveillance protocol)

Hospital acquired infection (HAI): Positive blood culture obtained from a patient who has been hospitalised for ≥48 hours. If the patient was transferred from another hospital, the duration of in-patient stay is calculated from the date of the first hospital admission. If the patient was a neonate/baby who has never left hospital since being born.

OR

The patient was discharged from hospital in the 48hr prior to the positive blood culture being taken.

OR

A patient who receives regular haemodialysis as an out-patient.

OR

Contaminant if the blood aspirated in hospital.

OR

If infection source/entry point is surgical site infection (SSI).

Healthcare associated infection (HCAI): Positive blood culture obtained from a patient within 48 hours of admission to hospital and fulfils one or more of the following criteria:

Was hospitalised overnight in the 30 days prior to the positive blood culture being taken.

OR

Resides in a nursing, long term care facility or residential home.

OR

IV, or intra-articular medication in the 30 days prior to the positive blood culture being taken, but **excluding IV illicit drug use**.

OR

Had the use of a registered medical device in the 30 days prior to the positive blood culture being taken e.g. intermittent self-catheterisation or percutaneous endoscopic gastrostomy (PEG) tube with or without the direct involvement of a healthcare worker (excludes haemodialysis lines see HAI).

OR

Underwent any medical procedure which broke mucous or skin barrier i.e. biopsies or dental extraction in the 30 days prior to the positive blood culture being taken.

OR

Underwent care for a medical condition by a healthcare worker in the community which involved contact with non-intact skin, mucous membranes or the use of an invasive device in the 30 days prior to the positive blood culture being taken e.g. podiatry or dressing of chronic ulcers, catheter change or insertion.

Community infection: Positive blood culture obtained from a patient within 48 hours of admission to hospital who does not fulfil any of the criteria for healthcare associated bloodstream infection.

Not known: Only to be used if the bacteraemia is not an HAI, and unable to determine if Community or HCAI

REVIEW ARTICLE

The Hospital Water Environment as a Reservoir for Carbapenem-Resistant Organisms Causing Hospital-Acquired Infections—A Systematic Review of the Literature

Alice E. Kizny Gordon,[1] Amy J. Mathers,[3] Elaine Y. L. Cheong,[4,5] Thomas Gottlieb,[4,5] Shireen Kotay,[3] A. Sarah Walker,[1,2] Timothy E. A. Peto,[1,2] Derrick W. Crook[1,2] and Nicole Stoesser[1]

[1]Modernising Medical Microbiology Consortium, Nuffield Department of Medicine, John Radcliffe Hospital, University of Oxford, and [2]Oxford Biomedical Research Centre, United Kingdom; [3]Division of Infectious Diseases and International Health, Department of Medicine, University of Virginia Health System, Charlottesville; [4]Department of Microbiology & Infectious Diseases, Concord Repatriation Hospital, Sydney, and [5]University of Sydney, Australia

Over the last 20 years there have been 32 reports of carbapenem-resistant organisms in the hospital water environment, with half of these occurring since 2010. The majority of these reports have described associated clinical outbreaks in the intensive care setting, affecting the critically ill and the immunocompromised. Drains, sinks, and faucets were most frequently colonized, and *Pseudomonas aeruginosa* the predominant organism. Imipenemase (IMP), *Klebsiella pneumoniae* carbapenemase (KPC), and Verona integron-encoded metallo-β-lactamase (VIM) were the most common carbapenemases found. Molecular typing was performed in almost all studies, with pulse field gel electrophoresis being most commonly used. Seventy-two percent of studies reported controlling outbreaks, of which just more than one-third eliminated the organism from the water environment. A combination of interventions seems to be most successful, including reinforcement of general infection control measures, alongside chemical disinfection. The most appropriate disinfection method remains unclear, however, and it is likely that replacement of colonized water reservoirs may be required for long-term clearance.

Keywords. carbapenem-resistant; carbapenemase; healthcare-associated infections; outbreak; water.

Over the last 10–15 years, clinically relevant carbapenem-resistant organisms (CROs), such as *Pseudomonas aeruginosa, Acinetobacter baumannii,* and the Enterobacteriaceae, have disseminated globally [1]. Genes encoding for important carbapenemases, such as *Klebsiella pneumoniae* carbapenemase (KPC), oxacillinase-48 (OXA-48), and the metallo-β-lactamases, are often transmitted between organisms by mobile genetic elements, such as plasmids, contributing to their spread. Limited treatment options and high mortality in those infected are particularly worrying. Hence, understanding reservoirs and transmission of common CROs and transmissible carbapenemases is a research priority.

Hospitals present a unique opportunity for bacteria to interact, proliferate, and infect vulnerable populations. The healthcare water environment, including potable water, faucets, sink surfaces and wastewater drainage systems (drains, sink/shower traps, toilets, drainage pipes), can be a reservoir for nosocomial pathogens, such as drug-resistant Enterobacteriaceae, *Pseudomonas* spp., and *A. baumannii* [2–4]. The prevalence of these multidrug-resistant organisms (resistant to ≥3 antimicrobial classes) is rising [5], and they will increasingly dominate the hospital environmental microbiome. Determining effective infection control (IC) measures to decontaminate environmental reservoirs and prevent cross-transmission of multidrug-resistant organisms between patients and the environment may minimize potentially lethal outbreaks. The aim of this literature review was to summarize studies identifying common CROs in the hospital water environment, the evidence for CRO transmission between this environment and patients, and successful IC interventions to terminate outbreaks and eliminate CROs from this environment.

METHODS

PubMed was searched using the following Medical Subject Headings (MeSH) and text terms: (enterobacter* OR pseudomon* OR acinetobacter) AND (drain OR sink OR shower OR faucet OR hospital water) (search date: 7–9 March, 2016). All abstracts in English, French, Spanish, and German from 1967 to the search date were screened. Articles were excluded if the full article was unavailable through PubMed or the

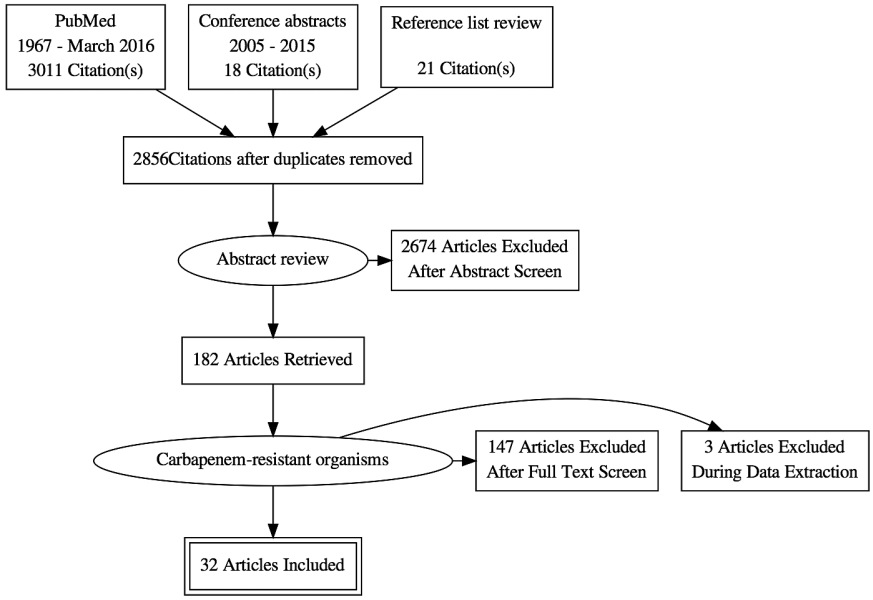

Figure 1. Flowchart of study selection process. Three studies were excluded during data extraction because the outbreak organism was not found in the water environment.

University of Oxford, if the study did not occur in the acute healthcare setting, if it involved hospital wastewater remote to patient care areas, or if the organisms of interest were not identified. Citations in the selected articles were reviewed for additional relevant reports.

Additional searches of conference abstracts were undertaken (9–10 March 2016) for the European Congress of Clinical Microbiology and Infectious Diseases (2005–2015), Interscience Conference on Antimicrobial Agents and Chemotherapy (2013–2014), Infectious Diseases Society of America ID Week (2004–2015), and the Australian Society of Infectious Diseases (ASID) meetings (2013–2015).

All studies involving CROs (organisms phenotypically nonsusceptible to ≥1 carbapenem or producing a carbapenemase) were then included. The ORION (Outbreak Reports and Intervention Studies of Nosocomial Infection) framework was used to assess outbreak reports [6]. Data were collected for the following variables: author, publication year, study design,

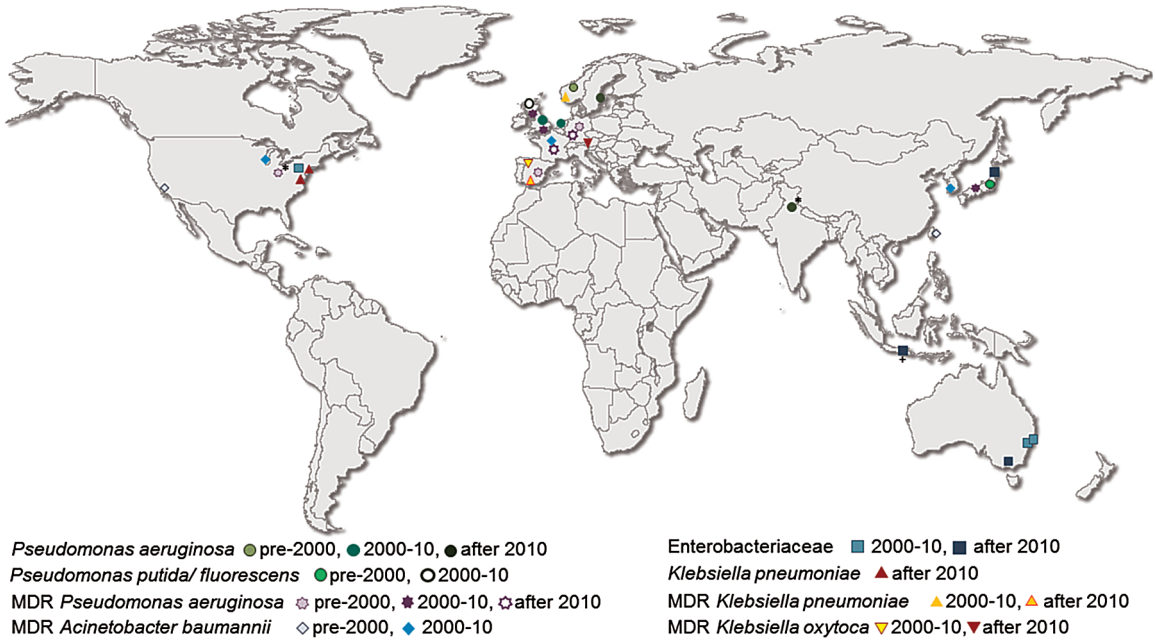

Figure 2. Geographic and temporal distribution of carbapenem-resistant organisms (CROs). The geographic and temporal distribution of the included studies based on the organism reported. MDR, multidrug-resistant (resistant to ≥3 antimicrobial classes). *Study period unknown. †Dewi et al [10] report *Acinetobacter* spp. and *Aeromonas* spp. along with Enterobacteriaceae.

organism, carbapenemase mechanism, reservoir(s), evidence of environment-patient transmission, and type/success of interventions (Supplementary Table 1). Authors of studies reporting terminating outbreaks were contacted (August 2016) regarding the ongoing success of any interventions.

RESULTS

Study Settings and Populations

Search and screening strategy results are shown in Figure 1. Thirty-two studies were included (Supplementary Table 1). Of these, 27 were outbreak investigations, and 5 were epidemiological surveillance studies [7–11]. Twenty-three were full articles, 6 were conference abstracts [10–15], 2 were letters [16, 17] and 1 was a short report [18]. The studies included data from Europe (n = 16), Asia (n = 7), North America (n = 6), and Australia (n = 3) (Figure 2). Thirty studies occurred between 1996 and 2015, with 50% of these since 2010. Two studies did not document the study time frame [8, 15]. Most were conducted in adult inpatients, with 7 in pediatric/neonatal populations or unspecified (Table 1). Eleven studies involved immunocompromised patients, including those with hematological malignancies [12, 19–22], solid tumors [22], primary immunodeficiencies [22], renal disease [18], burns [7, 8, 23, 24], or unspecified diagnoses [11]. Fifteen studies occurred solely in the intensive care setting [13, 15–18, 23, 25–33], and the others involved various medical/surgical wards, intensive care units, operating theaters, or the whole hospital (Table 1).

Patient Sampling Strategy and Risk Factors for CRO Infection/Colonization

In total, 926 patients from 31 studies were CRO colonized (n = 184), infected (n = 189), or unspecified (n = 553). In 22 studies, active patient screening was performed, varying in site (swab samples from the rectum, nose, throat, groin, axilla, perineum, perianal, wound, and catheter sites; samples of sputum, urine, stool, tracheal aspirate, blood, and gastric tubes) and frequency (twice weekly, weekly, or fortnightly). The prevalence of patient infection or colonization ranged from 1.6% to 26.7% (reported in 8 studies [8, 14, 19, 22, 24, 30, 31, 33]). Risk factor analysis for colonization/infection was performed in 4 studies [14, 24, 25, 31], and risks included preceding surgery, patient location, prolonged mechanical ventilation, older

Abbreviations: GIM, German imipenemase; IMP, imipenemase; KPC, *Klebsiella pneumoniae* carbapenemase; MIC, minimum inhibitory concentration; NDM, New Delhi metallo-β-lactamase; VIM, Verona integron-encoded metallo-β-lactamase.

[a]Some studies included multiple different species, so categories are not mutually exclusive.

age, burns, longer hospital stay, and drinking tea from a contaminated dispenser. Length of stay before colonization/infection was documented in only 10 studies, varying from 1 to 134 days [19, 24–26, 28–30, 32–34]. Mortality was assessed in 18 studies, with a mean rate of 25.7% (range, 0%–85%) [12, 16, 19–24, 26, 28–36]. However, 2 studies did not comment on whether deaths were attributable to the study organism(s) [28, 36].

Environmental Sampling Strategies

Hospital water environment investigations included sampling from faucets (n = 18), drainage systems (n = 17), sink surfaces (n = 16), and water (n = 14). Other environmental samples were taken in 26 studies, including medical equipment, patient environment, antiseptic solutions/liquid soaps, enteral nutrition, staff areas, and air samples. Sampling methods varied but typically included moist sterile swab/water samples of varying volumes. Only 5 studies detailed sink and drainage system design [18, 20, 21, 26, 30].

All studies identified the relevant CROs in the water environment, mostly in drains/traps, sink surfaces, and faucets (Table 2). CROs were found in other sites in 15 of 32 studies. The hands of healthcare workers (HCWs) were sampled in 6 studies [8, 17, 23, 27, 33, 36]; additional pharyngeal, rectal, and nasal swab samples were obtained in 2 [8, 33], 1 [33], and 1 [8] study respectively. The study CRO was not colonizing HCWs in any studies.

A53210128

CROs Investigated

Organisms studied included *P. aeruginosa*, *Pseudomonas fluorescens*, *Pseudomonas putida*, *A. baumannii*, and various Enterobacteriaceae (Table 3). Molecular carbapenemase identification was performed in 17 studies. The genes identified included bla_{IMP} (n = 6), bla_{KPC} (n = 5), bla_{VIM} (n = 4), bla_{NDM} (n = 1), and bla_{GIM} (n = 1) (Table 3). Multiple species of Enterobacteriaceae were involved in 7 studies, suggesting interspecies/intergenus resistance gene transfer [7, 10, 13, 14, 24, 26, 32], specifically demonstrated in vitro for bla_{IMP} and bla_{KPC} [7, 9, 32].

Microbiological and Typing Methods Deployed

Microbiological methods for culture and identification were clearly described for 11 studies [11, 19, 20, 22, 24–26, 29, 32, 33, 37], with no methods given in 7 [12–15, 17, 28, 35]. Methods differed in the media and biochemical tests used. Samples from patients in 2 studies [25, 34] were incubated in an enrichment broth; however, only 1 of these studies supplemented this with a carbapenem disc [34], following Centers for Disease Control and Prevention recommendations [39]. Antimicrobial susceptibility testing methods were reported in 26 studies and included disc diffusion, microbroth dilution, Etest and PCR. Seven of 32 studies did not report susceptibilities [7, 10–14, 24]. CROs were susceptible only to polymixin B/colistin in 8 of 16 studies that reported testing for colistin susceptibility [18, 21, 23, 27, 28, 30, 36, 37]. In 4 studies that did not test for colistin susceptibility, CROs remained susceptible only to amikacin [15, 16, 26, 35]. Variable susceptibility to fluoroquinolones, tigecycline, fosfomycin, other aminoglycosides, and β-lactams was found in the remaining 13 studies. One study reported that the outbreak organism (KPC–*Klebsiella pneumoniae*) became resistant to all antibiotics after initially being susceptible to gentamicin, tigecycline, and colistin [22]. Molecular typing was performed in all but 2 studies [8, 10], mostly using pulsed-field gel electrophoresis (Table 4).

CRO Transmission and IC Interventions

The organism under investigation was detected in both patients and the environment in all but 1 study where only the environment was assessed [10]. All studies found evidence of cross-transmission between patients and the environment based on epidemiological links and/or identical antimicrobial susceptibility phenotypes/molecular typing (Table 4).

Nine studies reported IC breaches that probably contributed to outbreaks. These included poor sink design [18, 20, 21, 26, 30], use of sinks for contaminated clinical waste disposal [20, 26, 37], storage of clean patient materials around sinks/sluices [21, 29], reuse of nonsterile surgical drapes and open drainage in the cystoscopy room [35], use of a single brush to clean sinks without between-site disinfection [26], blocked sewage pipes and waste pipe leaks [21], and failure to clean shower drains [21]. Nontouch sensor taps were a reservoir in 1 study [16].

Interventions to eliminate CROs were reported in 27 studies. Twenty-five studies included water environment decolonization interventions, including chemical disinfection (alcohol, chlorination, aldehydes, biguanides, sodium hypochlorite [bleach], acetic acid, hydrogen peroxide, silver nitrate, hot water, and pressurized steam), sterile water for high-risk patient care, assignment of sinks to hand hygiene only, and replacement of contaminated equipment, faucets, sinks or drainage systems (Figure 3). Two studies reported cleaning or disinfecting the water environment, but without details [17, 23]. Two studies described agents used to clean rooms but did not provide

Abbreviations: AFLP, amplified fragment length polymorphism; MGE, mobile genetic element; MLST, multilocus sequence typing; PCR, polymerase chain reaction; PFGE, pulsed-field gel electrophoresis; RAPD, random amplification of polymorphic DNA; REA, restriction enzyme analysis; Rep-PCR, repetitive element sequence-based PCR; VNTR, variable-number tandem repeat; WGS, whole-genome sequencing.

[a]Some studies used multiple methods, so categories are not mutually exclusive. One study did not perform any typing (Dewi et al [10]).

A53210128

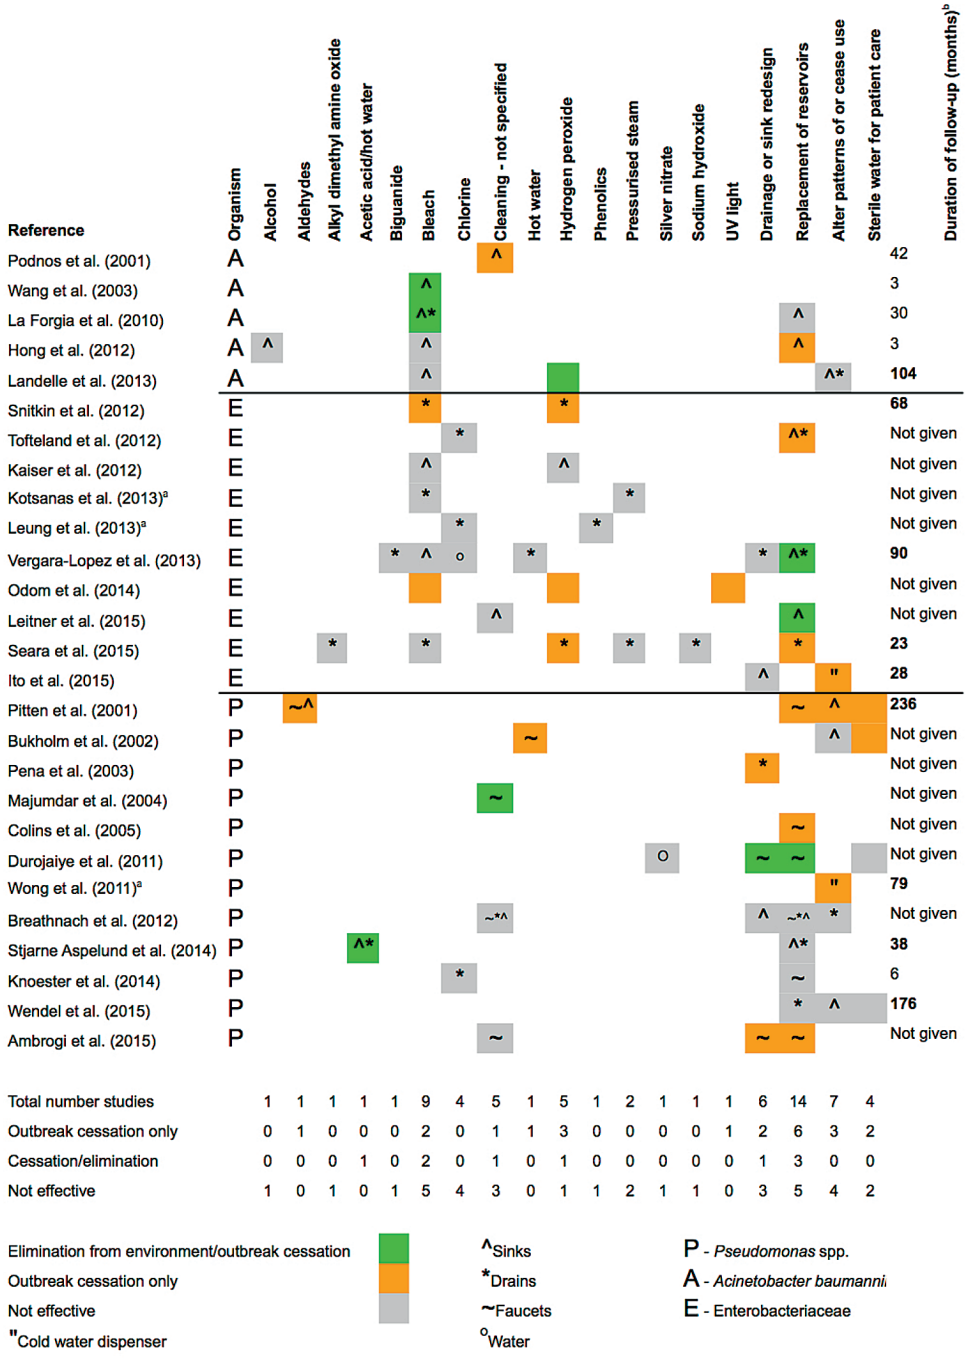

Figure 3. Infection control interventions and outcomes. Five studies did not report any interventions (Betteridge et al [7], Biswal et al [7], Kouda et al [38], Yomoda et al [9], Dewi et al [10]), and 5 reported only plumbing interventions (Wong et al [19], Wendel et al [29], Alter et al [15], Peña et al [35], and Ito et al [14]). For duration of follow-up (*right axis*), months shown in bold denote studies that responded to our communication.

specific information on disinfecting the water environment [11, 22].

Twenty-two studies reported enhancing general IC measures, including contact isolation, strict hand hygiene, active surveillance, reinforcement of cleaning and disinfection procedures, audits, and education sessions. Of the 25 studies that reported specific environmental interventions, 22 reported success in terminating the clinical outbreak, whereas just more than one-third of these managed to eliminate the organism from environmental reservoirs (Figure 3) [12, 16, 17, 20, 27, 28, 33, 37]. Interventions successful at disinfecting water reservoirs included cleaning of sinks and taps (details not given) [17], daily cleaning of sink surfaces with 0.1% sodium hypochlorite [27], weekly cleaning of sinks and plumbing with acetic acid/hot water [12], transferring all patients to a dedicated isolation unit and hydrogen peroxide vapor disinfection [37], replacing

A53210128

nontouch sensor taps with conventional taps [16], and replacing sinks or drainage systems [20, 33]. Kouda et al [38] reported success without giving details of interventions.

Only 7 of 22 studies reporting success stated the duration of follow-up after the intervention [23, 27–30, 33, 34], which ranged from 2 months to 3.5 years. The authors of 10 studies responded to our communication regarding further follow-up. Seven of these reported no further cases of the outbreak organism [14, 19, 22, 33, 36, 37, 38]. Kouda et al [38] attributed their success to ceasing use of a urinal and changes to mopping practices (details not given). Snitkin et al [22] occasionally isolated CROs from drains, but not the original outbreak organism. Wendel et al [29] reported ongoing sporadic patient cases and environmental isolation despite enhanced IC measures and banning storage of patient material around sinks, however further strain typing has not been done. Seara et al [34] reported 7 additional cases in 2015, but none in 2016. They found hydrogen peroxide vapor to be the most effective disinfectant. Stjarne Aspelund et al [12] reported re-emergence of the outbreak organism after sink replacement, but no further cases or environmental isolation since July 2015, a change thought attributable to weekly flushing of sink drains and waste pipes with acetic acid/hot water.

DISCUSSION

Hospital Water Environment as a Reservoir of CROs

Drains/traps, sinks and faucets were the most common reservoirs of CROs identified. Others included portable hair washing basins, water samples, drink dispensers, toilet bowls/brushes, and shower equipment (Table 2). Initial seeding of these reservoirs was potentially due to contamination from affected patients [20, 22, 25, 32, 33, 36, 37]. Large, complex premise plumbing systems could have areas of stagnation and corrosion, variable nutrient and microbiology loads, and water temperatures ideal for promoting bacterial colonization and biofilm formation [3, 4]. Once colonized, there may be further propagation via the wastewater drainage system to distal sink drains connected to the initial reservoir, and via direct or indirect water contact to other patients [2].

P. aeruginosa was the most frequent organism (41% of studies), and distributed across all water reservoirs. *A. baumannii* was found predominantly in sink basins, and Enterobacteriaceae most commonly in drains. These findings may reflect biological differences in which *Pseudomonas* spp. and *Acinetobacter* spp. are environmental colonizers surviving in low-nutrient conditions, whereas Enterobacteriaceae are predominantly of human origin and their concentration in drains may represent a different ecosystem and inoculation directly from patient waste. However, all these organisms are capable of colonizing water system biofilms [3]. Knowing the predominant site for each organism may help guide surveillance strategies, outbreak investigations, and IC interventions.

Because they can be horizontally transferred on mobile genetic elements, carbapenemase genes represent the most concerning mechanism of carbapenem resistance and may be readily transmitted in environmental reservoirs. Tofteland et al [32] found evidence of possible environmental bla_{KPC}-plasmid transfer between *K. pneumoniae* strains, and Betteridge et al [7] concluded there was likely environmental intergenera plasmid exchange between Enterobacteriaceae. Resistance genes and associated mobile genetic elements should therefore be characterized in CRO outbreak investigations. Despite this, only 56% of studies assessed carbapenemase production. The most common enzymes identified were bla_{IMP}, bla_{KPC}, and bla_{VIM}, consistent with previous prevalence reports [1]. Phenotypic surveillance may facilitate the detection of novel carbapenemases.

CRO Transmission Between the Hospital Water Environment and Patients

There was evidence of CRO transmission between the environment and patients based on phenotypic [8] or genotypic methods in all studies assessing this, but most studies used relatively low-resolution methods. Fourteen studies used >1 genetic typing method (Table 4), potentially allowing for greater discrimination. Despite this, transmission routes were difficult to characterize, possibly due to both limited sampling and typing resolution. Whole-genome sequencing (WGS) is a highly discriminatory typing tool increasingly used in outbreak/transmission investigations. Two studies used WGS, with Snitkin et al [22] highlighting its advantages, including confirmation of a monoclonal outbreak, identification of unexpected modes of transmission, and tracking several potential resistance mutations in newly colistin-resistant isolates.

Previous studies have found that HCWs may facilitate nosocomial transmission of multidrug-resistant organisms [3]. Notably, there was no evidence of HCW colonization in the studies reviewed. However, only 19% assessed HCWs, perhaps underestimating the role of HCWs in CRO transmission. Other confounders could include inappropriate timing of sampling and observer effects if staff were aware of surveillance during sampling. Despite the absence of HCW colonization, 10 studies concluded that HCWs were probably implicated in CRO transmission [17, 18, 20, 22, 23, 25, 27, 32, 36, 37]. Colonization of a sink in a medication room attended only by HCWs was cited as evidence for this in 1 study [20]. Most studies also reported a significant reduction in transmission with enhancement of general IC measures, including reinforcement of hand hygiene and contact precautions. However, the relative contribution of HCWs to CRO transmission remains undefined.

Within the hospital there are numerous opportunities for patient exposure to water and drainage reservoirs [4]. Transmission may result from direct or indirect water contact,

A53210128

or from droplets created during water activities, highlighting the importance of water delivery and wastewater design to minimize these risks. Seven studies recognized that poor design or use of sinks, drains, and sluice areas may have contributed to institutional outbreaks [18, 20, 21, 26, 29, 30, 37]. Guidelines for design of hand-wash basins generally include a large basin to contain splashes, taps that are not aligned directly over drains to minimize aerosols, no plugs or overflows, and ensuring that basins are not used for disposal of patient-related waste [40]. This guidance varies by country and application of the recommendations probably varies between institutions.

Effective IC Strategies

IC strategies used mostly included bundled approaches involving enhanced general IC measures, disinfection, and replacing reservoirs, making it difficult to ascertain the relative contribution of individual approaches. Enhancing general IC measures led to a reduction in clinical cases in most studies but often did not completely terminate outbreaks.

Chemical disinfection was most useful for environmental colonization with *A. baumannii* and *P. aeruginosa*. Faucet contamination with *P. aeruginosa* was successfully treated with aldehydes [36] or hot water [31], and Enterobacteriaceae with bleach, hydrogen peroxide vapor or UV light [11]. Eradication of sink colonization with *A. baumannii* was possible with bleach [27] or hydrogen peroxide vapor [37], however chemical disinfection was not effective for Enterobacteriaceae. In drain colonization, some success with eradicating Enterobacteriaceae and *A. baumannii* was reported using bleach [11, 22, 28] or hydrogen peroxide vapor [11, 22, 34, 37]. One study reported ongoing suppression of *P. aeruginosa* with weekly disinfection of sinks and drainage systems with acetic acid/hot water [12]. Use of hydrogen peroxide vapor was most promising, but this method is expensive and was ineffective in liquid and foam form [13, 34]. Bleach, hot water, UV light, and aldehyde-based disinfectants were effective in some studies, but other studies reported failures with these agents. Other agents were also used without success (Figure 3). Notably, the concentrations and deployment of agents varied widely; standardizing approaches would allow for more comparable outcome assessment.

Overall, the most successful intervention was replacing reservoirs (Figure 3). Replacing taps contained 67% of outbreaks associated with *P. aeruginosa* affecting faucets [15, 16, 18, 36]. Replacement of drains/drainage systems and sinks was always successful for Enterobacteriaceae colonization [20, 32–34] but failed with *P. aeruginosa* [12, 21, 29]. Other effective strategies included drainage or sink redesign, sterile water for care of high-risk patients, and prohibiting the storage of clean patient material around a sink. These findings may also be relevant for water-environment associated outbreaks with organisms that harbor other resistance mechanisms, such as extended-spectrum- β-lactamases. A list of current recommendations from international and national organizations on the prevention and control of CROs can be found in Supplementary Table 2; no organization makes recommendations regarding environmental sampling or chemical disinfectant.

Review and Study Limitations

General limitations of our study include potential publication bias and the language and literature source restrictions used in this review. Healthcare water environments are probably often neglected in outbreak assessments, which may result in an underestimation of the problem.

The heterogeneity in study methods also limits the generalizability of conclusions. Measuring the clinical impact of outbreaks was difficult; 23 studies did not give prevalence data, and 13 did not assess mortality rates. Screening of patients and the environment varied widely with regard to the methods used, frequency, and site. Rectal swab/fecal samples are recommended for patient CRO colonization screening [5], but 10 studies only sampled other body sites, and 9 did not screen patients at all. Consequently patient colonization may have been underestimated in up to 60% of studies.

Differences in environmental sampling, such as collecting water samples before or after tap flushing and use of varying water volumes, may affect sampling sensitivity. Microbiological methods differed between studies, and although the use of selective culture media may have improved detection, organisms with near-breakpoint minimum inhibitory concentrations could have been missed, underestimating the true prevalence and extent of environmental contamination. Molecular tests may increase sensitivity [29].

CONCLUSIONS

Water environment-associated CRO outbreaks have been reported increasingly in the last 5 years. Critically ill and immunocompromised patients are particularly at risk. Drains/traps, sinks and faucets were most frequently colonized, and *P. aeruginosa* was the predominant organism. Standardizing patient and environmental screening, and microbiological methods, when investigating CRO outbreaks may allow earlier detection of reservoirs. Carbapenemases should be characterized, and strains typed to confirm relatedness. WGS is a promising tool for determining transmission routes, reservoirs, and resistance mechanisms.

The incorrect design and use of hand-wash basins and other water areas may propagate outbreaks. Various IC interventions have been used with mixed results for each organism and reservoir. A combination of interventions is probably required to terminate outbreaks and eradicate CROs from the environment. Useful approaches include reinforcing general IC measures,

A53210128

combined with chemical disinfection using hydrogen peroxide vapor. Further studies assessing the effectiveness of different chemical disinfection strategies are needed. Replacement and improved management of colonized water reservoirs is also probably an important component of control.

Abstract

Objectives: Clinical utility of carbapenem antibiotics is under threat because of the emergence of acquired metallo-β-lactamase (MBL) genes. We describe an outbreak in an intensive care unit (ICU) possibly associated with contaminated sinks.

Design, setting and participants: Four clusters of gram-negative bacteria harbouring the MBL gene bla_{IMP-4} were detected in the ICU at Dandenong Hospital between November 2009 and July 2012. Epidemiological investigations were undertaken in order to identify a common point source. During September 2012, screening using rectal swabs for all ICU patients, and environmental swabs targeting all ICU handwashing sinks and taps were collected. Samples were cultured onto selective carbapenem-resistant Enterobacteriaceae (CRE) agar. Suspected CRE isolates were further characterised using the modified Hodge test and VITEK 2 and confirmed by polymerase chain reaction and sequencing of MBL genes. Clinical and environmental CRE isolates were typed by pulsed-field gel electrophoresis.

Results: Ten clinical isolates and one screening isolate of CRE (consisting of *Klebsiella pneumoniae* [5], *Serratia marcescens* [4], *Enterobacter cloacae* [1] and *Escherichia coli* [1]) were detected with the bla_{IMP-4} gene over the 30-month period. *S. marcescens* was isolated persistently from the grating and drain of eight central sinks. Molecular typing confirmed that clinical and environmental isolates were related. Tap water cultures were negative. Several attempts to clean and decontaminate the sinks using detergents and steam cleaning proved unsuccessful.

Conclusion: This report highlights the importance of identification of potential environmental reservoirs, such as sinks, for control of outbreaks of environmentally hardy multiresistant organisms.

One of the most concerning emerging resistance traits among gram-negative bacteria is the ability of these organisms to produce carbapenem-hydrolysing β-lactamases, which confer resistance to almost all β-lactams.[1] Carbapenem-resistant Enterobacteriaceae (CRE) are increasing in prevalence worldwide, causing growing concern, as they are often combined with non-β-lactam resistance to produce isolates that are multidrug resistant, have few treatment options available and are associated with high mortality rates.[2]

Although multiple resistance mechanisms have been identified, carbapenem resistance is often plasmid-encoded, allowing gene dissemination and a propensity to cause nosocomial outbreaks.[3-6]

We describe a CRE outbreak due to the presence of the metallo-β-lactamase gene bla_{IMP-4} in an intensive care unit (ICU) associated with contaminated sinks. This report highlights the key role of bacterial environmental contamination and sink design and usage in the propagation of CRE outbreaks.

Methods

Dandenong Hospital is a 440-bed tertiary referral hospital in Melbourne, Australia. The ICU has a 14-bed capacity, admitting both medical and surgical patients and averaging 1400 admissions yearly.

Ten ICU patients were found to have clinical specimens with Enterobacteriaceae harbouring the bla_{IMP-4} gene between November 2009 and July 2012. The ICU routinely screens for vancomycin-resistant enterococci (VRE) carriage using rectal swabs on admission, weekly and on discharge. During the 4-week period from 6 September to 4 October 2012, CRE screening was performed in addition to the routine screen for VRE.

Environmental screening for CRE targeting all 28 wet area locations (including 11 sinks and taps, as well as water fountains and ice machines) was performed. Samples were recollected from CRE positive locations after successive decontamination attempts. A total of 97 samples were collected from taps, water, grates and drains (10 cm down and above the water trap interface where biofilm may be expected to persist).

All environmental and patient screening swabs were cultured onto chromogenic agar (*Brilliance* CRE Agar, Oxoid). Suspect colonies were further characterised using the modified Hodge test and VITEK 2 (Biomérieux). All isolates with a meropenem minimum inhibitory concentration (MIC) ≥ 0.25 mg/L and a positive modified Hodge test result were forwarded for confirmation by polymerase chain reaction and molecular sequencing. Molecular typing using pulsed field gel electrophoresis (PFGE) was conducted on clinical and environmental isolates and interpreted as per the reference guidelines.[7]

Guidelines on ICU handwashing sink styles were reviewed to establish whether sinks met clinical design standards.[8]

Results

Ten clinical isolates (*Klebsiella pneumoniae* [$n = 5$], *Serratia marcescens* [$n = 4$] and *Enterobacter cloacae* [$n = 1$]) and one screening isolate (*Escherichia coli*) containing the bla_{IMP-4} gene were detected over the 30-month period. There were four distinct CRE clusters, commencing with three cases of *K. pneumoniae* in November 2009, followed by two cases of *S. marcescens* 6 months later, three cases (two *S. marcescens* and one *E. cloacae*) after another 11 months, and three cases of *K. pneumoniae* in July 2012.

Clinical characteristics, patient demographics and ICU admission details of all 11 patients are summarised in Box 1. Patients acquired CRE after a median length of stay in ICU of 10 days (range, 3–134 days). No

1 Demographics and intensive care unit (ICU) admissions for patients with carbapenem-resistant Enterobacteriaceae isolates

Patient	Underlying condition	Year of first positive culture	Culture type	Organism	Total hospital stay (days)	ICU stay (days)	ICU admissions in past 12 months	Total carbapenem therapy (days)	Outcome
1	Small bowel perforation, post-hernia repair	2009	Blood	*Klebsiella pneumoniae*	229	134	0	14	Discharged
2	Urosepsis, multiorgan failure	2010	Urine	*K. pneumoniae*	44	16	0	0	Discharged
3	Bilateral pneumonia	2010	Bronchial washings	*K. pneumoniae*	61	33	0	0	Discharged
4	Pneumonia	2010	Intercostal catheter swab	*Serratia marcescens*	44	32	0	2	Discharged
5	Pneumonia	2010	Endotracheal aspirate	*S. marcescens*	46	6	0	0	Discharged
6	Buttock abscess	2011	Urine	*S. marcescens*	49	10	0	0	Discharged
7	Pneumonia	2011	Penile swab	*S. marcescens*	46	22	0	3	Discharged
8	Congestive cardiac failure	2011	Sputum	*Enterobacter cloacae*	57	4	0	0	Died
9	Ischaemic stroke	2012	Sputum	*K. pneumoniae*	31	3	0	3	Died
10	Periprosthetic hip fracture	2012	Urine	*K. pneumoniae*	46	8	0	0	Discharged
11	Ketoacidosis	2012	Rectal screen swab	*Escherichia coli*	11	4	2	0	Discharged

patient died due to clinical CRE infection. Patient 1 had a prolonged CRE bacteraemia that responded to removal of a central venous catheter, the presumed source of infection.

A total of 111 rectal swabs were collected from 71 patients. Only one patient (Patient 11) was CRE-positive with an *E. coli* isolate detected.

Antibiotic resistance profiles of clinical isolates indicated resistance to β-lactams and meropenem with MICs ⩾1 mg/L. All *S. marcescens* clinical isolates were sensitive to piperacillin/tazobactam, ciprofloxacin and amikacin, while *K. pneumoniae* and *E. coli* were only sensitive to amikacin. *S. marcescens* environmental isolates showed a higher meropenem MIC of ⩾16 mg/L.

S. marcescens was the only species recovered from environmental samples and was isolated persistently, even after six attempts to decontaminate the grates and drains of eight of the 11 central sinks in the ICU. Tap spout and water cultures were negative for CRE.

Three of the four *S. marcescens* clinical isolates from 2010 and 2011 were indistinguishable or closely related by PFGE to four isolates from sinks. *S. marcescens* was isolated from an intercostal catheter swab of Patient 4, matching two sink isolates; Patient 5 had an endotracheal aspirate identical to two different sink locations; and the urine isolate from Patient 6 was closely related to a different sink. The isolate from Patient 7 was unable to be typed by PFGE.

Sink inspection revealed aged and deteriorating porcelain, even though sinks were only installed in 2005. Sink design did not comply with Australasian clinical design standards,[8] with a small, shallow sink and a tap that directed water over the drain (Box 2). The design of the ICU sinks led to poor use for hand hygiene (although measured hand hygiene compliance using alcoholic hand rub was around 70% within the unit) and the potential for organisms residing down the drain to be splashed back onto staff hands or contaminate patient areas. It was also revealed that the handwashing sinks had been used incorrectly, with staff disposing clinical waste and residual antibiotics directly into drains. Further enquiry also revealed that a single brush had been used to clean down the drains of all sinks in the ICU without disinfection between sinks.

Cleaning was attempted in an effort to rid the organisms from the sinks.

2 Existing design of intensive care unit sink compared with a design that complies with Australasian standards[8]

A: Existing sink, showing water spray directly over drain. **B:** Compliant sink design, showing larger basin and less forceful water flow directed away from drain, to prevent splash back and contamination with drain contents. ◆

A53210128

First, cleaning of grates and drains using single-use, soft brushes was attempted, but repeat screening revealed continued CRE growth. Next, in addition to the brushes, hypochlorite deep cleaning was used after the scrub; however, heavy CRE growth was again evident 1 week later. Finally, an attempt using pressurised steam decontamination (Jetsteam Maxi with plunger tool attachment, Duplex) for 1 minute at 170°C on grates and drains appeared to eradicate almost all CRE at Day 1 (one sink remained colonised); however, repeat testing 3 days after steam treatment showed re-emergence of CRE in all previously affected sinks.

Discussion

We report an outbreak of CRE in an ICU with identical organisms isolated from patients and an environmental source (sinks).

Dissemination of carbapenemase-resistant bacteria has been reported previously in an ICU in Australia, with 62 patients infected or colonised with gram-negative bacteria from multiple genera containing the bla_{IMP-4} gene.[9] The gene is carried on a highly mobile plasmid making it efficient for nosocomial transmission. The gene can reside in multiple genera of hardy environmental organisms that can establish a reservoir within biofilm.

Identifying the outbreak using molecular methods allowed us to establish clonality between clinical and environmental isolates and to propose a mechanism whereby patient contamination may have occurred. Although we cannot prove that the sinks were the source of patient infection, the persistence of the organism within the environment was a concern. Attempts at sink sterilisation were futile, and complete eradication will require future sink removal and replacement with appropriately designed sinks.

Others have reported outbreaks of multiresistant bacteria such as extended-spectrum β-lactamase-producing *K. pneumoniae* linked to imperfect sink design requiring sink cleaning, replacement and/or improved sink practices to successfully control the outbreaks.[10]

Our data should act as a reminder on the importance of appropriate hospital design, adequate environmental cleaning and antimicrobial stewardship in the hospital setting.

Stamps of greatness

Karl Landsteiner (1868–1943)

LANDSTEINER was born on 14 June 1868 in Vienna, Austria. He studied medicine at the University of Vienna and graduated in 1891. For 5 years he studied chemistry in Wurzburg (with Emil Fischer) and Munich, but then returned to Vienna and transferred his interest to pathological anatomy.

In 1898 he became an assistant to the institute of pathological anatomy in Vienna, in 1908 the prosector at the Wilhelminaspital, and in 1911 professor of pathology at the University of Vienna. After the upheavals of World War I he went first to Holland and then, in 1922, to the Rockefeller Institute for medical research in New York, where he continued work even after being made Emeritus Professor in 1939.

From 1900 he studied the agglutination of blood from different individuals, and in 1909 he outlined the human blood types, thus making blood transfusion possible. Landsteiner received the Nobel Prize in Medicine in 1930 for this work, which he continued at the Rockefeller Institute.

During his time in Vienna he also studied (in collaboration with others) poliomyelitis, first showing that the disease was infectious, and then isolating the causative virus.

In the early 1940s at the Rockefeller Institute, he was part of the team that discovered the Rh factor in blood, adding to his work on blood transfusion and compatibility of donors.

Throughout his career he contributed many fundamental principles to the science of immunology and knowledge of antigens and anaphylaxis, and was the recipient of many academic honours and awards. He died on 26 June 1943 after suffering a heart attack while working in his laboratory two days earlier.

Philatelically he was honoured on the centenary of his birth in 1968 by both Austria and Germany.

A Long-Term Low-Frequency Hospital Outbreak of KPC-Producing *Klebsiella pneumoniae* Involving Intergenus Plasmid Diffusion and a Persisting Environmental Reservoir

Ståle Tofteland[1]*, Umaer Naseer[2,3], Jan Helge Lislevand[1], Arnfinn Sundsfjord[2,3], Ørjan Samuelsen[2]*

Abstract

Background: To study the molecular characteristics of a long-term, low frequency outbreak of bla_{KPC-2} in a low prevalence setting involving the hospital environment.

Methodology/Principal Findings: KPC-producing bacteria were screened by selective chromogenic agar and Real-Time PCR. The presence of antibiotic resistance genes was ascribed by PCRs and subsequent sequencing, and the KPC-producing isolates were phylogenetically typed using PFGE and multi-locus sequence typing. Bla_{KPC-2}-plasmids were identified and analysed by S1-nuclease-PFGE hybridization and PCR based replicon typing. A ~97 kb IncFII plasmid was seen to carry bla_{KPC-2} in all of the clinical isolates, in one of the isolates recovered from screened patients (1/136), and in the *Klebsiella pneumoniae* and *Enterobacter asburiae* isolates recovered from the environment (sinks) in one intensive care unit. The *K. pneumoniae* strain ST258 was identified in 6 out of 7 patients. An intergenus spread to *E. asburiae* and an interspecies spread to two different *K. pneumoniae* clones (ST27 and ST461) of the bla_{KPC-2} plasmid was discovered. *K. pneumoniae* ST258 and genetically related *E. asburiae* strains were found in isolates of both human and environmental origins.

Conclusions/Significance: We document a clonal transmission of the *K. pneumoniae* ST258 strain, and an intergenus plasmid diffusion of the IncFII plasmid carrying bla_{KPC-2} in this outbreak. A major reservoir in the patient population could not be unveiled. However, the identification of a persisting environmental reservoir of strains with molecular determinants linked to human isolates, suggests a possible role of the environment in the maintenance of this long-term outbreak.

Introduction

The *Klebsiella pneumoniae* carbapenemase (KPC) was first identified in the USA in a *Klebsiella pneumoniae* isolate dated from 1996[1] and has subsequently been reported worldwide.[2] High prevalence rates of KPC have been reported from regions and countries such as USA, Israel, China, and Greece, while a number of countries have reported hospital outbreaks and sporadic cases of KPC-producing *K. pneumonia.* [2]

KPC has been identified in various species of Enterobacteriaceae and non-fermenters such as *Pseudomonas aeruginosa* and *Acinetobacter baumannii.* [2] Further, bla_{KPC} has been identified on plasmids differing in size and structure. This broad species distribution and plasmid diversity is likely due to the location of bla_{KPC} in a functional Tn*3*-based transposon structure (Tn*4401*) with a high transposition frequency.[3] With respect to *K. pneumoniae*, multilocus sequence typing (MLST) has shown that the global dissemination of KPC-producing *K. pneumoniae* is dominated by isolates belonging to a hyperepidemic clonal complex including sequence type (ST) 258.[4] Although the dissemination and outbreaks of KPC seems to be associated with specific clones several reports are describing outbreaks where several clones and different species are involved [5,6] as well as individual patients containing different species harbouring $bla_{KPC.}$[7,8,9]

In many countries the emergence of KPC-producing bacteria has been associated with import of isolates from high prevalent areas. In Norway, the first case of *K. pneumoniae* with KPC was associated with import from Greece in 2007 at a hospital in the southern part of Norway.[10] Subsequently, five additional clinical isolates were identified at the same hospital and a nearby hospital from patients with no recent history of travel or hospitalisation abroad. In this study we describe this long-term outbreak with regards to the molecular characteristics of these isolates, plasmid

A33210128

content and dissemination, and the identification of KPC-producing isolates in the hospital environment.

Materials and Methods

Hospital setting

Sørlandet Hospital (SH) is a 683-bed general hospital enterprise located in three different cities in the southern part of Norway. Due to sharing of some specialized medical functions a certain degree of interchange of patients between the hospitals occurs. Two hospitals belonging to Sørlandet Hospital, SH-Arendal (SH-A), and SH-Kristiansand (SH-K), as well as a tertiary hospital (Oslo University Hospital – Rikshospitalet (OUH-RH)) where involved in this outbreak. A screening programme was implemented during outbreak investigation involving a 12-bed (8 single rooms and one 4-bed room) surgical/medical intensive care unit (ICU-A) at SH-A.

Faecal and environmental screening programme

Faecal screening of ICU-A patients was initiated after the identification of clinical case number 6 (K66-62). Prospective screening was performed on patients ($n = 50$) on admittance and discharge from the ICU-A during a first screening period from 8th of May to 19th of October 2010, and then only on discharge from the ICU-A during a second screening period from 19th of October to 1st of April 2011 ($n = 65$). Retrospective screening was attempted on 29 patients that had been hospitalized in the ICU-A at overlapping intervals with patient 6. Seventeen of these were still hospitalized and screened, whereas 4/12 discharged patients were subjected to screening. Patients staying in the ICU-A for more than 14 days were screened repeatedly every second week.

Screening of the environment was undertaken on two occasions, from the 7th to the 9th of June 2010 and on the 27th of December 2010. The screenings involved sink drains in the ICU-A (n = 19), the neighbouring post-operative unit, the coronary unit, and taps for water to dialysis machines in the ICU-A. Environmental samples were obtained with sterile, cotton-tipped swabs (COPAN swabs®). Most areas examined were moist, but the cotton-tip was occasionally moistened when the area examined appeared relatively dry. Screening positive locations were disinfected and then controlled by monthly screening.

Isolation of KPC-producing bacteria and detection of bla_{KPC} during the screening programme

Screening for KPC-producing bacteria was performed using ChromID ESBL agar medium (bioMerieux, la Balme-les-Grottes, France) and an enrichment medium (tryptic-soy broth containing 2 mg/L cefpodoxime). Real-Time PCR of bla_{KPC} was performed directly on suspensions from the swab, enrichment medium, and colonies from the ChromID ESBL agar[11].

Bacterial strains and clinical data

Clinical data and data on bacterial strains investigated in this study are listed in Table 1 and 2.

Species identification

Bacterial identification was performed using the VITEK2 ID-GNB system (bioMérieux, Marcy l'Etoile, France) and/or MALDI-TOF (Microflex LT, Bruker Daltonics) with the MALDI Biotyper 3.0 software version.

Antimicrobial susceptibility testing

Antimicrobial susceptibility of the isolates was determined using Etest (bioMérieux) according to the manufacturer's instruction. The results were interpreted using breakpoints from the European Committee for Antimicrobial Susceptibility Testing.[12]

Molecular characterisation of KPC-producing isolates

PCR and sequencing for bla_{KPC}, bla_{TEM}, bla_{SHV}, bla_{CTX-M}, and a multiplex PCR for the most prevalent plasmid-borne bla_{AmpC} -genes was performed as previously described (Samuelsen JAC 09). Isolates were typed by pulsed-field gel electrophoresis (PFGE) of *Xba*I-digested total genomic DNA.[10] Strain relatedness was analysed using BioNumerics version 6.0 (Applied Maths, Sint-Martens-Latem, Belgium) using the band-based dice coefficient and the unweighted pairs geometric-matched analysis dendrogram with a position tolerance of 1% for optimization and band comparison. Final comparison of bands for the interpretation of relatedness was performed in accordance with Tenover criteria.[13] Multi-locus sequence typing (MLST) was performed on *K. pneumoniae* isolates according to the protocol described on the *K. pneumoniae* MLST web site http://www.pasteur.fr/recherche/genopole/PF8/mlst/Kpneumoniae.html.

Plasmid analysis

Plasmid profiling was performed using S1-nuclease digested plasmid DNA, separated by PFGE.[10] Subsequently, plasmid DNA was blotted onto nylon membrane and hybridised with bla_{KPC} specific probes to identify carrier plasmids. Furthermore, plasmids were classified into incompatibility groups using the PCR based replicon-typing (PBRT) scheme of Carattoli[14] and hybridisation with replicon FII specific probes as previously described.[10]

Transfer of resistance

Conjugal-transfer experiment was carried out in Luria-Bertani broth at 37°C for clinical strain K47-25 as donor and rifampicin-resistant E. coli J53-2 as recipient, mixed in a 1:9 ratio respectively. Transconjugants were selected on LB-agar plates (Becton Dickinson, Sparks, MD) supplemented with 100 mg/L rifampicin (Sigma-Aldrich, St. Louis, MO) and 2 mg/L ceftazidime (Sigma-Aldrich).

Ethics statement

This study focuses on the molecular characteristics of bacterial isolates collected as part of the clinical management and microbiology routine work. Faecal screening was performed according to the guidelines from the local hospital and collection of clinical data as part of outbreak investigations for implementation of appropriate infection control measurements. Consequently, ethical approval was not obtained for the study.

Results

Clinical cases

Six KPC-producing *K. pneumoniae* isolates from clinical samples were recovered in SH from November 2007 to April 2010 (Table 1 and Table 2). The first two isolates had been characterised previously.[10] The first patient had been hospitalized on Crete in September 2007 prior to hospital admission in Norway. The other patients had no history of recent travel abroad. 5 isolates were recovered from SH-A, whereas the isolate from patient 2 was recovered from SH-K. After the identification of KPC-producing *K. pneumoniae*, measures for contact isolation were initiated for all

patients. When patient 1 was readmitted at SH-K in March 2008 measurements for contact isolation was however not implemented. Retrospective analysis of patient histories revealed that all SH-A patients had been hospitalized in the same ICU (ICU-A) as the index patient prior to detection of the KPC-producing isolates. However, during their stay the patients had been admitted to 12 different wards. Further, conventional epidemiological evaluation[15] was able to establish epidemiological links between patient 1 and 2, and 3 and 4, while a possible link was suggested between patient 4 and 5 (Table 2). Time and space overlaps between the clinical cases 1 and 3 as well as 5 and 6 could not be provided for, representing time intervals of 10 and 11 months, respectively.

Several recognized risk factors for ESBL colonization and infection[15,16,17,18] were present in all the patients that had been admitted to the ICU-A prior to isolation of KPC-producing *K. pneumoniae* (patient 1, 3–6) (Table 2). All patients were above 65 years of age. KPC-producing *K. pneumoniae* bacteraemia was recognized in one patient, whereas the findings in the other patients were regarded as most likely to be colonisations associated with artificial ventilation or urinary catheter. One patient died, but the KPC-producing *K. pneumoniae* was not considered to be attributable to infection or death in this patient (Table 2).

ESBL-producing bla_{KPC}-negative *K. pneumoniae* were also recovered in ambulatory urinary samples due to urinary tract infections (UTI) from three of the of the patients 26, 16, and 4 months after the initial isolation of the KPC-producing *K. pneumoniae* isolates, respectively (Table 1).

Patient screening

In the patient screening programme only 1/136 patients were positive for KPC-producing Enterobacteriaceae (patient 7). Patient 7, being hospitalized in room 5 for his entire ICU-A stay, was identified with KPC-producing *K. pneumoniae* (K66-73) and *Enterobacter asburiae* (K66-74) upon discharge (Table 1), while negative upon admission five days earlier. Room 5 was disinfected using a persulfate based disinfectant after having been occupied by patient 6 and then patient 7 was the first to be admitted two days later.

Environmental screening

KPC-producing bacteria were detected in 4/19 environmental locations in the ICU-A (sink drains in room 5, 6, 9, and the rinsing room). Bla_{KPC}-positive *K. pneumoniae* were identified in June 2010 from the sink drains in room 5 (K67-11 and K67-15) and room 6 (K67-13 and K63-14), and bla_{KPC}-positive *E. asburiae* from the sink drain in room 5 (K67-12 and K67-16) (Table 1). The sinks and sink traps were decommissioned and the connecting pipe elbows were disinfected using a chlorine disinfectant before new sinks and sink traps were installed. Monthly environmental screening of these positive locations was then undertaken. Bla_{KPC}-positive *K. pneumoniae* was again recovered from the sink in room 6 on two occasions in December 2010 triggering a new environmental screening in the ICU-A (data not shown). Additional sink drains in the ICU-A was investigated, and two new locations that were not subjected to investigation in June 2010 were now identified with bla_{KPC}-positive *K. pneumoniae* (room 9) and bla_{KPC}-positive *E. asburiae* (room 9 and the rinsing room, data not shown).

Although bla_{KPC}-positive isolates have been identified in the environment no additional clinical cases has been identified since patient 6.

Molecular characterisation of the isolates

PFGE and MLST typing revealed that 14 *K. pneumoniae* isolates from both patients and the environment, including the three bla_{KPC}-negative *K. pneumoniae* UTI-isolates, belonged to two clonally related pulsotypes (A1 and A2), that by MLST were typed to ST258 (Figure 1, Table 1). Distinct *K. pneumoniae* PFGE/MLST-types were recovered in patient 5 (K57-33; pulsotype B/ST461) and isolates from the sink drain in room 6 (K67-13 and K67-14; pulsotype D/ST27). PFGE of the *E. asburiae* isolates revealed two closely related pulsotypes corresponding to the *E. asburiae* (pulsotype C1) isolate from the screening patient (patient 7; K66-47) and the two *E. asburiae* (pulsotype C2) isolate from room 5 (K67-12 and K67-16). The bla_{KPC}-gene was sequenced in all isolates from patients and from the environmental in June 2010 and found to be bla_{KPC-2} (Table 1). The bla_{KPC}-positive *K. pneumoniae* ST258 isolates harboured bla_{SHV-11}, bla_{SHV-12}, and bla_{TEM-1}, whereas the three bla_{KPC}-negative *K. pneumoniae* ST258 UTI-isolates, harboured bla_{SHV-12} and bla_{SHV-11}, but were negative for bla_{TEM}. The distinct *K. pneumoniae* STs in patient 5 (K57-33) and from room 6 (K67-13 and K67-14) harboured bla_{SHV-1} and lacked the bla_{SHV}-gene, respectively. The bla_{KPC}-positive *E. asburiae* isolates were devoid of bla_{SHV} but harboured bla_{TEM-1} (Table 1). PCRs for bla_{CTX-M} and the most prevalent plasmid-borne bla_{AmpC} genes were negative.

Plasmid analysis

S1-nuclease-PFGE profiles revealed the presence 2-3 plasmids in all isolates ranging from~40–~240 kb (Table 1, Figure 2). Hybridization with bla_{KPC}-specific probes identified a bla_{KPC}-carrier plasmid to approximately 97 kb in all bla_{KPC}-positive isolates of *K. pneumoniae* and *E. asburiae*. In the bla_{KPC}-positive *K. pneumoniae* isolate from patient 1 (K47-25) an additional bla_{KPC}-plasmid of ~160 kb was identified. PBRT and hybridization characterized the ~97 kb plasmid as an IncFII replicon plasmid. Except for the 97 kb bla_{KPC}-plasmid, separate plasmid profiles were recognized in the other *K. pneumoniae* pulsotypes/STs and the closely related *E. asburiae* clones. The plasmid profile among the *E. asburiae* isolates were identical (Table 1, Figure 2).

Interestingly, the plasmid profile of the pulsotype A/ST258 bla_{KPC}-negative *K. pneumoniae* clinical UTI isolates was devoid of the ~97 kb bla_{KPC}-plasmid, indicating loss of this plasmid (Table 1).

Transferability of bla_{KPC} resistance

In vitro plasmid-transfer experiments using K47-25 as the donor strain to *E. coli* resulted in transconjugants with a frequency of 2.5×10^{-7} per donor cells.

Antimicrobial susceptibility

The antimicrobial susceptibility profile of the isolates is shown in Table 3. Variable levels of reduced susceptibility to carbapenems were observed in all the bla_{KPC}-positive isolates whereas the three ESBL-positive bla_{KPC}-negative *K. pneumoniae* ST258 UTI isolates were susceptible to carbapenems (Table 1). A similar susceptibility profile with high-level resistance to penicillins and cephalosporins, resistance to ciprofloxacin, tobramycin, and amikacin, but susceptibility to gentamicin, were common to all *K. pneumoniae* ST258/pulsotype A isolates. In contrast, the other bla_{KPC}-positive *K. pneumoniae* pulsotypes were susceptible to ciprofloxacin, tobramycin, amikacin, and the gentamicin MIC was lower. The bla_{KPC}-positive *E. asburiae* isolates found in the screening positive patient (patient 7) and the environment showed resistance to ciprofloxacin, but were susceptible to the aminoglycosides.

All bla_{KPC}-positive *K. pneumoniae* ST258 isolates were resistant to colistin. 2 of 3 bla_{KPC}-negative *K. pneumoniae* UTI isolates were susceptible to colistin, whereas one isolate was resistant (K67-05) displaying a clearly visible double zone (MIC 0.5 mg/L and MIC 16 mg/L).

Discussion

The dissemination of multidrug resistance plasmids among Gram-negative bacteria is one of the major factors contributing to

the spread of antimicrobial resistance.[19] However, information about plasmid-dissemination during outbreaks is relatively limited. Often the focus is restricted to specific bacterial species and the dissemination of plasmids into different species might be overlooked. Highly mobile plasmids resulting in 'plasmid-borne outbreaks' may delay the recognition of an outbreak, and adds an additional layer of complexity to the molecular investigation of such outbreaks.[20] Plasmids have previously been linked to outbreaks of multi-drug resistant (MDR) Gram-negative bacteria[21,22,23,24,25], including nosocomial outbreaks of bla_{KPC}-containing plasmids in some studies.[5,7,8,20,26,27,28,29] Here we describe the dissemination of a KPC-plasmid between strains and species during a small long-term nosocomial outbreak in a low-prevalence setting as well as the possible role of the environment in this context. To the best of our knowledge this is the first nosocomial outbreak report of KPC-producing bacteria from the Nordic countries.

I*n vivo* mobility is indicated by identification of the ~97 kb IncFII bla_{KPC-2}-plasmid in four distinct MLST/PFGE types of *K. pneumoniae* and *E. asburiae*. This observation was supported by successful *in vitro* conjugation of bla_{KPC}-plasmids. bla_{KPC} – containing Tn*4401* has been documented on plasmids of different sizes belonging to different incompatibility groups.[30,31,32,33,34] While mostly being reported on broad host IncN plasmids[31], bla_{KPC} has recently been reported on narrow host range IncFII plasmids as well, promoting efficient spread within members of Enterobacteriaceae.[33,35,36]

It is well known that plasmid-transfer can occur *in vivo*, but less is known about plasmid-transfer occurring in the hospital environment. We can only speculate were the plasmid-transfer has occurred in this setting. The first clinical cases were associated with the hyperepidemic *K. pneumoniae* ST258 strain before plasmid-dissemination were observed into other *K. pneumoniae* STs (ST27 and ST461) and *E. asburiae*, all of them devoid of non-β-lactam resistances except the latter displaying low-level ciprofloxacin resistance. The KPC-producing *E. asburiae* remained clinically silent throughout the outbreak and first appeared in faecal screening of patient 7. Faecal screening was not performed on any of the clinical patients, thus whether KPC-producing *E. asburiae* was carried by any of these patients remains elusive. The finding of a distinct *K. pneumoniae* (ST27) with the ~97 kb KPC-plasmid in the hospital environment but not in patients could either be due to the unrecognized presence in patients and *in vivo* plasmid-transfer or that the plasmid-transfer have occurred in the environment before acquisition by a patient.

Interestingly, loss of bla_{KPC}-plasmids, ~160 kb plasmid in patient 1 and the ~97 kb plasmid in the three bla_{KPC}-negative *K. pneumoniae* UTI isolates, was observed in *K. pneumoniae* ST258 indicating either a high fitness cost or reduced plasmid stability. Experiments to determine the fitness cost related to the ~97 kb plasmid and its stability are ongoing.

Reservoirs in the patient or health care worker populations and the environment represent principle modes of spread in nosocomial outbreaks with the patient population being the most important reservoir in high-frequent outbreaks.[37] Introduction of the *K. pneumoniae* ST258 clone has caused major outbreaks in many hospitals.[38] It is possible that a high level of adherence to standard precautions prevented the establishment of a major gastrointestinal reservoir in our patients, and thus, the prerequisite of a major high-frequent outbreak, were not present.[37,39,40,41] The lack of a patient reservoir and the persistence of the outbreak despite the long interval between known clinical cases could indicate other possible reservoirs contributing to occasional transmissions and maintenance of the outbreak. Health care workers were not screened for faecal or hand carriage partly as no individuals with additional risk factors including dermatitis[37] could be identified and partly due to the fact that the current Norwegian health authority guidelines advocates against screening of health care workers in nosocomial outbreaks of multidrug resistant Gram-negative bacteria.[42] KPC-producing bacteria were detected in as much as 21% of environmental locations in screening samples from sink drains in the ICU-A. Moist surfaces and especially sink drains have been focused in several studies as a possible environmental source of transmission of Enterobacteriaceae, especially *Klebsiella* spp, to patients.[43,44,45,46,47,48] Although the environment were decontaminated and sinks were

A53210128

replaced, KPC-producing *E. asburiae* and *K. pneumoniae* were recovered during further environmental screening, suggesting that these strains can survive well in that environment. Contamination of the hands of health care workers due to occasional backsplash during hand washing in a contaminated sink and sink drains[44,46,47,49] or through moist surfaces near sinks and faucets[45] has been suggested as a possible mode of transmission to health care workers and subsequently to patients in the ICU setting, facilitating low-frequent transmissions. The epidemiological link between patient 6 and 7 through their succeeding use of room 5 and the isolation of pulsotype identical KPC-producing *K. pneumoniae* ST258 from both patients and the sink drain in that room as well as the recovery of closely related KPC-producing *E. asburiae* from faecal screening in patient 7 and the sink drain could suggest a possible environmental source of colonization of patient 7.

Investigation revealed that several sinks were heavily contaminated by bacteria presumably from waste water washed down the sink after cleaning of patients. A 'bed bath'-system for cleaning of patients were implemented to shortcut this opportunity. Repetitive disinfection with a biofilm active disinfectant was considered, but disinfection was only performed on two occasions; in June 2010 and January 2011.

In conclusion; the outbreak involved clonal spread of the hyperepidemic *K. pneumoniae* ST258 stain as well as interspecies plasmid transmission of a ~97 kb bla_{KPC}-plasmid into two other distinct *K. pneumoniae* strains and intergenus spread to *E. asburiae*. The establishment of a local environmental reservoir was documented. The spread among patients has probably occurred partly as a result of transmission between patients in some of the clinical cases, but we infer the possibility that the outbreak was maintained and prolonged with additional clinical cases added due to spread from environmental sources.

Short Report

Potential infection control risks associated with chilled beam technology: experience from a UK hospital

T. Inkster*, C. Peters, H. Soulsby

Department of Microbiology, Queen Elizabeth University Hospital, Glasgow, UK

Energy efficiency
Infection control

SUMMARY

Energy efficiency technologies are now a feature in hospital design, with active chilled beams an example of one in use worldwide. Such innovations have clear benefits but there is a paucity of information with respect to any infection control risks. We describe our experience of chilled beam technology from one of our hospitals where we faced challenges with cleaning and episodes of water ingress including condensation. We highlight the importance of infection control risk assessment in relation to new technologies and the implementation of appropriate risk mitigation.

Introduction

While active chilled beam technology is in use in hospitals globally including Scandinavia, Australia, and USA, their introduction has been largely driven by energy-saving advantages [1]. Active chilled beam technology delivers fresh air to the patient bedroom and is designed to integrate into suspended ceiling systems. Primary air from the supply ducting passes through nozzles into the room. The air movement creates low pressure and draws air back in from the room over the cooling coils. This is termed secondary (entrained) air and mixes with the primary air to be redelivered through diffusers (Figure 1).

In addition to energy conservation, advantages include thermal comfort and quiet operation [2]. Acknowledged disadvantages are the production of condensation and cleanliness issues [2]. Furthermore the large amounts of bedding used in healthcare settings can lead to the abundance of lint, which can become trapped within the beams [2]. There is a paucity of published data on infection control risks of chilled beam technology with no infection outcome-based clinical trials. Concerns remain regarding the impact of the recycled pathway of airborne pathogens intrinsic to the active chilled beam concept [3,4]. The American Society of Heating, Refrigerating and Air-Conditioning Engineers (2017) notes that chilled beams should not be used in intensive care units, protective isolation or source isolation rooms, toilets, procedure rooms, delivery rooms, endoscopy rooms, or clean rooms due to 'cleaning difficulty and potential for build-up of contamination'. The recirculation within the room interferes with the concept of a clean-to-dirty pathway for clean diluting air to remove pathogens from the contaminated air. There is potential for recirculation of pathogens within the breathing zone of patients and staff but this is an area of active research with computer modelling and other technologies and may depend on factors such as aerosol size, other heat sources in the room and human plume influences on air movements [5].

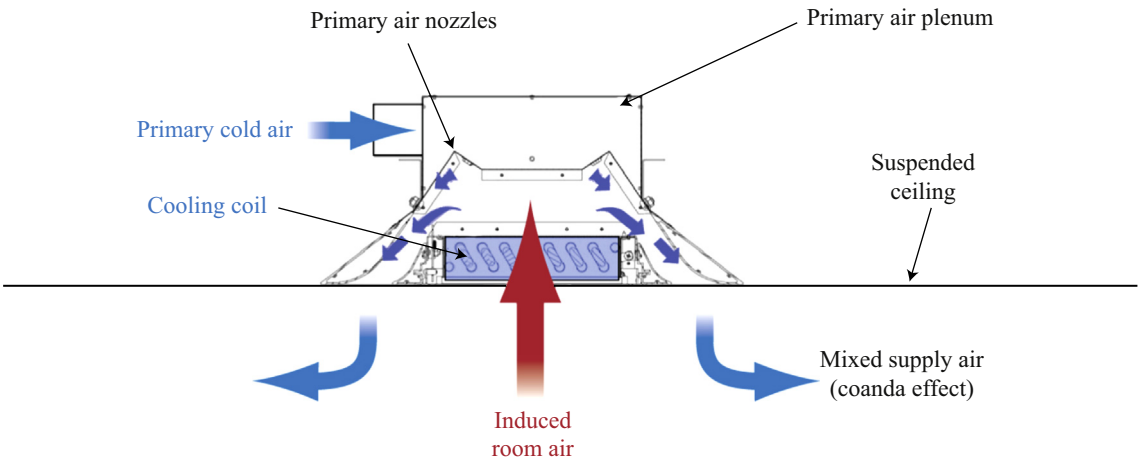

Figure 1. Active chilled beam technology. From: https://tacoadvancedhydronics.wordpress.com/category/radiant-cooling-chilled-beams/.

Current UK and Scottish Health Technical Memorandum guidelines for ventilation in healthcare premises are non-specific and give little guidance as to the suitability of chilled beam technology within healthcare premises [6]. However, the neutropenic and source isolation room concept are incompatible with chilled beams by token of the mandatory unimpeded clean-to-dirty pathway. Where chilled beams are in use in hospitals, guidance states that control settings should ensure that external components of the beam are always above the dew point. With reference to cleaning, access for cleaning and the impact of maintenance requirements should be considered [6]. We would recommend that water safety groups include chilled beam technology as a water source and that these are identified as a risk during the design phase as well as during maintenance. Our hospital has 1677 beds with active chilled beams installed in all patient rooms apart from the critical care and bone marrow transplant units.

Methods

Since our hospital opened in 2015 we have made a number of observations in relation to chilled beam technology which may have infection control implications.

Results and discussion

Cleaning

There have been issues with both access to clean and cleaning frequency. This is a clear disadvantage to the technology in a large hospital. The risk is intrinsic to the design which relies on entrained air from the room space, carrying fibres, skin squames and aerosols passing over the fins of the coils to be cooled/heated. This particulate matter tends to collect and stick to the metal (Figure 2). Others state that as the fin surfaces of an active chilled beam unit are relatively well gapped, dust and dirt particles tend not to bridge the fin surface; this does not reflect our experience [7].

The models in use in our hospital are not of the kind that allow easy removal of the entire beam for full-scale cleaning and decontamination. Cleaning is cumbersome and required on a six-week rotation due to visible build-up of dust, despite manufacturers suggesting six months to yearly. Access to clean can be problematic when patients are occupying the room, as the chilled beam is situated directly above the patient's bed. High patient turnover makes chilled beam cleaning impracticable as part of the standard discharge clean.

No filter is present, so all recirculated air will either carry with it the pathogens back into the room or deposit on to the beam. This poses an even greater risk when condensation drips

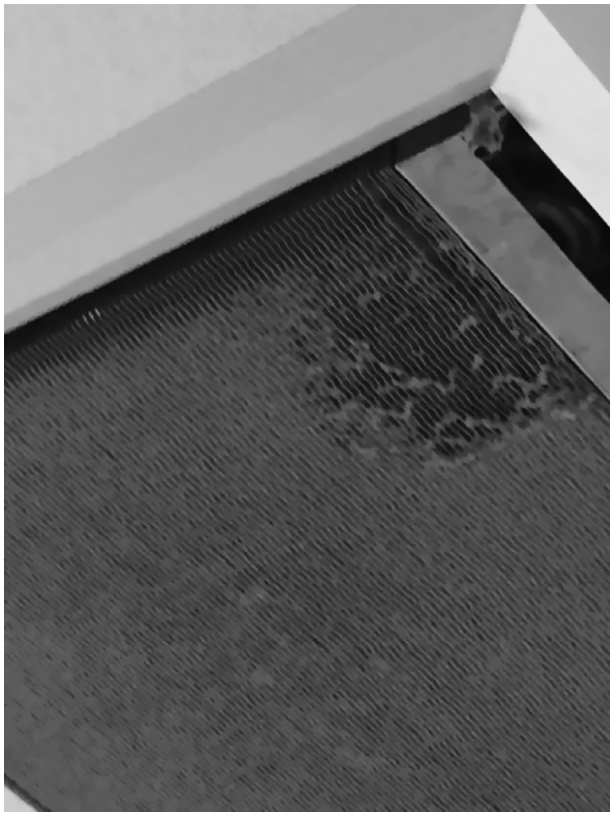

Figure 2. Photograph of chilled beam.

Box 1

Veillonella sp.
Stenotrophomonas sp.
Acinetobacter sp.
Paenibacillus pabuli
Klebsiella pneumoniae
Psychrobacter phenylpyruvicus

through the accumulated dust, as has occurred on several occasions.

Surface swabs from the chilled beams in our hospital have grown multiple organisms (Box 1). These include: (i) skin commensals in keeping with skin squame contamination (raising the possibility of meticillin-resistant and -susceptible *Staphylococcus aureus* also being present and recirculated); (ii) fungi, in keeping with moisture and a carbon source being present in the collected dust; (iii) enteric organisms: in keeping with possible airborne particles of bacteria entering into patient room from toilet and collecting on beams; (iv) environmental Gram-negative bacteria, in keeping with circulating moisture- and dust-borne environmental organisms. Surface swabs were undertaken in one of our general wards following reports of leaking from the chilled beams and observations of dust. These were plated directly on to blood agar, cysteine–lactose and electrolyte-deficient (CLED) agar and Sabouraud plates. In total, areas of the chilled beams from 19 rooms were swabbed. Prior to cleaning, 22 out of 49 (45%) samples were positive. In the two weeks post cleaning, four swabs out of 42 were positive (9%).

This is evidence of the potential biohazard posed by pathogens in the accumulated dirt on the fins of the beam and in keeping with the theoretical risk of airborne pathogens stagnating in the beam instead of being removed from a clean-to-dirty pathway. The likelihood is that as time goes on there will be an increasing bioburden of pathogens building up on the coils presenting an increasing hazard, particularly when combined with condensation events but not restricted to these [5].

Condensation, water leaks, and water contamination

Condensation should not occur on chilled beams and this is a prerequisite for safe functioning in healthcare [1,5,8]. The design and monitoring should be set up to eliminate this risk. Riffat states that 'when the panel surface temperature is lower than the dew point of room air, condensation on panel and pipe surfaces occurs, which can lead to damage from dripping water and an unacceptable room air condition' [1]. This is potentially serious in healthcare settings, particularly with immunocompromised patients. Condensation encourages mould and bacterial growth posing an infection hazard even in small amounts [9]. The degree of hazard depends on the bioburden, the environmental conditions, patient characteristics and effectiveness of the air change dilution effect. We have noted frequent condensation events: most have involved two or three beams in one ward area at a time, but on one occasion 106 rooms throughout the building were affected at the same time. It is not clear if this is due to temperature settings being too low for the dew point or if the dehumidification was planned to be in the air handling unit and is not present in some. Alteration to the dew point to operate above it has been undertaken to mitigate this risk and we have not been made aware of any further issues.

Our experience is not unique, with condensation issues being documented outside healthcare settings in office buildings and a school [10]. These were due to leaks in the duct system preventing sufficient air from reaching the beams [10].

As chilled beams use a water supply system within the hospital, with potential for leakage into clinical areas, the water supply requires temperature monitoring and attention to biocide usage if the water becomes contaminated. The circulating water system poses a *Legionella* spp., *Pseudomonas* spp. and other waterborne pathogen risk.

Leakage of supply water in our hospital has occurred from fittings. This phenomenon is supported by microbiology testing which isolated *Pseudomonas oleovorans* from the beam water system and from swabs from the leakage, external to the beam. This is also crucially backed by a history of water ingress to rooms. Whereas condensation on the beam causes 'indoor rain' as tiny droplets of condensation coalesce on the fins and fall into the room, leakage from the piping drips into the rim and drips from a corner in a gravity-directed pathway with the fins remaining dry [7]. *Pseudomonas aeruginosa* has also been isolated from the circulating water in our hospital chilled beam system.

There is no prospectively designed clinical trial based on infection rates that would give evidence for suitability of the use of this chilled beam technology in healthcare settings. Comparison for the UK context would need to be between full fresh air supply with and without chilled beams with standard cleaning methods and measuring healthcare-associated infection rates prospectively. The basis for the advantage of the chilled beam system in the published validation based on computer modelling and prototype testing was that conventional air-conditioning in hospitals included recirculation and indefinite pressure regimes, which is not the starting point in the UK [5]. The validation did not consider infectious aerosols emitting from a patient or infectious doses of various pathogens, nor did it include a comparison of different air change rates.

The proper functioning of a chilled beam system has been described as a balancing act, with temperature, humidity, volumes of outside air and occupancy all playing a role. Hospitals using chilled beam technology should be aware of the potential issues with access to clean, cleaning frequency, and the possibility of condensation or water leaks and subsequent risks from contaminated dust and water. Staff should be encouraged to report any condensation or water leakage events. Chilled beams should be included on a cleaning

schedule and frequency should be determined according to levels of dust build up. Infection control teams should consider chilled beams as a potential environmental source when investigating incidents/outbreaks.

A limitation of our report is that our experience is based on observations from a single centre only and may not reflect experience elsewhere. Further studies are required to delineate the infection control risks associated with such energy-saving efficiency methods which are likely to feature more commonly in future hospital builds.

In conclusion, when designing new hospitals, consideration should be given to the potential infection control risks associated with such energy-saving initiatives, with early involvement of the infection control team to ensure that risks are fully delineated and risk mitigation measures implemented. We would value more detailed reference to chilled beam and other energy efficiency technologies within national specifications for healthcare premises.

Executive summary

Preamble

This current review and update of HTM 04-01 is intended to move users of the document towards a holistic management of water systems via Water Safety Groups (WSGs), Water Safety Plans (WSPs) and other initiatives.

This version draws together and updates the previous guidance and includes recommendations for the safe management of water systems, via the integration of the principle of WSGs and WSPs (first introduced in the HTM 04-01 *Pseudomonas aeruginosa* addendum – published in March 2013), and how to manage and minimise the risks to health from various aspects, ranging from clinical risks, microbial and chemical contamination, changes to the water system, resilience of the water supply etc. It also introduces a stronger emphasis on staff competencies and the implementation of water hygiene awareness training.

Introduction

The development, construction, installation, commissioning and maintenance of hot and cold water supply systems are vital for public health. Healthcare premises are dependent upon water to maintain hygiene and a comfortable environment for patients and staff, and for treatment and diagnostic purposes.

Interruptions in water supply can disrupt healthcare activities. The design of systems should ensure that sufficient reserve water storage is available to minimise the consequence of disruption, while at the same time ensuring an adequate turnover of water to prevent stagnation in storage vessels and distribution systems.

This Health Technical Memorandum (HTM) gives comprehensive advice and guidance to healthcare management, design engineers, estate managers, operations managers, contractors and the supply chain on the legal requirements, design applications, maintenance and operation of hot and cold water supply, storage and distribution systems in all types of healthcare premises. It is equally applicable to both new and existing sites.

Aims of this guidance

The current review and update of HTM 04-01 is intended to move users of the document towards a holistic management of water systems via WSGs, WSPs and other initiatives.

It has been written to promote good practice for those responsible for the design, installation, commissioning, operation and maintenance of water services in healthcare premises, by:

- highlighting the need for robust governance and management;
- outlining the remit of the WSG and how this relates to the provision of safe water in healthcare premises;
- outlining key criteria and system arrangements to help stop the ingress of chemical and microbial contaminants and microbial colonisation and bacteria proliferation;
- illustrating temperature regimes for sanitary outlets to maintain water hygiene;

- ensuring the safe delivery of hot water;
- outlining how the correct selection of system components and correct use by occupants can help preserve the quality and hygiene of water supplies;
- providing a point of reference to legislation, standards and other guidance pertaining to water systems;
- providing a basic overview of possible potential waterborne pathogens;
- giving an overview of some of the different water systems (including components) and their safe installation, commissioning and operation and maintenance;
- providing typical system layouts and individual component location;
- providing information on thermostatic mixing valve configurations, appropriate usage and maintenance requirements;
- identifying key commissioning, testing and maintenance requirements for referral by designers, installers, operators and management;
- identifying key commissioning, testing and maintenance requirements for referral by designers, installers, commissioners, operators and management.

Controlling waterborne pathogens

The guidance gives comprehensive guidance on measures to control waterborne pathogens. While *Legionella* control is, in the main, associated with poor engineering configuration and maintenance, with no evidence of patient-to-patient or patient-to-outlet transfer, *P. aeruginosa* may be transferred to and from outlets and the water from both patients and staff. Suspected *P. aeruginosa* waterborne infections require additional investigations to determine the source and interventions from infection control specialists and microbiologists. Therefore, a temperature control regime is the traditional strategy for reducing the risk from *Legionella* and for reducing the growth and colonisation of other waterborne organisms within water systems. To prevent growth of *P. aeruginosa* and other waterborne pathogens, controls are necessary to manage the water system before and after the outlet.

As with all control measures, temperatures should be monitored at regular intervals to verify effective control.

Because of the complexity of hot and cold water distribution systems and the difficulty of maintaining a temperature control regime in some healthcare facilities, this guidance suggests that additional chemical, physical and other water control methods that have been shown to be capable of controlling microbial colonisation and growth may also be considered.

Main changes from the 2006 edition of HTM 04-01

- This 2016 edition of HTM 04-01 provides comprehensive guidance on measures to control waterborne pathogens such as *Pseudomonas aeruginosa, Stenotrophomonas maltophilia, Mycobacteria* as well as *Legionella*.
- This edition has been updated to align with the Health and Safety Executive's (HSE's) recently revised Approved Code of Practic e for Legionella (L8) and its associated HSG274 guidance documents.
- The Addendum to HTM 04-01 published in 2013 (and now Part C of HTM 04-01) introduced the concept of WSGs and WSPs. Part B of the HTM now includes updated guidance on the remit and aims of the WSG and WSP.
- New guidance has been included on the hygienic storing and installation of fittings and components and on the competency of installers/plumbers working on healthcare water systems. The guidance also outlines that any person working on water distribution systems or cleaning water outlets needs to have completed a

water hygiene awareness training course. An example course outline is included.

- Guidance on sampling techniques for, testing for, and the microbiological examination of *Pseudomonas aeruginosa* samples – originally in the HTM 04-01 Addendum – is now included in Part B to complement similar guidance on *Legionella*.

Glossary and abbreviations

In addition to the definitions listed below, other definitions can be found in the Water Supply (Water Fittings) Regulations 1999; BS 6100; BS 8558; and BS EN 806.

Augmented care units/settings – There is no fixed definition of "augmented care"; individual providers may wish to designate a particular service as one where water quality must be of a higher microbiological standard than that provided by the supplier. While this document provides broad guidance, the water quality required will be dependent on both the type of patient and its intended use. Most care that is designated as augmented will be that where medical/nursing procedures render the patients susceptible to invasive disease from environmental and opportunistic pathogens such as *Pseudomonas aeruginosa* and other alert organisms. In broad terms, these patient groups will include:

a. those patients who are severely immunosuppressed because of disease or treatment: this will include transplant patients and similar heavily immunosuppressed patients during high-risk periods in their therapy;

b. those cared for in units where organ support is necessary, for example critical care (adult paediatric and neonatal), renal, respiratory (may include cystic fibrosis units) or other intensive care situations;

c. those patients who have extensive breaches in their dermal integrity and require contact with water as part of their continuing care, such as in those units caring for burns.

Backflow – Flow upstream, that is in a direction contrary to the intended normal direction of flow, within or from a water fitting.

Biofilm – a complex layer of microorganisms that have attached and grown on a surface. This form of growth provides a niche environment for a wide range of microorganisms to interact and where the secretion of exopolysaccharides by bacteria will form an extracellular matrix for both bacteria and other unicellular organisms such as amoebae and flagellates to remain in a protected state.

Dead-leg – a length of water system pipework leading to a fitting through which water only passes infrequently when there is draw off from the fitting, providing the potential for stagnation.

Healthcare-associated infections (HCAI) – encompasses any infection by any infectious agent acquired as a consequence of a person's treatment or which is acquired by a healthcare worker in the course of their duties.

Healthcare facility/building – all buildings, infrastructure, equipment, plant, embedded systems and related items that support the delivery of healthcare and services of all types, irrespective of their ownership or operation by third parties.

Healthcare organisations: organisations that provide or intend to provide healthcare services for the purposes of the NHS.

Point-of-use (POU) filter – a filter with a maximal pore size of 0.2 µm applied at the outlet, which removes bacteria from the water flow.

Redundant pipework (also known as blind end): a length of pipe closed at one end through which no water passes.

Thermostatic mixing valve: valve with one outlet, which mixes hot and cold water and automatically controls the mixed water to a user-selected or pre-set temperature.

Waterborne pathogen: microorganism capable of causing disease that may be transmitted via water and acquired through ingestion, bathing, or by other means.

Water outlet: (In this document) refers mainly to taps and showerheads, but other outlets, as indicated by risk assessments, may be considered important.

Water Safety Group (WSG): A multidisciplinary group formed to undertake the commissioning and development and ongoing management of the water safety plan (WSP). It also advises on the remedial action required when water systems or outlets are found to be contaminated and the risk to susceptible patients is increased.

Water safety plan (WSP): A risk-management approach to the safety of water that establishes good practices in local water distribution and supply. It will identify potential hazards, consider practical aspects, and detail appropriate control measures.

Water supply [to the healthcare facility]: The water supplied can be via:

- the mains water supply from the local water undertaker;
- a borehole (operated by the healthcare organisation as a private water supply);
- a combination of mains water and borehole supply;
- emergency water provision (bulk tankered water or bottled drinking water).

Water undertaker – the role of a water undertaker is defined in a number of sections of the Water Industry Act 1991.

Wholesomeness: standards of wholesomeness are defined in section 67 of the Water Industry Act 1991. Separate legislation for public and private supplies sets out the prescribed concentrations and values for water and are detailed in the following legislation: the Water Supply (Water Quality) Regulations 2000 for water from a public supply; or the Private Water Supplies Regulations 2009 for water from a private supply.

0 Policy and regulatory overview: water safety and the healthcare estate

Introduction

0.1 The National Health Service (NHS) has a corporate responsibility to account for the stewardship of its publicly funded assets. This includes the provision, management and operation of an efficient, safe estate that supports clinical services and strategy.

0.2 This corporate responsibility is carried by all accountable officers, directors with responsibility for estates & facilities and their equivalents, chairs, chief executive officers and non-executive board members. Together they have a responsibility to enact the principles set out in this document, provide leadership and work together to implement the necessary changes to provide a safe, efficient high quality healthcare estate.

0.3 To achieve this, quality and fitness-for-purpose of the healthcare estate is vital. Health Technical Memorandum (HTM) 04-01 seeks to set out the quality of, and standards for, water safety in the healthcare estate.

0.4 A healthcare organisation's Water Safety Group (WSG) (see Part B) is pivotal in ensuring that decisions affecting the safety and integrity of the water systems and associated equipment do not go ahead without being agreed by them. This includes consultations relating to decisions on the procurement, design, installation and commissioning of water services, equipment and associated treatment processes.

0.5 The quality and fitness-for-purpose of the estate are assessed against a set of legal requirements and governance standards.

Adhering to the guidance outlined in this HTM will be taken into account as evidence towards compliance with these legal requirements and governance standards.

Compliance of the healthcare estate

0.6 Principles related to the safety of healthcare estates and facilities are enshrined in the Health and Social Care Act 2008 (Regulated Activities) Regulations 2014, specifically Regulation 12(2)(h) and Regulation 15 of the Act.

Note

There are numerous other statutes and legal requirements that NHS organisations, supporting professionals, contractors and suppliers must comply with. These are covered in the respective Health Building Notes (HBNs), Health Technical Memoranda (HTMs) and the NHS Premises Assurance Model (NHS PAM).

Health and Social Care Act 2008 (Regulated Activities) Regulations 2014

0.7 Regulation 12(2)(h) decrees that registered providers must assess:

- the risk of, and prevent, detect and control the spread of, infections, including those that are health care associated.

0.8 Appropriate standards of cleanliness and hygiene should be maintained in premises used for the regulated activity. DH (2015) issued 'The Health and Social Care Act 2008 Code of Practice on the prevention and control of infections and related guidance' (the HCAI Code of Practice), which contains statutory guidance about compliance with regulation 12(2)(h) (see paragraphs 0.15–0.17).

0.9 Regulation 15 of the Act states that:

(1) All premises and equipment used by the service provider must be–

a. clean,

b. secure,

c. suitable for the purpose for which they are being used,

d. properly used

e. properly maintained, and

f. appropriately located for the purpose for which they are being used.

(2) The registered person must, in relation to such premises and equipment, maintain standards of hygiene appropriate for the purposes for which they are being used.

Note

The "registered person" means, in respect of a regulated activity, the person who is the service provider or a registered manager in respect of that activity.

A "service provider" means a person registered with the CQC under Chapter 2 of Part 1 of the Health and Social Care Act 2008 as a service provider in respect of that regulated activity.

Regulator requirements

0.10 The CQC independently regulates all providers of regulated health and adult social care activities in England. The CQC's (2015) 'Guidance for providers on meeting the regulations' explains how to meet regulations 12(2)(h) and 15 outlined above.

0.11 Failure to comply with the Health and Social Care Act 2008 (Regulated Activities) Regulations 2014 and the Care Quality Commission (Registration) Regulations (2009) is an offence, and the CQC has a wide range of enforcement powers that it can use if a provider is not compliant. These include the issue of a warning notice that requires improvement within a specified time, prosecution, and the power to cancel a provider's registration, removing its ability to provide regulated activities.

Examples of governance and assurance mechanisms arising from primary legislation (not exhaustive)

NHS Constitution

0.12 The Health Act 2009 places a duty on bodies providing and commissioning NHS services to have regard to the NHS Constitution. The Health and Social Care Act 2012 further applied this duty to the new bodies created by that Act or by amendments to the 2012 Act.

0.13 The NHS Constitution "sets out rights to which patients, public and staff are entitled". It also outlines "the pledges which the NHS is committed to achieve, together with responsibilities that the public, patients and staff owe to one another to ensure that the NHS operates fairly and effectively".

0.14 It commits the NHS to ensuring **"that services are provided in a clean and safe environment that is fit for purpose, based on national best practice (pledge)".** In order to deliver on this pledge, the NHS should take account of:

- the NHS Premises Assurance Model (NHS PAM) – the NHS PAM identifies where the NHS Constitution needs to be considered and where assurance is required;
- national best practice guidance for the design and operation of NHS healthcare facilities (such as HBNs and HTMs).

The HCAI Code of Practice

0.15 A complex range of issues distinguishes healthcare environments from most other building types. One of the most important of these relates to the control of infection. Infection prevention and control teams should be consulted on any design decisions and a risk analysis conducted on the many issues of design involving water systems (see Health Building Note 00-09 – 'Infection control in the built environment'). To manage and monitor the prevention and control of infections effectively, the HCAI Code of Practice requires a WSG and a water safety plan (WSP) to be in place.

0.16 The information outlined in HBN 00-09 follows the general principles given in the HCAI Code of Practice, which sets out criteria against which a registered provider will be judged on how it complies with Regulation 12(2)(h) of the Health and Social Care Act 2008 (Regulated Activities) Regulations 2014 on the prevention, detection and control of infections, particularly waterborne infections in relation to this document.

0.17 The law states that the HCAI Code of Practice must be taken into account by the CQC when it makes decisions about registration against the cleanliness and infection control requirement. The regulations also say that providers must have regard to the Code when deciding how they will comply with registration requirements. Therefore, by following the Code, registered providers will be able to show that they meet the requirement set out in the regulations. However, the Code is not mandatory. A registered provider may be able to demonstrate that it meets the regulations in a different way (equivalent or better) from that described in this document. The Code aims to exemplify what providers need to do in order to comply with the regulations.

Figure 1 illustrates how DH estates and facilities best practice guidance (such as the NHS PAM and HTMs) aligns with the statutory and policy framework. This guidance is fundamental to ensuring that NHS trusts are able to deliver on their commitments under the NHS Constitution and to comply with the CQC's fundamental standards.

Never events

0.18 NHS England's never events policy framework defines "never events" as serious, largely preventable patient safety incidents that should not occur if the available preventative measures have been implemented by healthcare providers. On the list of never events is scalding of patients. The risk of scalding for vulnerable patients (children and young people, older people, and disabled people) is a particular problem in healthcare premises. HTM 04-01 provides guidance on reducing the risk of scalding.

Health and safety legislation

0.19 In the UK, the control of legionellae falls within the requirements of the Health and Safety at Work etc. Act. This Act also places duties on design teams, suppliers and installers to ensure that articles or substances for use at work are safe and without risks to health and that any information related to the article or substance is provided. The Management of Health and Safety at Work Regulations 1999 provide a broad framework for controlling health and safety at work. The Control of Substances Hazardous to Health Regulations 2002 (COSHH) provide a framework of actions designed to assess, prevent or control the risk from bacteria like *Legionella* and take suitable precautions.

0.20 The Health and Safety Executive's (2013) Approved Code of Practice 'Legionnaires' disease: The control of legionella bacteria in water systems (L8)' contains practical guidance on how to manage and control the

risks in water systems. The HSE has published complementary technical guidance in HSG274, which is split into three specific areas:

- Part 1 – evaporative cooling systems;
- Part 2 – hot and cold water systems; and
- Part 3 – other risk systems.

0.21 In addition, under the Reporting of Injuries, Diseases and Dangerous Occurrences Regulations (RIDDOR), there is a duty for employers to report any cases of legionellosis in an employee who has worked on hot and cold water systems that are likely to be contaminated with *Legionella*. Cases of legionellosis are reportable under RIDDOR if:

a. a doctor notifies the employer; and
b. the employee's current job involves work on or near cooling systems that are located in the workplace and use water; or work on water-service systems located in the workplace which are likely to be a source of contamination.

0.22 With regard to enforcement responsibilities, the Health & Safety Executive will take the lead with regard to incidents involving *Legionella*. See the 'Memorandum of understanding between the Care Quality Commission, the Health and Safety Executive and local authorities in England'.

Security

0.23 Accessibility to all plant and equipment should be limited to authorised personnel only (see NHS Protect's (2012) 'Guidance on the security and management of NHS assets').

Water regulations

0.24 As well as complying with the recommendations outlined in this document, the design and installation of the hot and cold water services, new or extended, in any healthcare premises should also comply with:

- the Water Supply (Water Fittings) Regulations 1999;
- Defra's guidance to the Water Supply (Water Fittings) Regulations;
- recommendations of the water suppliers in the Water Regulations Advisory Scheme's (WRAS) 'Water Regulations Guide', and
- any other requirements of the local water undertaker.

Water Supply (Water Fittings) Regulations 1999

0.25 These Regulations set legal requirements for the design, installation, operation and maintenance of plumbing systems, water fittings and water-using appliances. They have a specific purpose to prevent misuse, waste, undue consumption or erroneous measurement of water and, most importantly, to prevent contamination of drinking water.

0.26 These Regulations apply in all types of premises supplied, or to be supplied, with water from a water undertaker. They apply from the point where water enters the property's underground pipe, to where the water is used in plumbing systems, water fittings and water-using appliances. However they do not apply in premises that have no provision of water from the public mains supply.

Water Supply (Water Quality) Regulations 2000

0.27 These Regulations cover the quality of water supplied by water undertakers for public distribution which is intended for domestic purposes; these purposes include drinking, cooking, food preparation, washing and sanitation. Water supplied meeting these quality requirements is referred to as wholesome water.

Private Water Supplies Regulations 2009

0.28 These Regulations cover private sources of water intended for human consumption including drinking, cooking, food preparation or

other domestic purposes, such as boreholes and wells. Water meeting these quality requirements is referred to as wholesome water. These Regulations also place duties for monitoring and control of the quality of public water supplies where these are then further distributed to other users on separate premises by the water company's bill payer (this arrangement is often referred to as onward distribution).

0.29 Local authorities are the regulators for private water supplies and have a number of statutory duties under the Private Water Supplies Regulations.

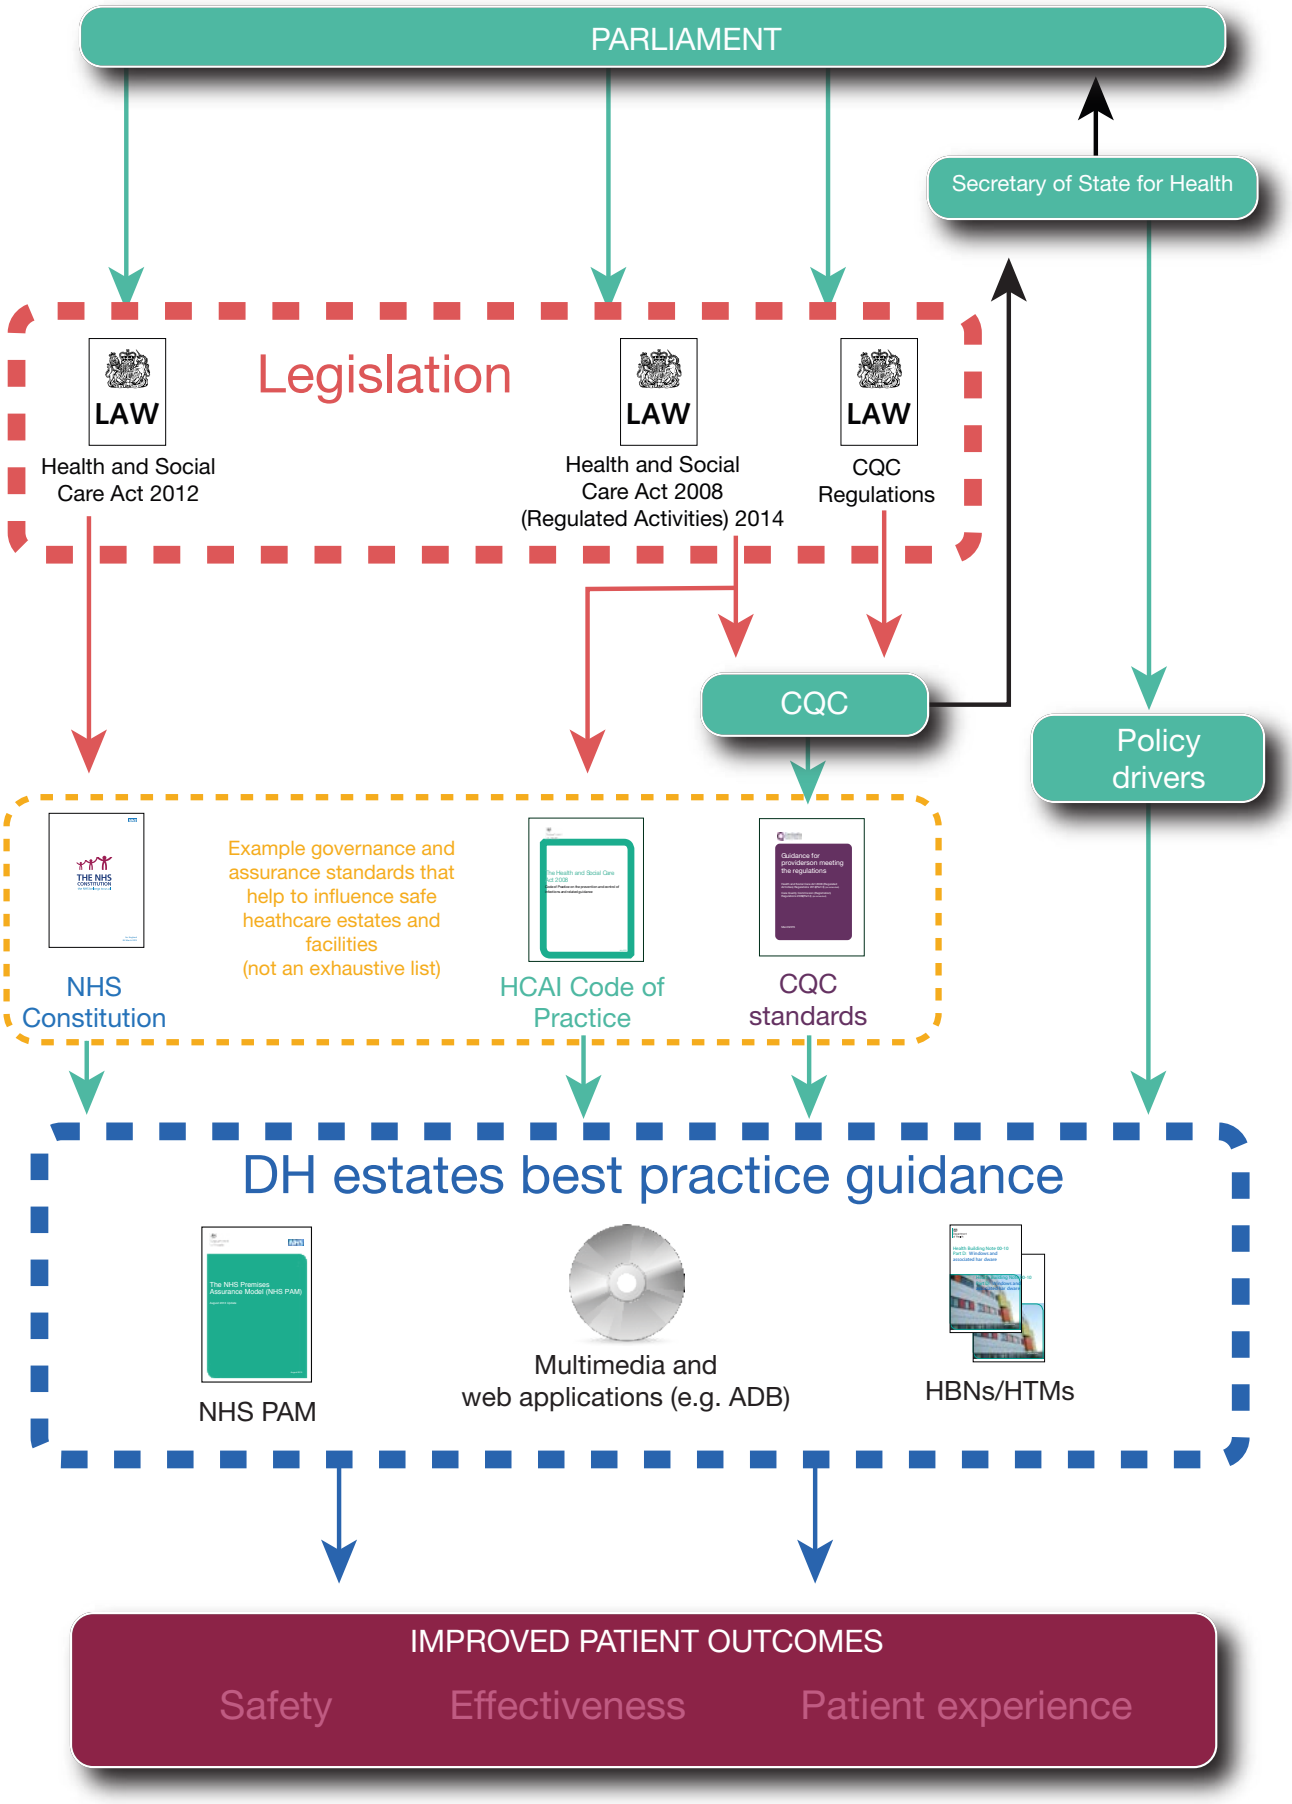

Figure 1 How best practice guidance on the safety and quality of healthcare estates and facilities fits in with the legislative and policy framework. (The statutes and mandatory requirements shown in this figure are not exhaustive. See Note after paragraph 0.6.)

1 Introduction to HTM 04-01

1.1 This edition of HTM 04-01 – 'Safe water in healthcare premises' supersedes HTM 04-01 – 'The control of *Legionella*, hygiene, "safe" hot water, cold water and drinking water systems' published in 2006.

1.2 This guidance has been revised to take account of HSE's revision of its Approved Code of Practice and guidance on regulations 'Legionnaires' disease: The control of legionella bacteria in water systems (L8)' and its complementary technical guidance HSG274.

1.3 This HTM gives comprehensive advice and guidance to healthcare management, design engineers, WSGs, estates managers and operations managers on the legal requirements, design applications, maintenance and operation of hot and cold water supply, storage and distribution systems in all types of healthcare premises. It is equally applicable to both new and existing sites.

1.4 The document comprises three parts. This part (Part A) outlines the principles involved in the design, installation and testing of the hot and cold water supply, storage and distribution systems for healthcare premises. Some variation may be necessary to meet the differing requirements for the various water undertakers. Part B covers operational management. Part C covers water safety in augmented care settings. HTM 04-01: Supplement – 'Performance specification D 08: thermostatic mixing valves (healthcare premises)' contains guidance on the on-site testing and commissioning of thermostatic mixing valves.

General

1.5 Current statutory legislation requires both "management" and "staff " to be aware of their individual and collective responsibility for the provision of wholesome, safe hot and cold water supplies, and storage and distribution systems in healthcare premises.

1.6 Healthcare premises are dependent upon water to maintain hygiene and a comfortable environment for patients and staff, and for clinical and surgical care.

1.7 The safe development, construction, installation, commissioning and maintenance of hot and cold water supply systems and associated systems and equipment are vital for public health.

1.8 Interruptions in water supply can increase the risk of microbial ingress especially if these result in depressurisation of the supply pipework. The design of systems should ensure that sufficient reserve water storage is available to minimise the consequence of disruption, while at the same time ensuring an adequate turnover of water to prevent stagnation in storage vessels and distribution systems.

1.9 Measures to control the spread of microorganisms in healthcare premises include hand-washing but also the regular use of antimicrobial hand-rubs, and this can result in a significant reduction in the use of wash-hand basins. Under-use of taps encourages colonisation and growth with *Pseudomonas aeruginosa*, *Legionella* and other waterborne organisms. The design team should be aware

of this and, accordingly, consider how local infection policies with regard to hand hygiene and the use of antimicrobial hand-rubs might impact on the frequency of use of wash-hand basins and the volume of water being distributed (see also paragraphs 5.7–5.12 in Part B on the extent of utilisation).

Legislation, standards and guidance

1.10 As well as complying with the recommendations outlined in this document, the design and installation of the hot and cold water services, new or extended, in any healthcare premises should also comply with:

a. the Water Supply (Water Fittings) Regulations 1999, Defra guidance and the recommendations of the water suppliers in the Water Regulations Advisory Scheme's (WRAS) 'Water Regulations Guide', and any other requirements of the local water undertaker;

b. the HSE's Approved Code of Practice and guidance on regulations 'Legionnaires' disease: The control of legionella bacteria in water systems (L8)', which requires that sources of risk are identified and assessed and a written scheme of control is put in place in respect of controlling *Legionella* in water systems.

Notes

1. The Water Supply (Water Fittings) Regulations 1999 are set out – along with Defra's (1999) guidance (see References) and with the water industry's interpretation of these provisions – in the WRAS 'Water Regulations Guide'.

2. Special measures may have to be introduced to remove chloramines from mains water supplied to renal dialysis units. See guidance produced by the Renal Association.

General requirements

1.11 Where new healthcare premises are planned or existing premises are to be altered or refurbished, the WSG should be consulted at the earliest possible opportunity and water risk assessments be completed for all projects. This will enable the total water hygiene requirements to be assessed in the planning stages, and appropriate action taken, including ensuring that any pressure testing, flushing and cleaning does not lead to stagnation or contamination before being placed into service. The risk assessment should be reviewed once the system is operational.

1.12 At all stages of the design, installation and commissioning of new or extended water systems, the design team should liaise and consult with the local WSG in a timely manner, give consideration to HTM 04-01 Parts B and C and incorporate all operational managements requirement into their design.

1.13 Design teams and installers of hot and cold water distribution systems are required by the Water Supply (Water Fittings) Regulations 1999 to notify the water undertaker of any proposed installation of water fittings and to have the water undertakers' consent before installation commences. It is a criminal offence to install or use water fittings without their prior consent. Liaison with the local water undertaker is strongly recommended at an early stage to avoid problems of compliance in the design. Further information can be found on the WRAS website. See also paragraphs 1.19–1.20.

1.14 All water fittings used in the construction of systems referred to in this HTM must comply with the requirements of the Water Supply (Water Fittings) Regulations 1999 (Regulation 4: "Requirements for water fittings") and if

The water industry

Water supply

Defra is the government department responsible for safeguarding the natural environment. This includes the protection of the aquatic environment, water resources and drinking water quality. It has established a number of regulatory authorities to oversee these areas. A company may be appointed to be a water undertaker by the Secretary of State under Section 6 of the Water Industry Act 1991, with a duty under this Act to develop and maintain an efficient and economical system of water supply (see Chapter 2).

Ten water and sewerage companies provide water and wastewater services for 99% of the population of England and Wales and drinking water to 75%. (A number of water supply companies provide drinking water to most of the remainder of the population.)

Regulatory authorities

The Water Act 1989 provided for the establishment of several regulatory bodies whose functions are now set out in the Water Industry Act 1991 and the Water Resources Act 1991 and are summarised below:

a. the Office of Water Services (OFWAT), which regulates the prices set by the water companies, oversees the standards of service provision and protects the interests of water consumers. OFWAT also has ten regional WaterVoice committees that identify customer concerns, pursue them with the companies and report to the director-general of water services. OFWAT are overseeing changes to competition in the retail water market through the Open Water programme. These changes will allow businesses and other non-household customers to choose their supplier of water and wastewater services from April 2017. Retail services include things like billing and customer services.

b. the Environment Agency (EA) regulates the quality and controls pollution of “controlled” waters (that is, most inland and coastal waters) and protects the water resources in England and Wales.

c. the Drinking Water Inspectorate (DWI) regulates the quality of the public supply of drinking water in England and Wales.

d. Local authorities regulate private water supplies.

required be in accordance with relevant British Standards and codes of practice appropriate to their use.

1.15 Where water is required to be wholesome, all non-metallic materials in contact with water should comply with the requirements of BS 6920. Many of the materials satisfactorily tested against this standard are listed by WRAS in the ‘Water Fittings and Materials Directory’ or by the DWI in their published ‘List of Approved Products’. Some of these approval schemes also validate compliance against the mechanical performance requirements and where appropriate installation requirements set out in the Water Supply (Water Fittings) Regulations 1999. These fittings are considered compliant provided they are installed according to any conditions given with the approval. Additionally, fittings approved by BuildCert, NSF-WRc, Kiwa Watertec (UK) and WRAS, unless they specifically state they are not approved for

use under the Water Supply (Water Fittings) Regulations 1999, are deemed to meet these requirements. Currently no criteria exist to verify metallic materials. Only materials and fittings shown to comply with these regulations should be used (for example, registered in one of the approval lists given above).

Note

Organic materials increase the risk of microbial colonisation; materials should be chosen to minimise the risk where possible (see Chapter 3). See also Estates and Facilities Alert DH (2010) 03 – 'Flexible water supply hoses'

1.16 The provision of wholesome water to premises is governed by either the Private Water Supplies Regulations 2009 or the Water Supply (Water Quality) Regulations 2000 depending on how the water is supplied. Preserving water quality within premises is governed by the Water Supply (Water Fittings) Regulations 1999 (where water is supplied by a water undertaker), building regulations, approved codes of practice and technical standards intended to safeguard quality.

1.17 Only installers with the appropriate qualifications, regulatory knowledge and competence should be used to install and maintain water installations. There are seven Approved Contractors' Schemes authorised through the Water Supply (Water Fittings) Regulations 1999. All seven schemes require appropriate qualifications and knowledge of the regulations as part of their membership criteria. The seven schemes are:

- the Association of Plumbing and Heating Contractors (APHC)
- Anglian Water's APLUS
- the Chartered Institute of Plumbing and Heating Engineering (CIPHE)
- the Scottish & Northern Ireland Plumbing Employers' Federation (SNIPEF)
- Thames Water Approved Plumbing Scheme (TAPS)
- WaterMark
- the Water Industry Approved Plumbers' Scheme (WIAPS)

1.18 In addition to plumbing installers, four schemes (APLUS, TAPS, WaterMark and WIAPS) operate sector memberships for specialist areas of work covering external water services (below ground pipework etc), catering equipment and point-of-use (chilled water) equipment.

1.19 The WaterSafe register holds details from all seven Approved Contractors' Schemes for businesses who have registered and qualified plumbing installers (see also Part B).

1.20 A recognised benefit to using an Approved Contractor (including sector installers) is they can carry out some work without the need to provide advanced notification to the water undertaker and their work will be certified upon completion. A "work completed" certificate issued by a WaterSafe-recognised plumber provides a defence for property owners who are challenged by a water undertaker enforcing the Water Supply (Water Fittings) Regulations 1999 or during legal proceedings.

Hygienic installation and storage practices

1.21 Installers should adopt practices that reduce the likelihood of cross-contamination from tools, clothing or the environment. Separate clothing and tools used for other non-wholesome services such as sewerage and drainage systems should be kept separate and not used when working on hot and cold water systems.

1.22 Good working practices should be developed:

- to ensure that flushing and disinfection processes remain effective;
- to reduce the risk of seeding a system with anything that could lead to physical, chemical or microbiological

contamination;

- to reduce any damaging effects of the disinfection process through the need for multiple disinfection treatments.

Note

Guidance to principle of water supply hygiene can be found on Water UK's website.

1.23 Only components and sub-assemblies that have been hygienically stored (for example, wrapped in bags and or original packaging) should be used (see also paragraphs 3.42–3.44). All components and sub-assemblies should be inspected before installation to ensure they are clean and free of defect. Efforts should be made to ensure debris and or contamination do not enter the hot and cold systems during construction and maintenance works.

1.24 Where contamination is suspected, measures should be undertaken to neutralise their effects (for example, flushing and disinfecting).

Storage

1.25 Items and components intended for installation in hot and cold water systems should be stored in clean, dry locations. Pipework valves and fittings etc should be stored on suitable racking and not on the floor. Larger items of plant that may have to be offloaded from delivery vehicles and delivered directly to their final location should be appropriately covered and protected from damage.

Water hygiene training

1.26 It is important that any person who works on hot and cold water systems or who is responsible for cleaning water outlets should have completed a water hygiene training course so that they understand:

- the need for good hygiene when working with water distribution systems and water outlets; and
- how they can prevent contamination of the water supply and outlets.

Note

For new builds and refurbishments, it will be the contractor's responsibility to ensure that all operatives intending to work on the water system have completed water hygiene training covering associated risks of working practices and local requirements.

1.27 To ensure the delivery of safe wholesome water at all outlets and prevent contamination which may lead to a healthcare-associated infection, it is recommended that healthcare organisations implement a water hygiene training scheme which utilises local content where possible and is information appropriate for the target audience.

1.28 Consideration should also be given to integrating a health screening element into the training to help ensure those undergoing the training are not carriers of any waterborne diseases on the date of training and are aware of their responsibilities towards the water supply. It is important that individuals are aware of their duty to protect the health of patients, staff and visitors and that they are responsible for ensuring they inform their line manager if they come into contact with any disease that has the potential to cause harm.

1.29 As an example, the course should encompass the following topics (not exhaustive):

- organisational governance arrangements in relation to water hygiene and safety;
- familiarisation with local policies/ procedures in relation to the management and provision of water hygiene and safety;
- information on prominent waterborne

pathogens and their consequences;

- the ways in which water distribution systems and water outlets can become contaminated;
- the responsibilities of individuals to prevent the contamination of the water distribution system and water outlets and assisting in ensuring control measures in place are effective;
- how the safety of water can be maintained by good hygiene practices;
- system design;
- components/accessories (taps, TMVs);
- disinfection and cleaning equipment/ materials;
- how to store and handle pipes;
- organisation-specific control measures;
- the impact of getting it wrong;
- role of persons being trained;
- personal hygiene along with dealing with clothing, footwear, cleaning equipment/ materials, tools and storage when considering water hygiene (as applicable to each role).

Areas this HTM does not cover

1.30 Although many of this HTM's recommendations will be applicable, it does not set out to cover water supply for fire-fighting services nor water supply for industrial or other specialist purposes, other than to indicate precautions that should be taken when these are used in association with domestic water services. The point at which a domestic activity becomes an industrial process has not been defined, and the applicability will need to be considered in each case.

1.31 This HTM does not cover wet cooling systems such as cooling towers. Guidance on these systems is given in HSE's Approved Code of Practice and guidance 'Legionnaires' disease: The control of legionella bacteria in water systems (L8)' and HSG274 technical guidance Part 1.

1.32 While some guidance on other water-service applications is included, it is not intended to cover them fully. For:

- process waters used for laundries, see HTM 01-04 – 'Decontamination of linen in health and social care';
- endoscopy units, see HTM 01-06 – 'Decontamination of flexible endoscopes';
- primary care dental premises, see HTM 01-05 – 'Decontamination in primary care dental practices';
- renal units, see HBN 07-01 and HBN 07-02, the Renal Association's guidelines and ISO 13959 and 11663;
- sterile services departments, see HBN 13 – 'Sterile services department';
- hydrotherapy pools, see the PWTAG's 'Swimming pool water: treatment and quality standards for pools and spas';
- spa pools, see HSE/PHE's 'Management of spa pools: controlling the risks of infection';

Note

This document is currently being revised and will become HSG274 Part 4 – 'The control of legionella and other infectious agents in spa pool systems'.

- birthing pools, see HBN 21 – 'Maternity' and PWTAG's 'Swimming pool water: treatment and quality standards for pools and spas'.

2 Source of supply

General

2.1 The source of water supply to healthcare premises is by one or more service-pipe connections from the mains of a water undertaker. If the quantity and rate of flow is inadequate, or if the cost of providing the service connection appears to be uneconomical, alternative sources of supply such as boreholes or wells may be investigated or other water undertakers may be contacted.

2.2 The healthcare building needs could be met by using a private supply (see the Private Water Supply Regulations 2009) as an additional source to the water undertaker's supply provided the risk to health is fully assessed and the supply deemed acceptable for its intended purpose. In such cases, the water undertaker's supply should be the priority supply for drinking, culinary and special hygienic services. By limiting the use of the private supply to services not requiring the highest level of hygiene, the extent of treatment of the private supply may be reduced. Supplies used in this way should convey water through an entirely separate pipework system that is clearly labelled. Outlets served by the supply system should also be appropriately labelled.

Note

With regard to private water supplies, further guidance is given on DWI's website.

2.3 Provision should be included for alternative water supply arrangements to meet an emergency, regardless of the source or sources of supply finally adopted (see HBN 00-07 – 'Planning for a resilient healthcare estate'). Alternative arrangements would include a second service connection from the water undertaker or a private supply. In either case the alternative supply should not be vulnerable to the cause of loss of the original supply. Direct physical interconnection of pipework and valves of a water undertaker's supply with any private supply without adequate backflow protection is prohibited by the Water Supply (Water Fittings) Regulations 1999. The water quality requirements applicable to the main supply apply also to any alternative supplies.

2.4 The water undertaker and local authority must be advised if it is proposed to use any private supply as well as the water undertaker's supply, and advice should be sought on the limitations imposed in respect of break cisterns/RPZ (reduced pressure zone) valves and interconnections thereafter as required by the Water Supply (Water Fittings) Regulations 1999.

2.5 In England all water intended for human consumption is required by legislation to comply with the quality standards laid down in the Water Supply (Water Quality) Regulations 2000 and the Private Water Supplies Regulations 2009 (see Appendix 2 for an overview of all UK water legislation). These regulations apply to water sampled at the point where the water is available for use and embrace not just drinking water and water used for washing, but also water used in the preparation of food and beverages.

2.6 The responsibility for enforcing the Water Supply (Water Quality) Regulations for public water supplies rests primarily with the DWI,

and for private supplies it rests with the local authority. In respect of public water supplies, the water undertaker has a duty to provide water that is wholesome at the point of supply to premises and to demonstrate – by monitoring – that the supplies meet the above standards. Water undertakers are also required to carry out risk assessments of each of its treatment works and connected supply in order to establish whether there is a significant risk of supplying water that would constitute a risk to human health. Using a risk-based approach, local authorities have a duty to monitor public health and in particular where affected by water supplies.

Supplies from a water undertaker

2.7 The following factors should be taken into consideration in the initial stages of the design:

a. the water undertaker's requirements;
b. water supply quality variations (see paragraphs 2.11–2.15);
c. the type of disinfectant residual and the variability in its concentration;
d. maintaining water supplies in an emergency (see paragraph 2.16);
e. the estimated daily consumption, and the maximum and average flows required, together with the estimated time of peak flow;
f. the location of the available supply;
g. the quality, quantity and pressure required;
h. the cold water storage capacity required;
i. the likelihood of ground subsidence due to mining activities or any other reason;
j. the likelihood of there being any contaminated land on site;
k. the proposed method of storage and probable number and purpose of direct connections to pressure mains;
l. the minimum and maximum pressures available at the service connection;
m. details of the physical, chemical (including radionuclides) and microbiological characteristics of the water supply and scope of any possible variations in such characteristics;
n. the possibility of an alternative service connection from some other part of the water undertaker's network, including pressure details;
o. the water undertaker's contingency plans, which may result in disruptions to the quality or quantity of water supplied;
p. the proximity of the supply pipework to wastewater pipes and the materials used for the supply pipework (plastic pipework is permeable to oil-based leaks such as diesels etc).

Note

Regulations require notification to the water undertaker of any proposed changes and additions to the water supply system in the premises. Prior to making any changes, a risk assessment should be carried out and audited as detailed in Part B. Further details can be found on the WRAS website.

2.8 These initial design feasibility studies should normally reveal the need for any further treatment, pressurisation and storage of the water undertaker's supply to meet healthcare building requirements and enable an estimate of costs to be made.

2.9 BS EN 805, BS EN 806-1-5 and BS 8558 give further guidance on the procedures that should be followed when carrying out preliminary investigations in relation to new water supplies.

2.10 During the design stage, close collaboration with the water undertaker should be maintained, and consent must be sought on the final arrangements before proceeding with

the installation. These arrangements should include:

- siting of service connections, access chambers, metering, bypassing, flushing out, physical security of service connections, installation and provisions for the fire-and-rescue service, proximity to wastewater pipework etc;
- compliance with the Water Supply (Water Fittings) Regulations 1999.

Water supply quality variations

2.11 At different times of year or if an emergency affects a regular source of supply, water suppliers may use different sources of water to maintain supplies to an area, either separately or in combination by blending. While all the supplies will be wholesome and will meet the water quality standards set out in the Water Supply (Water Quality) Regulations 2000, the chemical composition of the water may vary.

2.12 One of the more common variations is in the hardness of the water, which is determined by the geology of the area from which the supply originates. By altering the source of the supply to an area, it is possible for the water to change from soft (for example total hardness of 50 mg/L as calcium carbonate ($CaCO_3$)) to hard (greater than 200 mg/L) or vice versa, causing users to notice differences with scaling in heating appliances, central heating and steam-raising plant, and with soap or detergent usage.

2.13 Water undertakers often access a variety of sources, which means that other possible changes may include temperature, taste or odour where the source changes between surface waters (such as rivers or reservoirs) and underground waters (such as borehole supplies). Differences may arise in dissolved iron, manganese or aluminium concentration and in the chlorine residual maintained in different supplies.

2.14 Healthcare organisations should liaise with their water supplier to find out whether it is likely that the quality of the water supplied may vary, either due to planned operational changes to the water sources used at different times of year, or in the event of an emergency that prevents the use of the regular source of supply (see HBN 00-07 – 'Planning for a resilient healthcare estate'). Where changes in the nature of supplies may be expected regularly, provision of water treatment facilities may be required within the healthcare facility to prevent complications occurring, such as scaling in central heating equipment, interference with sensitive medical equipment or adverse reaction from users.

2.15 Healthcare organisations should be aware of the type of disinfectant residual in the supply to their premises as it can have implications for choice of additional treatment. Under certain conditions, some water companies may also alternate the residual levels and type of disinfectant used (for example, chlorine and chloramine) between winter and summer.

Maintaining water supplies in an emergency

2.16 The Security and Emergency Measures (Water and Sewerage Undertakers) Direction 1998 is a statutory document produced under the provisions of Section 208 of the Water Industry Act 1991. Water suppliers have a duty arising from it to make and revise plans for the provision of essential water supply and wastewater services at all times. The Direction includes the duty for water suppliers to give priority to the domestic needs of the sick, older people, disabled people, hospitals, schools, and other vulnerable sectors of the population.

2.17 Healthcare organisations should cooperate with water suppliers in developing plans to maintain essential supplies of water in the event of major incidents. These plans might include (see also HBN 00-07 – 'Planning for a resilient healthcare estate'):

- The routine provision of public water supplies to the site from more than one water main, preferably using mains that are fed from different water supply

zones. Where mains are fed from different zones, particular care should be taken within the site to prevent direct interconnection and backflow between plumbing systems fed from the different supply zones.

Note: any arrangements designed-in should ensure there are no areas where water can stagnate (for example, dead-legs).

- Adequate storage cistern capacity and distribution arrangements within the healthcare facility to provide minimum volumes of water at the outset of a major incident to maintain hygiene and health for an initial period until other temporary arrangements can be introduced.
- The provision of facilities to connect to, and distribute water from, temporary storage cisterns such as pillow tanks at key locations within the site. Ground-level storage cisterns will require provision of booster pumps to either lift the water to existing storage cisterns or to distribute it directly through existing or temporary-site water mains.
- The provision of connection points to existing storage cisterns at suitable locations for delivery of emergency supplies of water, for example from tankers.
- Suitable distribution points for bottled water should be considered in the design process. This should work in conjunction with plans for the supply and distribution of bottled water for drinking to vulnerable patients and those unable to collect supplies from distribution points within the healthcare facility.

Private supplies

2.18 Private supplies independent of the water undertaker are governed by the Private Water Supplies Regulations 2009 and the Water Industry Act 1991. It is recommended that the Environment Agency (EA) and British Geological Survey (BGS) are consulted before considering a private water supply. In some situations, a licence may be required from the (EA) if more than 20 m^3/day is to be abstracted. Any borehole more than 15 m deep should also be registered with the BGS. If, for reasons of back-up or security of supply, there is a connection to the public supply (regardless of whether, or how often, it is used), the installations must comply with the Water Supply (Water Fittings) Regulations 1999. Private supplies should be registered with the local authority, which has the responsibility to maintain a register, risk-assess and monitor the wholesomeness of the supplies where these are used for domestic or food-production purposes.

2.19 The quality of water from a private supply is governed by the Private Water Supplies Regulations 2009. The standards are derived from the Drinking Water Directive and so are almost identical to those for public supplies. Reference should be made to the DWI's private water supply guidance.

2.20 The EA keeps records and maps of sources of private water supply together with details of the geological strata and water-bearing characteristics of the area under its control.

2.21 The feasibility of such a private supply should be decided by comparing the capital costs (of the construction of works, including mains, pumping plant, treatment plant etc) and revenue costs (of electricity for pumping, water treatment chemicals, direct and indirect maintenance and associated management costs, regular water analysis tests etc) with the long-term cost of water supply from the water undertaker over the predicted life-cycle of the installation. Due consideration should be given to the long-term costs of a private supply, and account should be taken of potential deterioration in water quality and/or capacity of the private supply source.

2.22 Where consideration is being given to the use of a private supply in a healthcare

environment, specialist assistance should be sought to:

a. confirm the integrity of the aquifer – that is, whether subject to surface water ingress/industrial effluent/radon/ nitrates/pesticides etc;
b. confirm the long-term quality of water and define requirements for water treatment;
c. design and specify the works needed;
d. carry out a full evaluation of the costs and practicability of a private supply compared to a connection from the water undertaker.

Other sources of supply

2.23 Greywater and rainwater should not be collected for use on, or in, healthcare premises.

Also see HTM 07-04 – 'Water management and water efficiency', which covers the use of greywater, rainwater and unwholesome borehole water.

3 Materials of construction

3.1 Any materials that come into contact with the water in a hot and cold water installation must comply with the requirements of the Water Supply (Water Fittings) Regulations 1999. To demonstrate compliance with these regulations, all non-metallic materials in contact with water should comply with the requirements of BS 6920. Currently no criteria exist to verify metallic materials. A number of lists exist for products and materials that have been assessed for compliance with the requirements and regulations (see paragraph 1.15). Further information on the selection of materials can be found in BS EN 805, BS EN 806-2, BS 8558 and BS 6920-1.

3.2 Materials of construction should be selected to take account of water quality and its potential corrosive properties. The water undertaker should be asked to provide details of any specific requirements and variability from standard conditions.

Note

Consideration needs to be given to substances that may be present in many rubber compounds, and are also occasionally associated with non-metallic materials such as plasticised (softened) plastics, which can provide nutrients for *Pseudomonas aeruginosa* growth. Most non-metallic materials meeting the full requirements of BS 6920-1 should not enhance microbial growth. Where oxidising chemicals are used, they may exacerbate leaching.

3.3 Water supplied by the water undertaker, although remaining wholesome, will nevertheless differ chemically. Some waters are slightly acidic while others are slightly alkaline, and this affects the choice of materials for pipes, fittings and cisterns. The water undertaker also blends water and, accordingly, the character of the water supply may vary from time to time. It will therefore be necessary to consult the water undertaker for advice on what materials should be avoided.

3.4 The choice of materials for piping and fittings should also take into account the nature of the soil in which the piping is to be laid. The materials selected should, where necessary, resist possible corrosion both inside and outside. The extent, if any, of anti-corrosion treatment of the outside of the piping will depend on the analysis of the soil. The advice of the water undertaker should be sought on the protective measures usually adopted in the area.

3.5 Corrosion (or erosion) can be caused by the motion of water when it is in a turbulent state and thus subject to rapid changes in pressure. At moments of low pressure, minute vapour or gas bubbles may be released which collapse with implosive force the moment the pressure is increased. The collapse of such bubbles on a metallic or concrete surface will quickly cause deep pitting or erosion of that surface. The design team should therefore avoid high velocities, the sudden increase of pressures or pulsating pressures.

3.6 Metallic piping should not be installed in contact with corrosive building products and materials.

3.7 Corrosion may result from galvanic action where dissimilar metals are connected. Dissimilar metals should therefore be avoided as far as practicable, but if that is not possible, it should be determined that deterioration through galvanic action is unlikely to occur, or effective measures should be taken to avoid deterioration.

3.8 The materials generally used for the conveyance of water in healthcare premises are copper, steel, stainless steel and plastics. Lead is no longer allowed under the Water Supply (Water Fittings) Regulations 1999 for pipework or solders. Lead-free solders only should be used (see also paragraphs 3.33 and 5.1–5.5).

3.9 Substances leached from materials of construction of pipes, cisterns or other water fittings in contact with water must not adversely affect the quality of water stored or drawn for domestic or food-production purposes (Water Supply (Water Fittings) Regulations 1999).

3.10 Direct gas-fired water heaters are particularly prone to corrosion and scale formation, and the inside of these heaters should be provided with suitable linings to limit these effects.

Steel pipes and fittings

3.11 Where steel is used for bolts, nuts and slip-on couplings, adequate protection from corrosion should be provided. This usually takes the form of bitumen coating, but bitumen is not permitted in contact with water required to be wholesome (that is, to be used for normal domestic or food-production purposes).

3.12 Unless adequately protected, steel is liable to corrosion both internally and externally, and therefore should not be used untreated. Steel piping is usually supplied zinc-galvanised, but depending on the character of the water to be conveyed, it may be necessary to use piping with an internal coating of either epoxy resin or polyurethane lining, which requires special application techniques (see the Water Industry Specification WIS 4-02-01 – 'Operational requirements: in situ resin lining of water mains').

3.13 External protection for piping may consist of bitumen or tar-wrapping with reinforcing layers of fibreglass or a plastic cladding.

3.14 Where screwed steel piping is used, any threads exposed after jointing should be painted or, in the case of underground piping, thickly coated with a bituminous compound or other suitable composition to prevent corrosion.

3.15 If the soil is corrosive, the pipes should be additionally protected by means of bitumen and fibreglass cloth wrappings.

3.16 Screwed steel piping is jointed with screwed socket joints, using fittings of wrought iron, steel or malleable cast-iron. A jointing compound or tape, which may be one of the many proprietary makes, should be used according to the manufacturer's instructions. Compounds containing red lead must not be used because of the danger of contamination of the water. Jointing compounds should not support microbial growth, should comply with BS 6920-1, and should have been assessed and shown to be appropriate (for example, suitable approvals) for the intended application (see paragraph 1.15). Care should be taken to remove any burr from the ends of pipes and to prevent the entry of excess jointing material. Steel piping may also be jointed with screwed flanges of steel or cast-iron or with mechanical couplings.

Stainless steel

3.17 Stainless steel is being increasingly used in hot and cold water service systems. Reference should be made to Chapter 3 of SHTM 04-01 Part E – 'Alternative materials and filtration' and also the British Stainless Steel Association's (2002) 'Operational guidelines and code of practice for stainless steel products in drinking water supply'.

Copper pipes and copper/copper alloy fittings

3.18 Copper in general is resistant to corrosion. Unless resistant to dezincification, brass fittings should not be used where water conveyed is capable of dissolving undue amounts of zinc from the fitting. External protection from corrosion for buried pipework may be obtained by using copper tube with a factory-applied polythene sheath. Dezincification-resistant material should be used for fittings that are concealed or inaccessible, for backflow prevention devices, and for temperature and pressure-relief devices on heating systems. Copper piping should conform to BS EN 1057 as appropriate for underground or above-ground installations.

3.19 Fittings should comply with the requirements of BS EN 1254-1–6. Copper piping may be jointed by means of compression joints or capillary joints or push-to-connect fittings made from copper or copper alloys. Effective capillary joints in copper pipes can be achieved if care is taken in their construction. For underground use, when using fully annealed copper piping, the fittings should be a manipulative joint.

3.20 Lead-free materials should be used in the formation of all wholesome water pipe capillary joints.

Solder and flux

3.21 When soldering copper tube and fittings, refer to WRAS Information and Guidance Note 9-04-02 – 'Solder and fluxes' (see also paragraph 3.33 on the prohibition of lead solder). If wax-based soldering flux is used, it should be used sparingly and be compliant with BS 6920. It poses a risk of bacterial contamination to the system, which can be difficult to eradicate.

Plastics

3.22 Most water systems operate at modest pressures and at a maximum temperature of 70°C. Such operating conditions are within the specified performance of plastics being produced in a range of sizes and costs suitable for healthcare premises. Most ranges of plastic pipework are not suitable for renal dialysis applications, where water at a temperature of 95°C is regularly circulated for sanitation and there is an incompatibility with reverse osmosis-treated water used in renal dialysis.

3.23 Advantages of plastic include corrosion resistance, lightness of weight, ease of handling and fully weldable systems.

3.24 Disadvantages include poorer mechanical strengths than metals, greater thermal expansion (about seven times that of copper), low temperature and shorter distances between pipe supports. The latter can be alleviated by employing the manufacturer's longitudinal tray that extends the distance between supports.

3.25 Materials in common use for plastic pipework are medium-density and high-density polyethylene, the latter being stronger. Unplasticised polyvinyl chloride (uPVC) pipework has mainly been replaced by the stronger chlorinated polyvinyl chloride (PVC-C). PVC pipes to BS 3505, BS EN 1452 (parts 1–5) and BS 3506 are of a rigid material that has a greater tensile strength than polyethylene, but is less resistant to fracture. These materials are less susceptible to frost damage than metal pipes. Although freezing is unlikely to damage the pipe, it will result in interruption of supply, and subsequent leakage from joints may occur.

3.26 Polyethylene pipes are generally not susceptible to corrosion from either the water or the ground in which they are laid. However, they are not recommended in any soils contaminated with organic materials likely to permeate the plastics and taint the water such as coal gas, methane, oils, petrol or other organic solvents. However, plastics pipes incorporating a protective barrier (barrier pipes) may be used if tested to Water Industry Specification WIS 4-32-19 – 'Polyethylene pressure pipe systems with an aluminium

barrier layer for potable water supply in contaminated land'. Further advice is available from the report by UK Water Industry Research (UKWIR) "Guidance for the selection of water supply pipes to be used in brownfield sites" https://www.ukwir.org/site/web/content/reports/reports.

3.27 It is essential to consider the locality of exposed plastic pipes to ensure that there is no likelihood of mechanical damage and effects of UV light; otherwise suitable protection around the pipe will be necessary. Plastic piping should be adequately supported and incorporate adequate means of accommodating expansion, bearing in mind that plastic pipes have a much greater coefficient of thermal expansion than metal pipes.

3.28 Methods of jointing employed include compression joints with insert liners, flanged, screwed and fusion-welded joints, as well as joints of the spigot and socket type. The method of jointing employed is dependent on the bore of the pipe and the applied internal pressure, and should be in accordance with the manufacturer's recommendations. A competent fitter who has been trained under an approved scheme should make joints.

3.29 Manufacturers tailor plastics used in pipes and fittings for specific applications and factors such as pressure, temperature and life-cycle analysis, which take into account specific water qualities inclusive of oxidation levels. Manufacturers' recommendations should be strictly followed when selecting appropriate pipes and fittings for a particular application. Assumptions should not be made that a pipe/fitting suitable for one application can be used in any application. For example, pressure requirements or the suitability for cold water use may not mean it has been designed and tested for hot water use; equally suitability for one high temperature application may not be suitable for another high temperature application. Incorrect selection may not be covered by the manufacturer's warranties and may result in shortened service life.

Multi-layer pipes

3.30 Multi-layer pipes are becoming more available and may consist of plastics or metal layers, for example aluminium pipe with an external and internal sheath of plastic. BS EN ISO 21003 should be used to demonstrate the performance of such pipes and fittings before considering their selection.

Iron pipes and fittings

3.31 Ductile iron is little used nowadays, but it may be encountered in the course of a refurbishment project or in areas of hostile soil conditions. Cast-iron has good resistance to corrosion, and this is further enhanced if the casting skin on the metal is still intact. Although ductile iron pipes are thinner than grey iron pipes, their resistance to corrosion is at least as good, and there is evidence that they tend to be more resistant. In assessing the life expectancy of ductile iron pipelines, account should be taken of any intended higher operating pressures that may be used or permitted.

3.32 In made ground containing ashes and clinker, or in certain natural soils such as aggressive waterlogged clays, and saline and peat marshes, additional external protection may be required. This may be provided by the use of protective coatings such as bitumen or coal-tar sheathing, by protective tapes, by loose polythene sleeving or, in certain circumstances, by concrete. Water undertakers are using more composite materials in pipework to overcome the risks.

Lead

3.33 The Water Supply (Water Fittings) Regulations 1999 prohibits the use of lead in wholesome and domestic water systems. No new lead piping or lead solder should be installed or used in any building. In the unlikely event of any lead pipework being discovered in existing healthcare premises, it should be removed as soon as practicable.

Concrete

3.34 Protection of concrete pipes may be required against sulphate and acid attack. The minimum size available in concrete pipework is 150 mm diameter, and therefore its practical use for healthcare premises is very limited.

3.35 Standard concrete pipes may be used when not subjected to internal pressure. Pre-stressed concrete pipes are available as pressure pipes, but only in larger sizes.

Asbestos cement pipes and fittings

3.36 Asbestos cement pipes generally withstand corrosion but may have to be protected when laid in soil of high sulphate content. If iron fittings are used, both internal and external protection should be applied.

3.37 Specialist advice should be taken if work on materials containing, or suspected of containing, asbestos is to be carried out. See also the EA's regulatory position statement 008 – 'Leaving decommissioned pipes in excavations'.

Flexible water supply hoses

3.38 Flexible hoses (also known as tails) have become a convenient method of connection between hard pipework and sanitary fittings and/or equipment. They typically comprise a steel-braided outer sheath with a synthetic lining.

3.39 There have been reports of high counts of *Pseudomonas* and *Legionella* in water samples taken from outlets fed by flexible lined hoses due to colonisation of the lining. Materials such as ethylene propylene diene monomer (EPDM) rubber may be susceptible to microbial colonisation. Careful selection of materials for their suitability for wholesome water systems is needed and they should be verified before being used.

3.40 New lining materials are now available such as polyethylene (PE), cross-linked polyethylene (PEX), linear low-density polyethylene (LLDPE) and post-chlorinated PVC (PVC-C) and should be compliant with BS 6920 (see paragraph 3.1).

3.41 Flexible hoses should be used only for the following applications:

- to allow for vibration of equipment;
- to accommodate vertical displacement of high and low baths and sinks;
- to facilitate essential maintenance and access of bespoke equipment when no alternative is available.

Note

Where fitted, flexible hoses should be kept as short as possible and be kink-free so as to not affect flow.

Cleanliness and hygiene

3.42 All pipes, fittings, valves, sub-assemblies, calorifiers, cisterns etc intended to form part of the hot and cold water service installation should be supplied to site cleaned, free from waterborne pathogens, particulate matter and other residues. All items should be identified as intended for water supply services.

3.43 Pipes should be capped at both ends and suitably wrapped in bundles. Pipe joint fittings should be suitably bagged or capped and boxed. Larger items of plant such as pumps, calorifiers etc should have connections blanked with plugs or flanges.

3.44 Where possible, leak-testing should be carried out using nitrogen or medical quality compressed air or oil-free dry compressed air. This must be carried out by competent personnel (see HSE's GS4 – 'Safety requirements for pressure testing'). Where water is used for test purposes, it should be supplied from a wholesome source. For pre-assembled items such as bathroom pods, all moisture should be removed before being delivered to site and be packaged in such a way as to prevent contamination from waterborne pathogens during transport and storage.

4 Water treatment and control programmes for hot and cold water systems

General

4.1 When control of the microbiological safety of water systems cannot be achieved throughout the system by maintaining temperatures, additional control strategies should be considered to reduce the risk of waterborne infection. Commonly used strategies include the use of filtration, pasteurisation or the use of biocides. Any biocide added to a water system should be dosed at the lowest concentration required to protect patient safety and ensure no undue exposure of individuals to harmful concentrations (refer to the COSHH Regulations 2002).

4.2 Some biocides require the system to be taken off-line before treatment; in these cases, users should take great care to ensure water cannot be drawn for bathing, food preparation or drinking until the treatment chemical has been completely flushed from the system. The WSG should ensure that measures are taken to protect vulnerable patients such as those in renal dialysis units.

Note

When building a new haemodialysis unit, a separate mains water supply should be considered so that other areas of the healthcare facility may be dosed without affecting the RO plants. If this cannot be achieved and biocides are required, appropriately monitored control systems need to be in place.

4.3 A biocidal product for this purpose is defined as one which controls harmful or unwanted organisms within water systems. The EU Biocides Regulation 528/2012 regulates the use of biocidal products that have been proven to be safe and effective for their intended uses. Within the EU, suppliers of active substances must be registered and as such there is a list of registered products and suppliers (Article 95 list). Within the UK the HSE is the designated authority for overseeing implementation of biocides.

4.4 The Drinking Water Directive, transposed into law in the Water Supply (Water Quality) Regulations 2000 (as amended) for public water supplies, and in the Private Water Supplies Regulations 2009 for private supplies, sets out additional separate requirements for products and substances that may affect water intended for human consumption. This ensures that treatment chemicals suitable for use in the preparation and distribution of drinking water have no adverse effects on the quality of water intended for human consumption. The DWI publishes a list of products approved for treatment of drinking water supplies.

4.5 The WSG should be satisfied that the design, specification and commissioning will enable the water treatment systems to achieve the required biocide concentrations throughout the system at all times to minimise microbial risk. The impact of treated water on the materials and components of the existing system should be taken into account along with advice from the necessary suppliers and installers. Within a healthcare facility, the detrimental effects of biocidal treatment, such as corrosion of metal components and deterioration of plastics and elastomers, should be taken into consideration as biocide use may

shorten the lifespan of particular components. Complete flushing of the system should be carried out and verified before being brought into use. Concentrations and stand times should be assessed and controlled.

4.6 Where treatment systems produce a discharge as part of the process, an appropriate air break to the drain must be installed such as a type AA air gap or an air-break-to-drain device in accordance with BS EN 1717 clause 9.

Biocidal treatment

Note

Any biocidal treatment system should not adversely affect the materials of construction.

4.7 In addition to maintaining a temperature control regimen, there may be occasions where additional biocidal treatment is required for the effective control of *Legionella* and other opportunistic waterborne pathogens. However, the selection of suitable treatment is complex and depends on a number of parameters, and the chosen biocide should be properly managed. This is particularly the case with cold water services compared with hot water services where, with the benefit of circulation, water is returned to the calorifier/water heater and is then pasteurised. However, it should be taken into consideration that effective concentrations of some biocides are difficult to achieve in hot water systems due to gassing off. For water intended for consumption, the biocide concentrations must not exceed prescribed concentrations for drinking water.

4.8 Where biocides are used to control microbial growth in water systems, as with the temperature regimen, meticulous control and monitoring programmes should be in place if they are to be effective. However, careful consideration should be given to any equipment that is connected to the water system that may be affected by the application of a biocide (for example, renal departments, haemodialysis units and neonatal units).

4.9 To meet legislative requirements, biocides used for water treatment must:

- contain an active substance approved for that use (subject to product-type) under the Biocidal Products Regulations (or be under review for the relevant product-type) and the biocidal product consisting of or containing that substance must be authorised for the product-type (subject to the transitional arrangements while the active substance review is ongoing);
- be suitable for drinking-water use.

4.10 The WSG should be actively involved in the decision-making process and should involve consultation with the water undertaker to ensure the suitability of biocidal products for their intended application.

4.11 There is no single water treatment regimen that is effective and appropriate in every case, and each system has both merits and limitations. The implementation of a biocide regimen together with maintaining temperature control requires constant vigilance to ensure the safety of particularly vulnerable patients in healthcare premises. For example, dedicated treatment and supply arrangements may be required for renal and haemodialysis units or for making up infant feeds where concentrations of biocides in the water would be harmful to patients.

4.12 Each water treatment system should be validated and monitored to demonstrate that the correct biocide concentration is being achieved for controlling microbial growth and does not exceed prescribed or guideline values under differing flow rates and water demands.

4.13 The frequency of biocide monitoring and verification, in addition to temperature monitoring, will depend on the treatment regimen selected. Each treatment system should have a failsafe mechanism to prevent overdosing while also ensuring that effective concentrations are maintained throughout

the system. When a water system is being purged and is initially dosed, checks should be made at various system outlets to ensure that satisfactory concentrations of treatment chemicals are being achieved throughout the system. Automatic leak detection of the biocidal treatment system is also recommended for hazardous substances.

4.14 The effective concentrations of biocides used to treat water systems in highly colonised systems or during commissioning of new installations in healthcare domestic water systems may initially need to exceed the safe concentrations for human consumption as stated in water legislation and may make the water unwholesome. The biocidal treatment systems used should be selected with care and must comply with the requirements of the Water Supply (Water Quality) Regulations 2000 and COSHH Regulations. Where there has been a requirement to provide biocides at concentrations above those permitted for drinking water approval, agreement should be sought from the WSG. In such circumstances the water system should be off-line and drinking-water outlets should be clearly labelled as unsuitable for ingestion (this includes the making up of neonatal feeds).

Note

When water treatment and control programmes are effectively maintained to control *Legionella*, there will be less likelihood of colonisation of other opportunistic microorganisms. However, in the case of *P. aeruginosa*, where the origin may be due to retrograde contamination from patients and/or staff, other local management control measures and monitoring will be necessary.

Chlorine dioxide

4.15 Chlorine dioxide is an oxidising biocide that is capable of reacting with a wide range of organic substances and has been shown to be effective in the control of organisms in water systems. The safe in situ generation of chlorine dioxide as a chemical for drinking water treatment is subject to BS EN 12671. Chlorine-dioxide-generating equipment should be selected to ensure product efficacy of greater than 90% to provide the optimum performance for the minimisation of total oxidants.

4.16 The use of chlorine dioxide as a control measure will depend on the design of the systems in use and, in an existing system, its operational history. See also HSG274 Part 2.

Copper/silver ionisation

4.17 Ionisation is the term given to the continuous release, by electrolytic action, of copper and silver ions into water.

4.18 The Water Supply (Water Quality) Regulations 2000 set a standard for copper of 2 mg/L, and this must not be exceeded.

Note

Currently the Drinking Water Directive does not include a prescribed concentration for silver, as there is insufficient toxicological data. The World Health Organization (WHO) (2011) states: “there is no adequate data with which to derive a health-based guideline value for silver in drinking water”. It continues: “special situations exist where silver may be used to maintain the bacteriological quality of drinking water [and] higher concentrations of up to 0.1 mg/L … could be tolerated in such cases without risk to health”.

4.19 Copper/silver ionisation requires soft water to prevent scaling of the electrodes, as maintaining adequate silver ion concentrations in hard water systems can be difficult because of scale build-up on the silver electrodes, potentially leading to the obstruction of copper and silver ion release. In addition, there have been cases of staining to sanitaryware in hard water areas. See also HSG274 Part 2.

Ozone and ultraviolet treatment

4.20 Whereas biocides dosed into the water are intended to be dispersive and will result in a biocide agent within the water system, ozone and ultraviolet (with appropriate pre-filtration) are intended to be effective close to the point of application. UV will only be active in waters of low turbidity and at the point where the water passes through the UV lamp housing. Ozone will only be effective very close to the point of application. Ozone and ultraviolet treatment will not ensure system control downstream in the hot and cold water service systems.

Note

Consideration needs to be given to the risk of bromate formation when using UV and ozone to further treat chlorinated mains water, which may contain bromide ions (see the DWI's research paper on the formation of bromate during drinking water disinfection).

Other water treatments

4.21 A range of biocidal treatment systems are available, and further advice on their use is given in HSG274 Part 2.

Point-of-use filtration

4.22 For pathogenic waterborne organisms including multi-drug-resistant strains, at a minimum, and in accordance with the organisation's water safety plan, a risk assessment should be made in order to determine whether sterilising-grade point-ofuse filters should be installed or whether taps need to be changed (see American Standard Test Method (ASTM) F838-05 – 'Determining bacteria retention of membrane filters utilised for liquid filtration').

4.23 During design and installation, it is necessary to ensure that:

- they comply with all appropriate regulations and meet EU legislation on the preparation of foodstuffs for infants and young children;
- tap outlets have appropriate fittings for attachment of filters;
- sufficient activity space between the filter outlet and the basin is provided so that an effective backflow prevention air gap (AUK3) is maintained, and hands can be comfortably washed without contaminating the body of the filter;
- there is sufficient flow once a filter has been fitted to enable effective hand-washing;
- the filters are changed at the intervals specified by the manufacturer.

4.24 In systems with high particulates, a prefilter may be necessary to prevent shortened lifespan due to filters clogging.

5 Metal contamination

5.1 If plumbing systems were installed before 1987 (in which lead pipes or lead-based solders are likely to have been used), it may be necessary to consult the water undertaker (see also paragraphs 3.8, 3.20 and 3.33).

5.2 The Water Supply (Water Quality) Regulations 2000 and the Private Water Supplies Regulations 2009 set an upper concentration for lead in drinking water of 10 µg/L. This value is likely to be exceeded if lead pipes are present or if copper pipes have been joined with solder containing lead. If drinking water contains more than 10 µg/L of lead, remedial action should be taken. The use of lead solder is prohibited on all plumbing installations where water is required to be wholesome.

5.3 Copper concentrations above 1 mg/L may cause staining of laundry and sanitaryware and increase the corrosion of galvanised iron and steel fittings. While the maximum allowable copper concentration in drinking water is 2 mg/L, most supplies will give a concentration at the tap of less than 1 mg/L.

5.4 Water supplies to certain specialist units such as maternity, neonatal paediatric, general paediatric and renal dialysis units (see the Renal Association guidelines) should be monitored to ensure that water quality is within acceptable limits. The design team should seek toxicological advice to ascertain the exact water quality requirements for specialist units.

5.5 Where the water supply is known to dissolve metals (for example, water with very low total dissolved solids), regular sampling to determine the condition of the system should be carried out. Strategic sampling points should be selected to ascertain that the level of metal contamination (for example, the dissolution of lead solder in capillary joints) in the water distribution does not result in limits above the stated safe levels.

5.6 Elevated concentrations of copper can occur in copper pipework systems with:

- naturally acidic (low TDS) water supplies;
- base-exchange softening;
- poor control of oxidising biocides;
- poor control of copper/silver ionisation;
- localised stagnation.

5.7 In some areas with known aggressive water issues, it is normal to specify corrosion-resistant pipework materials such as stainless steel or plastic. These materials may also need to be considered for demineralised, fully deionised and high purity water.

6 Water softening

6.1 Hard waters are unsuitable for many industrial and domestic purposes. Treatment may therefore be necessary to remove or alter the constituents to render the water suitable for particular purposes and increase the effectiveness of control measures.

6.2 Hardness is due to calcium and magnesium salts in the water and is expressed in terms of milligrams per litre as $CaCO_3$. Temporary (carbonate) hardness is related to the bicarbonate salts of calcium and magnesium. Permanent (non-carbonate) hardness is related to the other salts of calcium and magnesium – chlorides, sulphates, nitrates etc. The generally accepted classification of waters is shown in Table 1.

Table 1 Classification of water hardness

Description	Milligrams per litre (mg/L as $CaCO_3$)
Soft	0 to 50
Moderately soft	50 to 100
Slightly hard	100 to 150
Moderately hard	150 to 200
Hard	200 to 300
Very hard	Over 300

6.3 When the temperature of water is raised, the hardness will be reduced by some of the bicarbonate dissolved salts (temporary hardness) coming out of solution and forming solids in suspension, some of which will be deposited on heating surfaces to form an adherent limescale, thus reducing the heat-transfer rate. The tendency to form scale, and the morphology of that scale, is not just dependent on the hardness but also on the other chemical constituents of the water. For this reason scaling indexes such as Ryznar and Langelier combine various additional factors to assess the likelihood of scaling.

Note

Primary heating circuits that are filled/topped up by water supplied directly from the water mains should be treated with a chemical corrosion inhibitor. Specialist advice is given in BSRIA's BG50 –'Water treatment for closed systems'. In exceptionally hard water areas, additional measures may be required.

6.4 The extent of treatment required to prevent scale formation will depend on the process for which the water is being heated; it may therefore be necessary to achieve one of the following conditions:

a. replacement of calcium and magnesium salts by their more soluble sodium equivalents;

b. removal of all salts (demineralisation);

c. where water of enhanced purity is required for specialised uses, it can be produced from softened water by reverse osmosis or by demineralisation.

6.5 The most common water-softening process used for the protection of hot water calorifiers is base-exchange softening. This process removes permanent and temporary hardness from water. The technique uses an ion-exchange process in which the calcium and magnesium ions in solution are removed and replaced by sodium ions.

Note

All water softeners must be installed with an appropriate backflow prevention device in accordance with the Water Supply (Water Fittings) Regulations 1999. Where softeners discharge to a drain, they must have an appropriate air break to the drain installed such as a type AA or an air-break-to-drain device in accordance with BS EN 1717 clause 9.

6.6 Epidemiological studies have shown that the incidence of cardiovascular disease tends to be higher in areas with soft water supplies than in areas with hard water supplies. The association is clearest where the soft water supplies contain hardness below about 150 mg/L (as $CaCO_3$). The explanation is not known, but it is considered prudent, where possible, not to drink water that has been artificially softened to concentrations lower than this. Softened water may also tend to dissolve metals from pipes. Water softeners containing ion-exchange resins may be subject to bacterial contamination if not adequately maintained in accordance with the manufacturer's instructions (these may also require periodic disinfection). Softeners using salt-regenerated ion-exchange resins increase the sodium content of the water during softening, and this may be undesirable for young children and infants (including the making up of babies' bottles) and anyone on strict salt-restricted diets. These concerns can be avoided if water intended for drinking and cooking is not softened. See also paragraph 9.11.

6.7 Waters having a hardness of up to 400 mg/L have been used for public supplies without preliminary softening. While it is accepted that supplies for domestic purposes need not be softened, some water undertakers carry out partial softening.

6.8 The need for softened water in healthcare facilities for domestic purposes other than drinking and cooking should be considered on the merits of each case; if treatment is considered essential, the extent of softening should be the minimum to achieve an acceptable level. A generally acceptable range is between 80 and 150 mg/L, and not less than 60 mg/L, but this should not be taken as a requirement for healthcare facilities as it may be impracticable to achieve. The cost and difficulties of treatment may be prohibitive for certain waters if the hardness value is particularly high and the content of magnesium is appreciable.

6.9 Scale deposition is a significant problem in pipework, reducing flow, efficiency and increasing the surface area for biofilm formation. In hard water areas, softening may well be needed to reduce risk. Generally, within healthcare premises, softening of a hard water supply may be required on feeds to the following:

a. steam boilers – to prevent sludge and limescale building up (see BS 2486);
b. hot water services where outlets (particularly showers) are affected by limescale;
c. laundries – high maintenance costs and the uneconomic uses of soap or detergents are caused by the presence of hardness.

6.10 Other water-softening methods include physical water conditioning and magnetic water conditioning.

7 Filtration

7.1 Water delivered to premises may have been derived from various river and groundwater sources, the quality of which can be different, thus requiring a number of treatment processes. Filtration to an appropriate standard will normally have been carried out by the water undertaker or private water supply operator. Some treatment works use additional methods to remove minute and fine suspended particles from water. These include microfiltration, ozone, carbon and ion-exchange systems.

7.2 In exceptional circumstances or where a private water supply is used on site, additional on-site filtration may be required as part of a multi-barrier point-of-entry treatment system. Advice should be sought from the appropriate undertaker on the need and form of such treatment. For a list of approved products for private water supplies, visit the DWI's website.

Note

POU filtration is covered elsewhere in this publication.

8 Water storage

Note

Refer also to HSG274 Part 2.

8.1 Water is stored in healthcare premises for the following reasons:

a. to provide backflow protection;
b. to provide a reserve supply during disruption of the incoming cold water supply (this encompasses water quality as well as water quantity issues);
c. to reduce the maximum demand on the cold water supply;
d. to reduce the pressure from that of the distribution system.

Note

Separate arrangements are required to provide accommodation for the expansion of any water subjected to heat, that is, hot water and heating services.

8.2 The purpose for which the storage is used can vary, but has only a minor effect on its design. The following generally covers a typical range of uses:

a. cold water services, domestic, laundry etc;
b. cold water feed to hot water services;
c. pathology;
d. endoscopy units;
e. dental premises;
f. treated cold water for laundries, heating etc when local supplies are unsuitable;
g. break-tanks on cold water supplies serving points of use where backflow is, or is likely to be, harmful to health due to a substance representing a serious hazard (for example, supplies to pathology laboratories (see paragraphs 12.18–12.24 on the prevention of contamination));
h. fire-fighting.

Note

Feed and expansion cisterns for heating services, chilled water etc are excluded.

8.3 All water storage for domestic purposes should meet drinking-water quality requirements.

Note

Separate drinking water systems are not recommended for new buildings.

Water supplies

8.4 Where there is private supply in addition to the water undertaker's, it needs to be introduced separately into the healthcare facility's water storage system. See paragraphs 2.3–2.4 (connection arrangements and notification requirements) and 12.18–12.24 (backflow prevention requirements) for compliance with the Water Supply (Water Fittings) Regulations 1999.

Note

It is best practice to include the operation of valves in a regular maintenance and operation schedule to ensure they do not become seized. The flushing of the supply could be integrated into this programme to aid the prevention of stagnation of water at dead-ends. Additionally, advice from the water undertaker on an appropriate time period to undertake flushing cycles on supplies should be sought.

Extent of storage

8.5 Storage should be designed to minimise residence time in the cistern and maximise turnover of water to avoid stagnation and deterioration of water quality. Storage volume should be calculated on the basis of peak demand and the rate of make-up from source of supply. There may be more than one peak period during each day. The interval between peak periods is important as it affects the storage capacity based on the make-up flow. It also determines the available time for maintenance if twin cisterns are not installed. Unless the water supply is particularly vulnerable to disruption and subject to risk assessment (balancing the microbiological risk and contingency supplies), a nominal 12 hours' on-site storage is recommended. Reference should also be made to paragraphs 5.18–5.34 in HBN 00-07 – 'Planning for a resilient healthcare estate', which provides guidance on continuous water supplies and bulk storage.

8.6 There is currently no reliable guidance on the capacity of water storage. Design teams should therefore liaise with the commissioning trust to ascertain their recent records the quantity of water used over the previous five years. There is evidence that the historical values given for district general teaching hospitals that amounted to 900 L per day per bed are in excess of actual usage. If the proposed healthcare building development includes significant changes in function that introduce greater specialisms and more intensive treatment programmes, then the design team is advised to seek guidance from other healthcare organisations that are responsible for buildings of a similar nature.

Note

Useful data may be derived from the following:

- Water figures per unit of healthcare activity are published by the NHS Sustainable Development Unit. See Appendix 1.
- The Estates Returns Information Collection (ERIC) collects data from all NHS trusts on the consumption and associated costs of water.

8.7 The design team should ensure that the local water supplier is involved in proposals for planning the water storage values. CIBSE's Guide G – 'Public health engineering' gives further guidance on sizing cold water storage.

8.8 A summation of the average daily consumption for each ward unit contained in a building should be made. From the requirements of each building, the policy of water storage for the whole complex should be decided. It does not always follow that peak demands for each building will coincide, and therefore there may be scope for applying a diversity factor to the whole site.

8.9 Where the water requirement is to be met from a private supply, the summation for each building may require assessment on the basis of storing and using water according to the minimum treatment of the water for each particular use. Likewise, where the water is hard enough to require softening for certain domestic and/or laundry purposes, separate storage will be required, and this should be taken into account when assessing the total stored water.

8.10 Staff quarters and industrial areas may be remote from the main building and supporting departments. The laundry may serve a number of healthcare buildings as well as the premises

at which it is located. The storage requirement for such accommodation should therefore be calculated separately and integrated with the accommodation whenever this is practical.

8.11 Where new healthcare premises are to be built in separate phases, the water storage, supply and distribution service for the whole premises should, as far as possible, be planned and evaluated at the design stage. This will enable the total water supply requirement to be assessed in the planning stages, and appropriate areas of accommodation (but not tank storage) to be allocated. It is important that, where it is anticipated that a building will be occupied in phases, the storage levels can be raised as required. Commissioning should be carried out also as a planned process related to occupation following a risk assessment (see BS 8550). The design should facilitate compartmentalisation.

Location and form of storage

8.12 The location of storage will depend on the total volume required, the topography and layout of the site proposed for development, and the sources and adequacy of the water supply. A limited site footprint may call for much higher buildings to achieve the required accommodation. Depending on the supply water pressure, it may be necessary to install pressurisation equipment to boost the incoming supply. The cost of the supporting structure will have an important bearing on the solution adopted.

8.13 Where storage is located in individual buildings and an adequate supply is available from the water undertaker, a connection in accordance with the Water Supply (Water Fittings) Regulations 1999 to each point of storage may be the most economical arrangement. In such cases, interconnections between selected points of storage should be provided to deal with emergency and maintenance requirements, always providing that such interconnections do not contravene the Water Supply (Water Fittings) Regulations 1999 and do not result in water stagnating within the storage or distribution system.

8.14 Cisterns should not be located where there is any likelihood of flooding, excessive heat gain or any other factor that could affect the contents of the cisterns. They should not be installed in any location where access for general inspection or maintenance is restricted. Where refurbishment is undertaken, an assessment is carried out to ensure no adverse impacts occur on the temperature and quality of the water stored. As part of this assessment, climate change mitigation measures should be considered.

8.15 Separate systems are required to segregate domestic services (WC, hand-washing etc) from high-risk applications and equipment within such facilities as laboratory, pathology and mortuary departments.

8.16 An assessment of atmospheric and environmental (including feral wildlife such as birds etc) risks should be undertaken to ensure they do not affect the temperature or quality of stored water. If concrete water cisterns are to be considered, they should be designed to form an integral part of the building structure. The materials of construction, however, must comply with the Water Supply (Water Fittings) Regulations 1999.

8.17 As in the case of external storage, cisterns should be installed in positions where they can be readily inspected and maintained and where they will not be affected by frost or high temperatures.

8.18 To determine access requirements to cisterns, it is essential that a suitable and sufficiently comprehensive assessment of the risks for all work associated with cisterns is carried out to determine what measures and parameters are required under Regulation 3 of the Management of Health and Safety at Work Regulations 1999. For work in confined spaces this means identifying the hazards present, assessing the risks and determining what precautions to take.

8.19 Roof spaces in which cisterns are to be installed should have adequate trap doors or

other means of access and adequate lighting to facilitate inspection and maintenance.

8.20 Where storage is in ground, as distinct from being housed within a building, it is essential to ensure that there is no risk of contamination. Investigations of such risk require careful consideration of site conditions and should include such aspects as:

- flooding;
- subsidence;
- the location of sewers and drains and other buried services;
- the maximum and minimum height of the water table in the area;
- the natural drainage of surface water;
- ingress of contaminants such as dust, debris etc; and
- in the event of storage below a car-parking area or roads, the danger of oil/fuel seepage.

The future development of the healthcare building and probable extensions should also be taken into account in this respect. Accessibility should be limited to those who need access (see also NHS Protect's (2012) 'Guidance on the security and management of NHS assets').

8.21 Storage below ground should be adopted only as a last resort, and cisterns should be installed within a watertight bund allowing sufficient space all around and beneath the storage vessel to permit inspection and maintenance. Any underground construction arrangement, concrete or otherwise, not directly against earth will reduce the risk of contamination. The tank chamber should include provision for a sump to collect drainage water and any piping necessary to pump out tanks to the site drainage. The Water Supply (Water Fittings) Regulations 1999 require any buried concrete reservoir to be designed, constructed and tested in accordance with BS EN 1992-3.

Note

Refer also to the HSE's guidance on confined spaces.

Construction of cisterns

8.22 All storage cisterns:

- should be constructed in accordance with manufacturers' recommendations and should comply with the Water Supply (Water Fittings) Regulations 1999;
- should have been assessed and shown they are appropriate (for example, suitable approvals) for the intended purpose (see also paragraph 1.15); and
- should comply with BS EN 805, BS EN 806 (Part 1 to 5) and BS 8558. Glass-reinforced plastic (GRP) cisterns should comply with BS EN 13280.

8.23 The WRAS Information and Guidance Note 9-04-04 – 'Cold water storage systems – design recommendation for mains supply inlets' provides useful advice regarding the design of the inlet arrangements to ensure compliance with the Water Supply (Water Fittings) Regulations 1999. Of particular importance is the need to ensure cistern roof supports are of a type that do not retain water within the support, cause pockets of stagnation, or prevent the free flow of water throughout the cistern, as these have been shown to cause degradation of the stored water quality (see also Estates and Facilities Alert EFA/2013/004 – 'Cold water storage tanks'). Any other internal structures should be designed so as not to retain water, cause pockets of stagnation, or prevent the free flow of water throughout the cistern.

8.24 Depending on size and/or capacity, water storage should be divided into convenient compartments suitably interconnected and valved to facilitate cleaning, disinfection, repair, modification and inspection, without seriously disturbing the cold water service. Cistern strengthening should be by means of

stainless steel tie bars and not baffle plates. Where multiple cisterns are provided, they should be connected in such a way that there is equal flow to prevent stagnation. Pipework connections should also be arranged to ensure cross-flow across the cistern. A water meter should be considered at each inlet pipe to verify equal volumes are being used.

8.25 Separate cisterns should also be provided for storage of different water supplies, for example central-heating header cisterns, cold water storage, softened water, fire-fighting water, and high-risk areas (for example, laboratories, pathology and mortuary). Precautions should be taken to ensure that mixing does not take place between such supplies, and it should be noted that isolation by means of shut-off valves between them is not acceptable.

8.26 The materials used for storage cisterns serving healthcare should be appropriate for the intended use. The material selected should comply fully with the Water Supply (Water Fittings) Regulations 1999 (see paragraph 1.15). Pre-insulated sections are recommended where practicable.

8.27 Sectional cisterns fabricated from GRP or pressed steel provide a convenient means of bulk storage of water at atmospheric pressure. The components can be readily transported to site and, subject to unit multiples, they can be erected to give varying proportions of length to breadth and depth. It is also possible to make provision for future extension in capacity by an increase in available base area or, within limits, depth. If sectional cisterns are selected, designs with external assembly flanges and self-draining profiles should be used, since this arrangement facilitates easy cleaning of internal surfaces of the cisterns.

8.28 The Water Supply (Water Fittings) Regulations 1999 laid down the minimum requirements for wholesome water storage cisterns. Recommendations to comply with these are given in the WRAS 'Water Regulations Guide'. The requirements are indicated in Figure 2.

Note

Cisterns should be sited away from heat sources and be protected from heat gains by insulation. Adequate and safe access should be provided for inspection and maintenance (both internally and externally).

8.29 Each storage cistern or its compartment should also be provided with the following:

a. internal and external access ladders as necessary to comply with current health and safety requirements;

b. a full-way servicing valve at each inlet and outlet connection, except for cisterns providing water to primary circuits or heating circuits, overflow pipes, and warning pipes. Where practicable, all outlets should be taken from the base of the system and be sited opposite to the inlet;

c. a suitably-sized drain connection complete with isolating valve. The invert of the drain connection should be positioned so as to provide maximum drainage of the cistern.

8.30 Cisterns in roof spaces should be adequately supported on bearers placed under the longitudinal or lateral cistern section joints. To avoid distortion, a flat section of marine ply or equivalent should be sited between the support structure and the cistern. Final siting should be in accordance with the manufacturers' recommendations. See also the Note after paragraph 8.28.

8.31 The design may incorporate a watertight drip tray under the cistern to contain condensed water or leakage so as to avoid damage to accommodation below. The necessity of a drip tray or watertight bund with drainage will depend on individual case requirements. The floor of the drip tray or bund should be graded to a drainage sump complete with drain pipe. A single pipe should drain off any overflow water from the sump and lead to a discharge point at ground level where any water flow would be readily noticed.

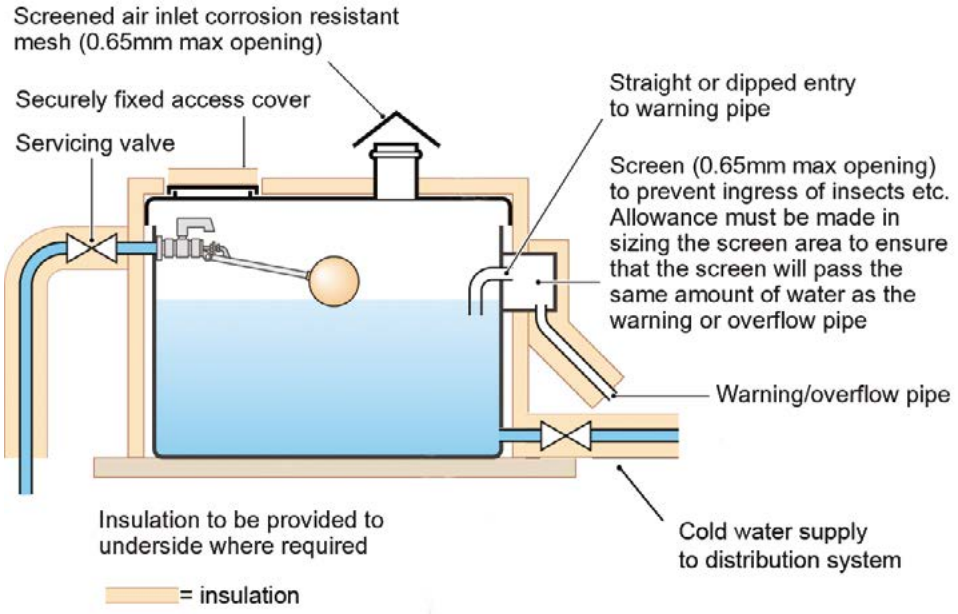

Figure 2 General wholesome water storage cistern arrangements

If it is not possible to terminate the discharge pipe from the sump so that any discharge of water can be seen, an audible alarm should be installed to warn of overflow conditions. Cistern support levels should be constructed to keep the valves clear of the water level in the drip tray or bund in the event of cistern leakage. Special requirements apply to the supporting of GRP sectional cisterns on bearers, and manufacturers' recommendations should be observed. The cistern should be provided with a warning pipe or a no less effective device to indicate leakage through the inlet control valve if this should occur.

8.32 On no account should a sectional cistern be installed on a concrete plinth (directly or on steel beams) that is protected by an asphalt membrane. Subsequent irregular settlement into the asphalt may lead to cistern distortion and leakage.

8.33 A consideration in deciding cistern shape and layout is the location of the services duct. Whereas the cistern room may be positioned aesthetically in relation to the building elevation, the duct serving it will be located to suit the internal layout. The pipe route from the system to the service duct will require access for inspection and protection from frost and heat gain.

8.34 Typical piping and valve arrangements for dual-cistern installations are shown in Figure 3. Supply and draw-off connections should be arranged to facilitate good through-flow and turnover of stored water without stagnation. Advice on interconnection is given in the WRAS leaflet "Interlinked cold water storage cisterns".

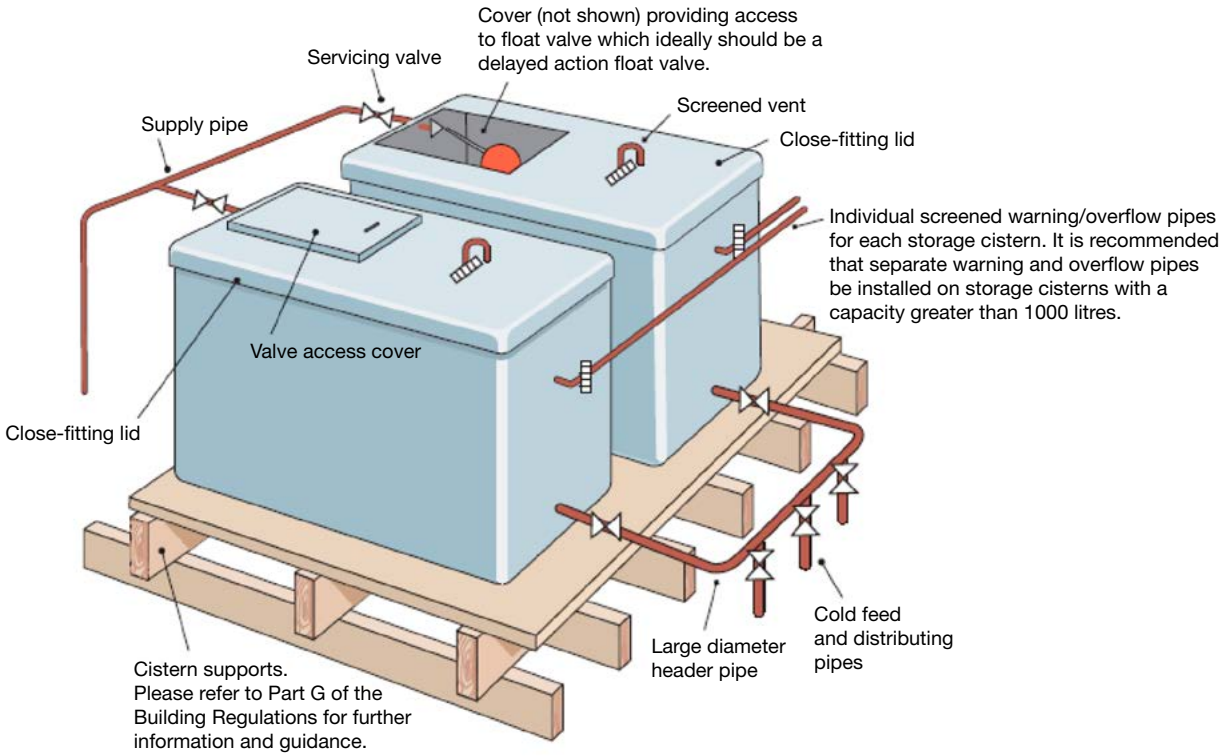
8.35 General space lighting should be provided in cistern rooms together with suitable power points for low voltage small tools and inspection lamps.

8.36 The contents and capacity of all cisterns should be clearly labelled as per the Water Supply (Water Fittings) Regulations 1999. The operational water level should be indicated.

Ancillary pipework, valves and fittings

8.37 The arrangement of the cisterns in the room should be such that the pipework runs are as short as possible, but accessibility and walkway clearances are ensured. Flanges on parallel runs should be staggered.

8.38 All cistern-room pipework and valves should be insulated and clearly labelled to identify their purpose.



Reproduced by kind permission of WRAS.

Figure 3 Piping and valve arrangements for dual-cistern installations

8.39 The use of delayed-action float-operated valves on water storage cisterns should be considered, since these help avoid stagnation of water in the cistern. They may not be suitable when the supply is pumped.

8.40 Strainers should be fitted within the water pipework system if not supplied integral to the valves, and are used to protect vulnerable valves and fittings against ingress of particulate matter. The installation of these fittings should allow adequate access for maintenance/ replacement, and they should be provided with means of upstream and downstream isolation as appropriate. Strainers can be a source of *Legionella* bacteria and should be included in routine cleaning, maintenance and disinfection procedures (see Chapter 7, Part B).

8.41 Service isolation valves should be fitted to all pipework preceding sanitary tapware, WCs etc for servicing, repair or replacement. Drain-valve provision may also be appropriate for certain installations, for example, service pipework to en-suite facilities. Suitable backflow prevention devices or arrangements should be provided appropriate to the fluid risk category (see the Water Supply (Water Fittings) Regulations 1999).

Expansion vessels

Further advice can be found on the WRAS website.

8.42 Expansion vessels (see Figure 4) are typically vertical in orientation and have a bladder or diaphragm either with nitrogen or with air fill in the upper space. They introduce a potential problem of microbial colonisation, including *Legionella*, as plantroom temperatures usually exceed that of the incoming water.

8.43 Such vessels should be appropriately sized, installed and operated in a manner that prevents the accumulation of debris, pockets of stagnating water and increases in temperature

within the vessels. They should preferably be of a design in which water passes through the vessel entering at low level and exiting at high level. (For smaller vessels it may be appropriate to utilise specialist valves which promote the flow of water within the vessels or allow sufficient pressure movement so that water is changed over during normal operation.) When larger vessels are installed, adequate flushing and drain-down connections should be provided at the top and bottom of flow-through vessels or at the bottom only of diaphragm or bladder types.

8.44 All materials in contact with water should have been assessed and shown they are appropriate (for example, suitable approvals) for the intended purpose (see paragraph 1.15). It is important that the expansion vessel is located on the cold feed rather than on the hot water side of the system.

8.45 Interconnecting pipework should be kept to a minimum, and the vessel should be sited and insulated to minimise heat gain. Where diaphragm or bladder-type vessels are used, they should be designed to ensure an adequate turnover of water within the vessel.

Note

Vessels where the diaphragm or bladder is designed to be replaceable may be considered as they will facilitate routine checking and/or replacement when contaminated.

Water meters

8.46 BS EN 806-2 Section 11 gives guidance on the design and installation of water meters.

8.47 Revenue meters are normally supplied and installed by the water undertaker to their specification, whereas the consumer may install sub-meters within their system.

8.48 Adequate sub-metering of water supplies should be provided so that supplies can be monitored for individual heavy-use departments. Such monitoring will assist in the detection of leaks or abnormal water demands. Water meters can be connected to an automatic monitoring system such as a BMS, which can identify anomalous consumption and lead to the early detection of leaks.

There are several types of vessel available including diaphragm or bladder type, with fixed and interchangeable (replaceable) bladders, as shown below. These internal bladders are often made of synthetic rubber such as EPDM and may support the growth of microorganisms including *Legionella*, so check to see if these are approved against BS 6920. Vessels with a 'flow through' design should provide less opportunity for water to stagnate and become contaminated (as in the latter design).

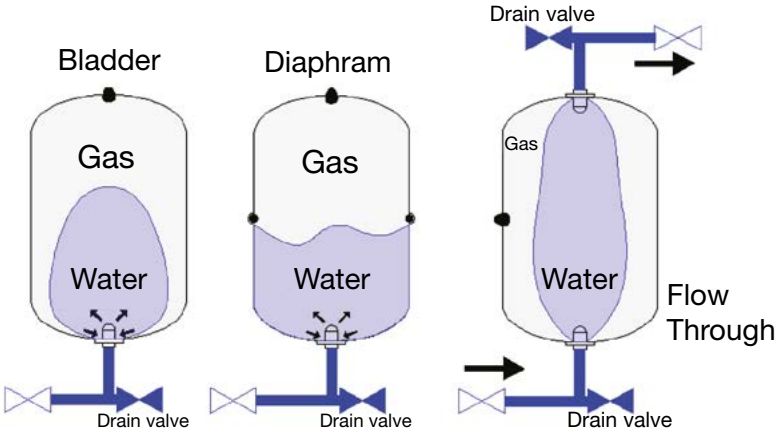


Figure 4 Expansion vessels

8.49 Only where downstream applications are considered critical and in need of a continuous supply of water should bypass arrangements be considered for consumer sub-meters. Where this is the case, sub-meters should have an upstream and downstream isolation valve. In case of servicing or replacement of the water meter, a replacement pipework insert should be stored in clean sterile conditions adjacent to the meter.

8.50 Meters should also be considered on the cold supplies to cisterns and hot water storage vessels where multiple units are installed supplying the same system. This will allow equal usage and turnover to be verified.

9 Cold water distribution system

9.1 The design and installation of the cold water distribution system should comply with the Water Supply (Water Fittings) Regulations 1999 and relevant parts of BS EN 806-2 and BS 8558. A simple cold (and hot) water system is shown in Figure 5.

Note:

All pipework should be insulated. All drains should discharge to waste via an appropriate air break to the drain such as a type AA air gap or an air-break-to-drain device in accordance with BS EN 1717 clause 9.

9.2 Cold water pipework runs should be designed and installed to reduce the risk of heat gain and should not be above or near heat sources including ceiling-mounted radiant heating panels. Cold water service mains should be run within a different ceiling space, riser or zone from other heat sources. This includes the hot water service distribution system and steam supply. If not possible, the cold water service and hot water services should be run apart as far as practicable and preferably with the hot water at a higher level than the cold.

9.3 All pipework and valves should be insulated, except for any exposed final connections to sanitary appliances. Insulation should be of an optimum performance (relating to thermal values and thickness) to minimise heat gains in order to achieve the temperature regime. The installation of insulated pipe supports and a vapour seal is recommended for all areas susceptible to heat gain and/or condensation. All insulation should be installed in accordance with BS 5970. All pipework should be arranged to eliminate or minimise dead-legs. Additional guidance can be found in BS 8558 Tables 6 and 7.

9.4 Currently there is no upper limit standard for drinking water temperature in European or domestic legislation. In normal circumstances temperatures should be delivered below 20°C but there is growing evidence that supply temperatures may rise above 25°C in summer months. Coupled with improvements in building thermal performance and climate change, rising cold water supply temperature is likely to become more problematical. The design aim should be to ensure that cold water temperature draw-off is as close to the supply temperature as possible (see also paragraphs 2.55–2.56 from HSG274 Part 2).

9.5 Government guidance to the Water Supply (Water Fittings) Regulations recommends that as far as is reasonably practical cold water temperatures should not exceed 20°C. As far as possible, the objective should be to design the cold water systems to ensure that the inlet, outlet and surface water temperatures of cisterns and cold water feed/header tanks for the hot water calorifiers are not greater than 2°C above that measured of the incoming water supply at the property boundary. Also, at cold water draw-off points, a temperature of no greater than 2°C above the temperature measured in cistern and cold water header tanks should be reached within two minutes (see also paragraph 11.1).

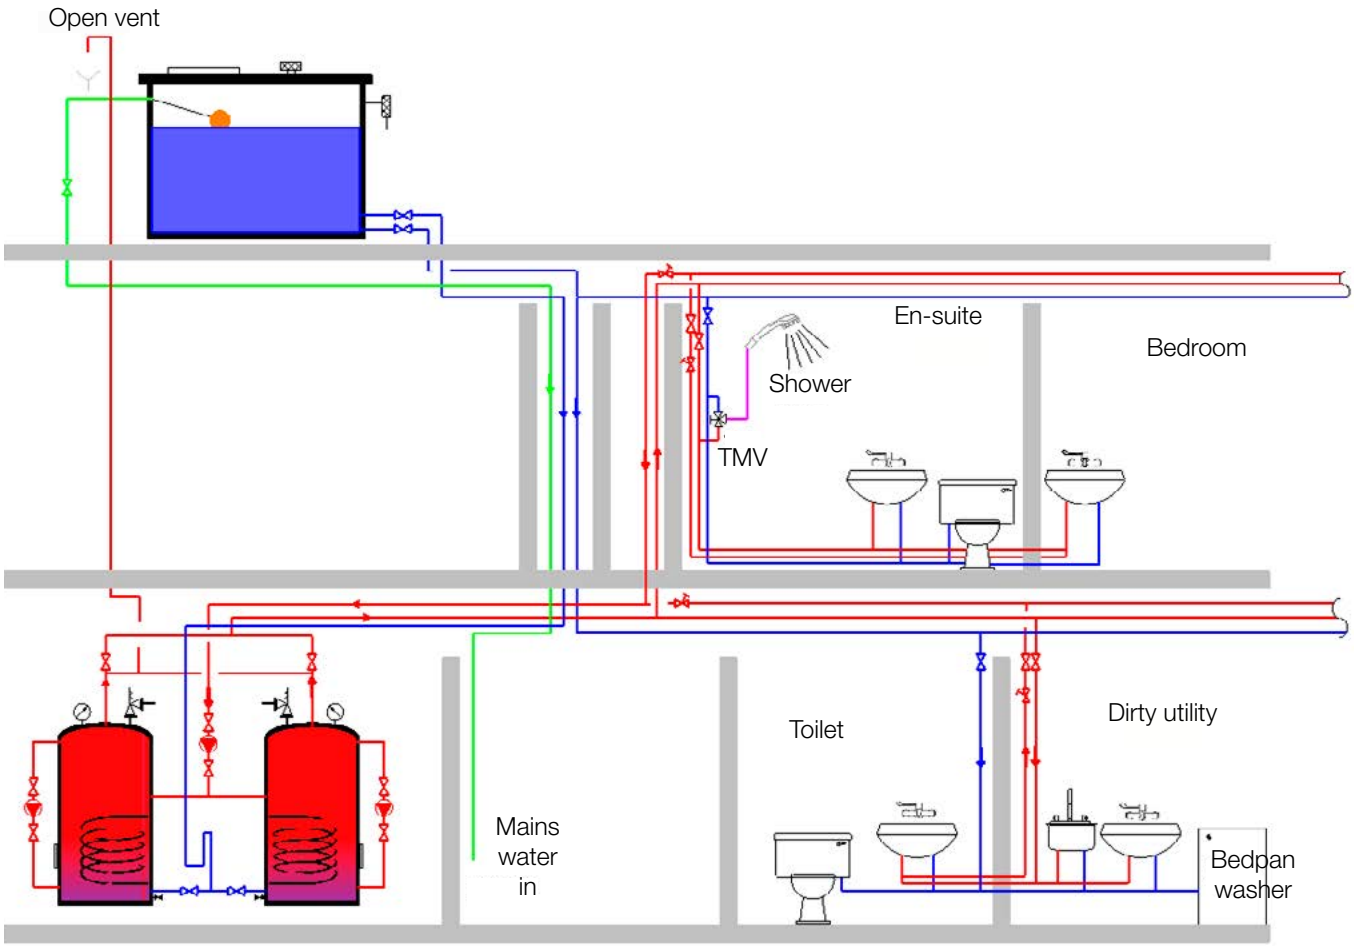

Figure 5 Schematic layout of a cold (and hot) water service system (note: this is a schematic only, and therefore all isolation valves and specific pipework configuration recommendations may not be included)

Note

For the control of *Legionella* and other waterborne organisms, 20°C is the quoted upper value above which multiplication of *Legionella* in particular begins to take place (see Part B, Chapter 4). It should be noted that during extremes of weather, environmental factors can influence the incoming water temperatures, particularly where water is provided from surface water sources.

9.6 Historical data should be sought on incoming cold water temperatures, especially during the summer and autumn, to allow these factors to be built into the design of the cold water system. If temperatures exceed 20°C, then further control measures should be implemented based on the risk assessment.

9.7 The control of water temperature in the cold water service, however, will essentially rely on good insulation and water turnover. Cold water services should be sized to provide sufficient flow at draw-off points and prevent stagnation.

9.8 Further cooling of cold water should only be considered in specialist units where people are at particular risk as a result of immunological deficiency, for example bone marrow transplant units. For other accommodation, the aim should be to promote turnover of cold water by means of the design of the distribution circuitry.

Note

Cooling water that may have been previously at a temperature conducive to *Legionella* growth will not reduce the risk of infection.

9.9 In all areas (particularly those with en-suite facilities), the aim should be to supply sanitary assemblies in series, with the WC connected as the final element to promote regular throughput of cold water. Elsewhere, pipeline routings should be run so that other outlets are connected in such a way that a WC or flushing device (for example, sluice hopper or pantry sink) provides the final element at the distal end of the branch – this may require pipe routing reversal (see Figure 6).

9.10 The cold water distribution system should be designed so that the pressure is the same as that for the hot water service at draw-off points. This may require the inclusion of pressure-reducing valves in the distribution pipework. If unequal pressures exist in the hot and cold water supplies to combination taps where water mixes in the body of the tap, a single check valve is required on each feed pipe to the tap to prevent backflow of water from one to the other.

Note

See also paragraph 10.53 on the fitting of in-line strainers.

Drinking water

9.11 When separate drinking-water systems have been provided, the policy has normally been to distribute directly from the mains without storage (nor softening), with stored cold water (down service) being used solely for supplies to WCs, wash-hand basins etc. Providing drinking water without storage may not be appropriate in healthcare premises because of the need to have some security of supply. The advantage of separate drinking and cold water services chiefly lies in the possibility of treating the latter (softening or other forms of treatment) without adulterating the drinking, cooking and food preparation supplies. The WSG should define a strategy either for separate supplies or for restricting the extent of softening (see also Chapter 6 on water softening).

9.12 Low water flow is often experienced in dedicated drinking water systems leading to stagnation, and the likelihood of temperatures exceeding 20°C. The preferred option may be to decommission dedicated drinking water systems totally. A risk assessment should show the optimum solution for patient safety.

9.13 A possible strategy, therefore, is to have a drinking water system that also provides WC flushing and, to some extent, this will assist water turnover and the maintenance of water quality. The disadvantage of the concept, apart from installation cost, is that the use of WCs, particularly in en-suite facilities, as the mechanism for achieving good utilisation in the cold water service no longer becomes possible (see paragraph 9.9). The concept for water turnover in en-suite facilities could still be achieved, however, if the cold water service were run in series to en-suite facilities with minimum dead-legs to draw-offs, with the final connection on the system being a highly utilised outlet, for example a sink. Automatic flushing WCs should be considered to assist with maintaining water turnover in cold water systems.

Note

Sensor-activated delivery devices that have a duty cycle feature to prevent stagnation should be considered. This feature should be activated only where required. Note that automatic flushing devices should not be located in accommodation used by patients who may become distressed by the noise.

Pumped systems

9.14 Where the pressure of the water undertaker's supply is inadequate, it will be necessary to use pressurisation plant. Similarly, pumping or pressurisation may be required for fire-fighting purposes.

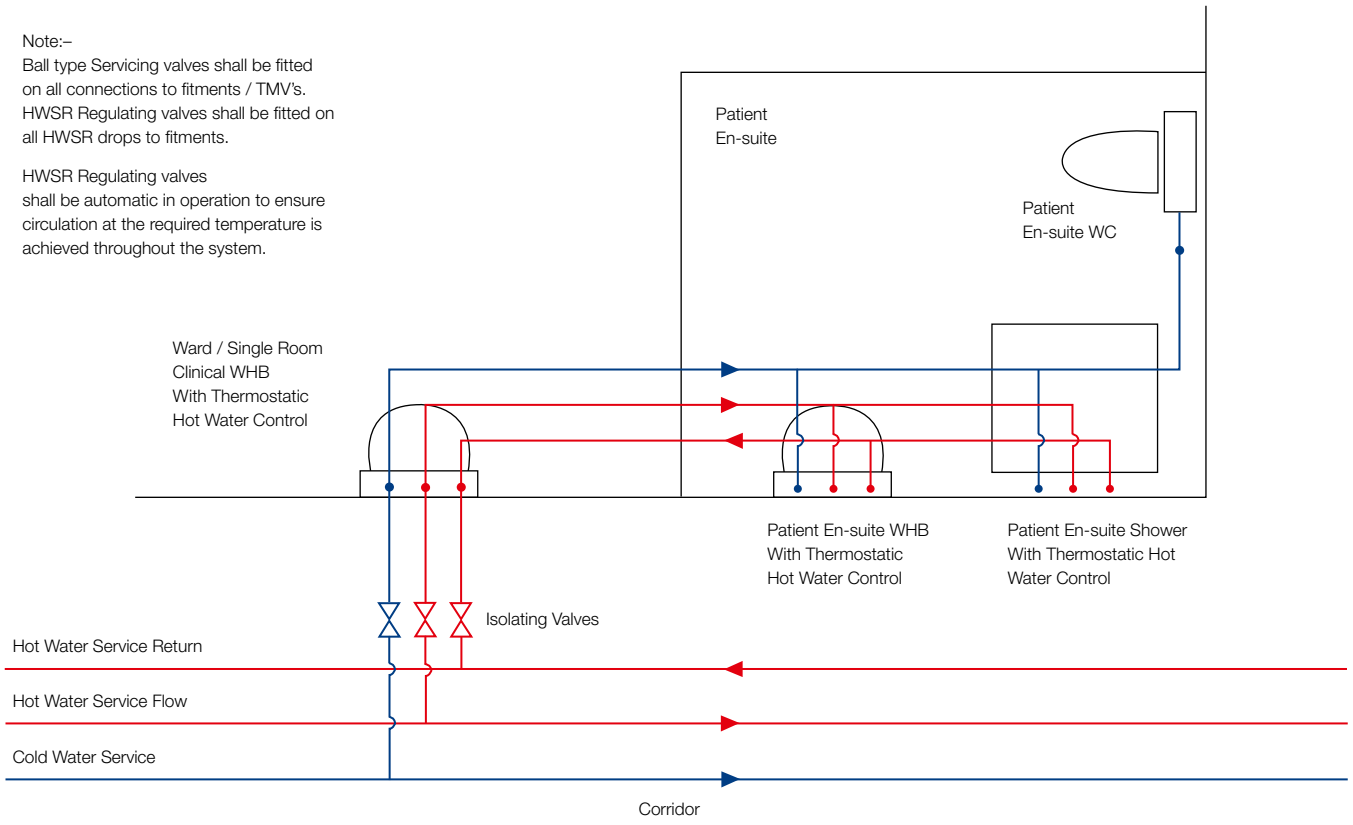

Figure 6 Piping arrangements for an en-suite facility

9.15 Various arrangements of pumping system are indicated in BS EN 806-1 Part 5 and BS 8558. Where booster pumps are to be installed, a break cistern will be required between the mains supply pipe and the pumps. This is required to comply with the Water Supply (Water Fittings) Regulations 1999 with regard to prevention of backflow. Any pump delivering more than 12 L/min must be notified to the water undertaker whose consent is required.

9.16 Control of the pump(s) should be fully automatic in operation and controlled by pressure sensors for the following reasons:

a. to reduce energy consumption;
b. to prevent heat gain from the pump to the water, which could become significant if large pumps are used;
c. to reduce wear on the pumps and hence reduce maintenance.

9.17 Factors to be considered when selecting pumps are:

a. quantity and pressure of water to be pumped;
b. the number of units required to obtain the necessary output and to provide adequate standby capacity;
c. the desirability of speed variation;
d. the degree of automatic sequence control required (but with manual override);
e. the characteristics of the system on both the delivery and suction sides, and in pumping efficiency and priming requirements;
f. the type of materials used in manufacturing the pumps relative to the chemical analysis of the water to be pumped;
g. ferrous materials should not be incorporated into wetted surfaces.

9.18 Depending on the circumstances, the operation and shutdown of pumps may be controlled by various methods (for example,

water-level float switches, pressure switches, flow switches, electrode probes or pneumatic systems). Certain services may also require the pumping equipment to be energised from the emergency electrical service as recommended in HTM 06-01 – 'Electrical services supply and distribution'.

9.19 Where two or more pumps are installed, automatic control should be provided to prevent stagnation. The design should ensure that appropriate resilience is considered.

9.20 The pumping sets for lifting to higher-level storage should be controlled from the level in the high-level tanks by transmitting sensors, level switches or other suitable devices. A low-level alarm should be arranged to give a warning when the storage volume of water falls to a predetermined low level.

9.21 The plantroom should be constructed with a waterproof and non-dusting floor, and non-dusting walls and ceiling. The floor should be constructed with a slight fall to a drainage trench that should terminate in a trapped gully. The trapped gully should incorporate provisions to either avoid or replenish any trap-water-seal loss. The plantroom will require adequate lighting, ventilation and heating (to prevent freezing or condensation), with electric power points and/or provision for low-voltage supplies for portable lighting and tools.

9.22 If heavy plant is to be installed that may need to be removed for testing, maintenance or replacement, fixed lifting beams of suitable capacity should be provided.

Specialist systems

9.23 Where water supplies are required for specialist systems such as endoscope cleaning installations, dialysis units etc (see also HBN 07-01 – 'Satellite dialysis unit'), the design team should consult the infection prevention and control team and equipment manufacturer to establish any specific water treatment requirements for the process. Additionally such systems also require backflow prevention arrangements to protect the source water supplies from contamination. The local water undertaker should be consulted:

- to clarify the backflow prevention arrangements or devices; and
- on any possible variation in the quality of its water supply or possible changes to the source of the supply.

Vending, chilled water and ice-making machines

Note

These should not be installed in augmented care areas.

9.24 The design, installation, location and risk assessment of all equipment should be approved by the WSG (see also HBN 00-09 – 'Infection control in the built environment'). The risk assessment should consider:

- carbon filtration in these devices, which are a high nutrient source for bacteria;
- cleanability and maintenance of the machine.

9.25 The water supply to this equipment should be taken from a wholesome supply via a double-check valve to prevent backflow and be upstream of a regularly used outlet with the minimum of intervening pipe-run, that is, less than 3 m. The supply should not be softened. Additionally, it should be established that the usage is sufficient to avoid deterioration in water quality, for example that the inlet water temperature does not exceed 20°C. The equipment should be positioned so that the warm air exhaust does not impinge directly on taps or hoses supplying cold water and to provide access for maintenance.

9.26 Design considerations include for example:

- no drinking fountain or vending machine should be installed at the end of the line (potential dead-leg);

- the pipework should be as short as possible from take-off point (mains water tee);
- the cold water supply pipework should be copper and fitted with a local isolation valve and drain valve;
- the flexible pipe connector should be kept as short as possible (see paragraphs 3.39–3.41).

Note

Flexible EPDM should not be used (see Estates and Facilities Alert DH (2010) 03 – 'Flexible water supply hoses').

9.27 Reference should also be made to the Food Safety (Temperature Control) Regulations 1995 and Food Safety (General Food Hygiene) Regulations 1995. The Automatic Vending Association of Britain (AV) 'Guide to good hygiene practice in the vending industry' should be followed regarding hygiene and water quality and hygienic operation of vending machines.

Vending machines dispensing carbonated drinks require special materials of construction which should have been assessed and shown to be appropriate (for example, suitable approvals) for the intended application (see also paragraph 1.15).

Other water uses

9.28 The guidance contained in this HTM is principally concerned with hot and cold water services used for domestic purposes within the interior of the healthcare premises.

9.29 This will include vending equipment, as above, and additional devices such as dishwashers and non-industrial clothes washing machines.

9.30 The cold water distribution system may also be used for non-domestic purposes outside the building but within the curtilage of the healthcare premises. This use may introduce potential hazards and reference should be made to HTM 04-01 Part B, Chapter 8.

10 Hot water services

10.1 Hot water services should be designed and installed in accordance with the Water Supply (Water Fittings) Regulations 1999 and relevant parts of BS EN 805, BS EN 806 (Parts 1–5) and BS 8558. The hot water system may be of either the vented or the unvented type.

10.2 The basic components of a hot and cold service system as used within healthcare facilities are shown in Figure 5; most installations will have additional features and components.

10.3 A vented system usually consists of a cold water storage cistern situated above the highest outlets, which feeds a hot water storage vessel (for example a calorifier or direct-fired boiler).

10.4 An unvented system usually has the hot water storage vessel connected to the mains water supply via a backflow prevention device and a pressure-reducing valve, or supplied via a break-tank or booster pump set.

See also HSE's:

- 'Managing the risks from hot water and surfaces';
- chapter 10 on hot water and surfaces in 'Health and safety in care homes'.

Hot water temperatures

10.5 Hot water is required in healthcare premises at various delivery temperatures for particular needs. The highest temperature, 55°C, is required typically in main kitchens, laundries, dirty utilities and food preparation areas. Elsewhere the delivery temperature for personal hygiene will depend on individual preference for comfort and safety of patients who require assistance. In circulating hot water systems, the highest temperature will be required at all draw-offs on a loop. To achieve this, see Note 2 below, the flow from the calorifier/water heater is required to be at least 60°C at its outlet with a minimum return temperature to it at 50°C.

Notes

1. Requirements in the Water Supply (Water Fittings) Regulations 1999 and ACoPL8 are prescribed to ensure efficient use and appropriate control of microbial elements in hot water systems. Guidance to these dual requirements recommends that, to comply, hot water should be delivered to the outlet 50°C within 30 seconds and 55°C within 1 minute of an outlet being opened.
2. The flow temperature of hot water out of the calorifier should be a minimum of 60°C. It should be a minimum of 55°C on flow and returns to all outlets and at the start of the hot water return. It should be a minimum of 50°C at the final connection to the calorifier.
3. Water system design should negate the need for trace heating in healthcare premises.

10.6 The individual outlets, taps, mixing valves or other outlet devices will be served from the circulating distribution system; this should be designed such that the minimum temperature

on all return loops should be at a minimum of 55°C. This will ensure a temperature of 55°C at all outlets within a maximum of 1 minute.

Note

Where the hot water return is local to the outlet, a much quicker response should be achieved: less than 30 seconds (typically less than 10–20 seconds). Failure to achieve this may indicate a hot water return fault and should be noted during subordinate loop monitoring. See also paragraph 10.59 on scalding risks.

10.7 A small number of localised hot water distribution systems can have advantages over one large centralised system. With smaller systems, hot water heaters are located closer to points of use, and it is therefore easier to maintain hot water distribution temperatures within recommended values. Balancing water flow rates in the hot water secondary distribution system becomes less of a problem, and distribution losses are reduced. A small localised hot water distribution system may comprise a gas-fired water heater or a storage calorifier. The adoption of localised hot water distribution systems will require the provision of local plantrooms.

10.8 With large centralised hot water systems, it is more difficult to maintain secondary distribution temperatures within recommended values; also, water flow rates in large secondary distribution systems can prove difficult to balance. This can be simplified by not overcomplicating the design for circulating systems (for example, by installing just one return to low level to accommodate the supply for two wash-hand basins back-to-back). See also paragraphs 8.42–8.44.

10.9 There are also maintenance factors to be considered. With a central hot water system, plant maintenance can be focused in one location, whereas with localised systems there will be a number of plantrooms at remote locations.

Hot water heater types

10.10 In most healthcare premises, hot water storage vessels include the heating source, which can be steam, high- or medium-pressure hot water, or electric immersion heating elements. The flow to the pipeline distribution system is normally taken from the top of the vessel, as too is the open vent, which may or may not be combined. The cold feed and return pipe should be connected to the vessel at the lowest point. Instantaneous water heaters for distribution systems have similar pipeline connections. They should be designed to have minimum water storage below the elements and should not be run to feed further outlets downstream. All water heaters should have been assessed and shown to be mechanically and materially appropriate (for example, suitable approvals) for the intended purpose (see paragraph 1.15).

10.11 Traditional design practice is for the use of vented hot water systems, which rely on a cold stored water feed and vent pipe to maintain its safe operation (that is, preventing water exceeding 100°C and maintaining fixed system pressures). Upon heating, expanded water can travel along both the cold feed and open vent pipework.

10.12 Means should be taken to prevent thermal circulation of hot water from the water heater to the cold-feed cistern occurring, leading to conditions conducive to microbial colonisation (for example, *Legionella*). It is common for an anti-thermal cycling loop to be installed on the cold water feed pipe between the water heater and the vertical cold water feed pipe, such as a U- or S-bend pipe configuration. When this arrangement is used, no heated water should extend upstream of the bend into the vertical cold water feed pipe.

10.13 To preserve the quality of stored water within the cistern, the practice of terminating the vent pipe (air vent) over the cistern is no longer permitted. The vent should be arranged to discharge over a separate air-break-to-drain arrangement (in accordance with BS EN 1717) or a visible Type AA air gap, and sited at a level

that takes account of the hydrostatic head of the system (see G20.3 in the WRAS 'Water Regulations Guide' or Figure 7 of BS 8558) to prevent unwanted discharges. The tundish should discharge to drain.

10.14 The vent pipe is critical to the safe operation of vented hot water systems and should be situated in a hygienic environment to prevent blockages of the vent. The ingress of small animals, insects, debris or dust should be prevented. Vents should be designed to prevent unnecessary discharges of hot water and should be sized in accordance with G20.3 in the WRAS 'Water Regulations Guide' and to Figure 7 of BS 8558. Where screens are used on the vent outlet, additional measures should be included to ensure the continuing operation of the vent. Suitable maintenance should be specified to ensure the vent outlet is kept free from the collection of dust or biofilms etc.

10.15 The calorifier or water heater should be provided with a suitable safety valve of appropriate size and vacuum release arrangement.

10.16 Most vessels have some means of access for inspection, either via a special panel or by removing the heating coils/elements. When new calorifiers are required, it should be specified that they have separate and adequately sized access panels.

10.17 The combined storage capacity and heater output should be sufficient to ensure that the outflow temperature, at continuous design flow from calorifiers or other heaters, is not less than 60°C under maximum design flow. This applies to both circulating and non-circulating hot water systems. The positioning of the control and high-limit thermostats, cold feed and return water connections should ensure that these temperatures are achieved.

10.18 There are three types of water heater:

a. instantaneous heater;
b. storage calorifier;
c. semi-storage calorifier.

Instantaneous water heaters

10.19 This type of heater can be further subdivided into:

a. instantaneous water heaters for single- or multi-point outlets: these devices usually serve one draw-off only and are either electrically or gas-heated. The general principles and limitations of instantaneous water heaters are in essence:

   i. the hot water flow rate is limited and is dependent on the heater's power rating;

   ii. the water in instantaneous water heaters is usually heated to about 55°C at its lowest rate, and its temperature will rise and fall inversely to its flow rate. Where constant flow temperature is important, the heater should be fitted with a water governor at its inflow. Close control of temperature is of particular importance for showers. To attain constant temperatures on delivery, water flow and pressure should also be controlled. Variations in pressure can cause flow and temperature problems when the heater is in use and when setting up or adjusting flow controls;

   iii. they are susceptible to scale formation in hard water areas, where they will require frequent maintenance;

   iv. this form of hot water heating should be considered only for smaller premises or where it is not economically viable to run a hot water circulation to a remote outlet;

   v. for electrical instantaneous point-of-use showering, consideration should be given to selecting an appropriate thermostatically controlled product (for example, those with BEAB Care Mark approval).

Note

Some designs of combination water heater are arranged to have the cold-feed tank above the hot closed water tank. These are not recommended for healthcare premises, but where they are used, careful consideration should be given to managing the risks from these types of systems, and this should be reflected in the risk assessment. See also Table 1 in HTM 04-01 Part B.

b. instantaneous-type water heaters for distribution systems: these devices, which normally use steam or high- or medium-pressure hot water as the primary heating medium, are designed to heat their rated throughput of water rapidly from cold to the design outlet temperature. They can be used either to feed directly into a hot water distribution system or in conjunction with a separate storage vessel (often referred to as a buffer vessel), which reduces the load on the heater during periods of peak demand. This type of heater includes:

   i. hot water generators: these are vertical instantaneous water heaters that contain modular helical primary coils normally served by steam, medium temperature hot water (MTHW) or high temperature hot water (HTHW). The unit incorporates a temperature control device, which varies the rate of primary energy input so as to maintain a constant hot water flow temperature over a range of secondary flow rates through the heater;

   ii. plate heat exchangers: plate heat exchangers consist of a number of rectangular plates sandwiched between two flat endplates and held together by tie bolts. The plates have ports in all four corners that allow entry and discharge of the primary and secondary liquids. Primary liquid is directed through alternate pairs of plates while the domestic hot water is normally fed in a counter flow direction through the remaining pairs of plates. Each plate is sealed round the edges by a gasketing system, the design of which should ensure that fluids cannot, under normal operating conditions, either leak to atmosphere or mix. This type of heat exchanger can be extended easily, or shortened, to suit changes in hot water demand.

Storage calorifiers

10.20 Storage calorifiers are usually cylindrical vessels mounted either vertically or horizontally; the base of a vertical calorifier can be concave or convex, with the vessel being supported on feet. The latter design is preferred, as it avoids the annular space where the base joins the cylinder wall. Heater batteries are usually located near the bottom of the cylinder, which can give rise to an area of water beneath the battery significantly below the storage temperature. This “dead” area can provide an ideal breeding ground for bacteria. Galvanised cylinders are particularly susceptible to scale formation, which can also provide a source of nutrition and shelter for bacteria.

Note:

Galvanised cylinders are not recommended in new healthcare installations or for replacement.

10.21 The following points should be considered during the design process (see also paragraphs 10.27–10.28):

a. the entire storage volume should be capable of being heated to 60°C without permanent pockets of lukewarm water;

b. the shell lining should be resistant to bacterial growth;

c. sufficient access to ensure adequate cleaning of the shell should be provided;

d. a suitably-sized drain should be connected to the base of the calorifier.

Semi-storage calorifiers

10.22 These calorifiers can either have an independent heating facility such as oil or gas burners or electric elements, or use primary water/steam from a boiler to heat the water via a heat exchanger. The equipment is available in a range of storage capacities and recovery flow rates. This type of equipment is particularly suitable where systems are being decentralised and water heaters are required close to the point of use.

Sizing of hot water storage vessels

10.23 Storage should be calculated on the requirements of peak demand and the rate of heat input. There may be more than one peak period in each 24 hours. The interval between peak periods is important, as it affects the recovery time. See CIBSE Guide G: 'Public health engineering', which gives guidance on sizing hot water storage.

10.24 The installed hot water capacity should be sized for current needs and should not be designed with built-in capacity for future extensions.

10.25 Some devices are optimistically rated so that, at a continuous demand equal to their design rating, the flow temperature can fall below 60°C. Semi-storage or high-efficiency minimum storage calorifiers and instantaneous heaters are especially prone to this if under-sized.

Stratification in storage vessels, calorifiers, water heaters and associated buffer vessels

10.26 Stratification will occur in any storage calorifier, heater or associated buffer vessel; the temperature gradient will depend on the rate of draw-off and heat input. In some calorifier designs, stratification is significantly more pronounced and is a feature of their design. There will always be a volume of water in the temperature range that encourages maximum growth of *Legionella*.

Note

Stratification: in a storage calorifier, the upper level above the heating element will be at operating temperature (60°C) during normal periods of demand. Below this level there will be a volume of water at a temperature between that of the return feed water and the operating temperature. A higher return temperature is preferable to ensure all water in the calorifier can be stored above 60°C. This level will vary as draw-off takes place according to the thermal input and rate of demand.

10.27 Storage and semi-storage calorifiers should be provided with independently pumped circulation from the top to the base of the calorifier; this is referred to as a "shunt pump". The pump should be run for long enough to ensure that the entire contents of the calorifier are raised to 60°C for an hour a day, often performed during periods of minimum demand. During periods of low draw-off, the temperature will readily achieve 60°C to effect disinfection. Control should be by a timing device that can be adjusted when the profile of demand has been established.

10.28 Some semi-storage/high-efficiency calorifiers are supplied with an integral pump that circulates water in the calorifier; in this case a second shunt pump is not required. A similar arrangement is included in some plate heat exchanger/storage vessel packaged systems where there is primary DHW circulation which

provides pasteurisation without the requirement of a further shunt pump on the vessel.

Unvented hot water systems

10.29 Hot water storage systems have traditionally been provided with an open vent pipe that relieves any steam generated in the event of failure of temperature controls. The open vent pipe also protects against rupture of the cylinder by expansion of water.

10.30 The use of unvented heating systems is covered in section G3 in Approved document G – 'Sanitation, hot water safety and water efficiency', which specifies the minimum safety precautions that should be taken when adopting such systems.

10.31 Where an unvented hot water system is connected directly to the water mains, no back-up will exist in the event of a water supply failure. Such an arrangement may also be unacceptable to the local water undertaker, since they will be required to meet the maximum demand at any time over a 24-hour period.

10.32 The design and installation of unvented hot water systems should comply fully with the Building Regulations and the Water Supply (Water Fittings) Regulations 1999.

10.33 The key requirements are that the temperature of stored water should be prevented at any time from exceeding 100°C and that discharges from safety devices should be conveyed to a safe and visible place and protected to prevent blockage and the ingress of birds, rodents or insects etc.

10.34 The discharge pipes from the temperature-relief valve and expansion valve should be carefully located so that they are readily visible – but do not present a risk to people – and protected to prevent blockage and the ingress of birds, rodents or insects etc.

10.35 Where the hot water is heated directly, for example by a steam or LTHW primary coil, a non-self-resetting thermal cut-out wired to a motorised valve on the primary coil should be provided for control of excessive temperature. This should further be protected by a direct-acting protection device.

Connection arrangements for calorifiers and water heaters

10.36 Where more than one calorifier or heating device is used, they should be connected in parallel, taking care to ensure that the flow can be balanced so that the water temperature from all the calorifiers exceeds 60°C at all times.

10.37 Installations should not include for series operation of calorifiers/heaters.

Provisions for maintenance

10.38 There should be adequate access to calorifiers for inspection and cleaning, removal and replacement of tube bundles and removal and replacement of the entire calorifier.

10.39 All calorifiers and water heaters should be fitted with a drain valve located in an accessible position at the lowest point on the vessel so that accumulated sludge may be removed safely and effectively from the lowest point. The drain should be of sufficient size to empty the vessel in a reasonable time.

10.40 Drain valves should be of the ball type to avoid clogging, and a drainage gully should be provided of sufficient size to accommodate the flow from the calorifier drain.

Sealed expansion tanks for unvented hot water systems

10.41 It is essential that the expansion vessel is located on the cold feed rather than on the hot water side of the system in an area not subject to heat gain. All expansion vessels should have a means of isolation and drain provision to allow periodic flushing.

10.42 These vessels should be appropriately sized to take account of the thermal expansion of the hot water service system. Otherwise, they should comply with the recommendations in paragraphs 10.45.–10.48.

Hot water distribution system

10.43 To achieve the required circulating temperatures, it will be necessary to provide some form of regulation to balance the flow to individual pipe branches serving groups of draw-off points, for example each washroom/toilet and en-suite facility.

10.44 The means of balancing the hot water circulation can be achieved by either manual or thermostatic regulating valves installed in the return loops to all outlets. There should be means of isolation, both upstream and downstream. Adequate access for servicing is also essential. Lock-shield valves should not be used for balancing.

10.45 In in-patient accommodation where en-suite facilities are provided, it is recommended that the hot water circulation be extended to draw-off points in series; for example, the supply to a basin, bath and/or shower should be run as one circuit (see Figure 6).

10.46 The operating pressures for both hot and cold water at draw-off points should be the same.

10.47 The domestic hot water system should not be used for heating purposes. This includes all radiators, towel rails, heated bedpan racks etc, whatever the pipework configuration.

10.48 Particular attention should be given to ensuring that pipework containing blended water should be kept to a minimum. Generally, the downstream supply from the mixing device should not exceed 2 m.

Note

The same restriction applies to communal blending, that is, where more than one outlet is served by one device. Central blending systems should not be used, since the length of distribution pipework containing water in the temperature range that supports *Legionella* growth would far exceed these maximum permissible lengths.

Hot water circulating pump

10.49 Hot water circulating pumps have traditionally been installed on either the flow or return. When installed on the flow, the arrangement comprises a full-bore non-return valve with a bypass into which the pump is installed (a non-return valve is also required in the return at the calorifier/water heater); appropriate valves and drain points are also required for servicing. The size of flow pipe is selected, with larger bores to begin with to ensure the maximum diversified simultaneous flow demand is achieved: the circulating pump bypass pipe size is selected to take account of the flow required to offset the heat losses in the flow and return pipework.

10.50 When installed in the return, the installation will require a downstream non-return valve, upstream and downstream isolation valves and drain valve. Installing the circulating pump in the return simplifies the valving arrangements and may improve circulation when draw-off is taking place. (During high demands, the flow from the calorifier may exceed that of the circulating pump in the flow resulting in the non-return valve at the calorifier closing.)

10.51 Duplex pumps should not be installed. A spare, clean, dry and ready-for-service replacement pump assembly with drain valve and non-return value should be available in the event of failure of the service pump.

Note

If a permanently installed standby pump is considered to be essential, the control system should automatically change over operation every 3 hours.

10.52 The electrical connection should be by means of a lockable socket outlet for either single- or three-phase as required.

In-line strainers

10.53 Where not integral to the fitting, in-line strainers should be fitted within the water pipework system to protect vulnerable valves and fittings (pressure-reducing, safety-relief and stop valves, terminal fittings including thermostats and solenoid valves etc) against ingress of particulate matter. The installation of these fittings should allow adequate access for maintenance/replacement and they should be provided with means of upstream (and downstream where appropriate) isolation. Strainers can be a source of microbial contamination including *Legionella* and *Pseudomonas aeruginosa* and should be included in routine cleaning, maintenance and disinfection procedures (see Chapter 7 of HTM 04-01 Part B).

Cold-feed cisterns

10.54 When separate cold-feed cisterns are provided for hot water service installations, they should comply with the requirements for cold water systems.

Note

Hot water cylinders with an integral feed and expansion tank should not be used.

10.55 Some instantaneous water heaters include a flow-limiting device to ensure that the rate of draw-off does not exceed the capacity of the heater to achieve the required temperature. Such devices are not recommended for larger systems as air can be introduced into the circulating system if taps are opened on upper floors during excess draw-off.

Service isolation valves

10.56 Service isolation valves should be fitted to all pipework preceding sanitary tapware and WCs etc for servicing, repair and replacement. These valves should not be used for balancing the hot water system. Drain-valve provision may also be appropriate for certain installations, for example service pipework to en-suite facilities. Care should be taken to ensure these do not constitute dead-legs. The design needs to ensure that there are enough isolation valves for maintenance and repair to allow essential services to continue (for example, on all riser connections and pipework entries to specific areas).

Water temperatures and delivery devices

10.57 With the change in focus towards improving the patient environment and minimising the risk of healthcare-associated infections, there has been an increase in the provision of single-bed rooms with en-suite facilities. Additionally, to promote good hand hygiene, wash-hand basin provision has increased significantly in all clinical areas. Effective hand-washing is best performed under running water at a safe, stable and comfortable temperature over basins/sinks (for clarification and design specifications, see HBN 00-10 Part C – ‘Sanitary assemblies’ and HBN 00-09 – ‘Infection control in the built environment’).

Note

The Water Supply (Water Fittings) Regulations 1999 place limits on the flow of water to draw-offs where plugs are not provided. Spray-type mixer taps are not recommended in healthcare premises; therefore, the type of tap should be carefully selected to minimise the formation of water droplets and aerosols. Water flow profile should be compatible with the shape of the wash-hand basin to avoid splashing. The fitting and basin combination should be such that the water stream never discharges directly into the basin's waste outlet (see HBN 00-10 Part C – 'Sanitary assemblies').

10.58 Components should be selected for their ability to minimise the accumulation of debris and splashing (including devices that deliver a smooth non-splashing/spraying flow), and to facilitate disinfection. See also paragraph 3.1.

Note

When selecting new taps, HBN 00-09 advises against using aerators, strainers and flow restrictors at the point of discharge.

10.59 The risk of scalding for vulnerable patients (young children and older people, disabled people and those with neuropathy) is of particular concern in healthcare premises caring for such individuals, and therefore thermostatic mixing devices could be needed for hot water outlets. A risk assessment for scalding risk versus the risk of infection from waterborne pathogens should be undertaken by the WSG. (Thermostatic mixing valves should comply with HTM 04-01: Supplement – 'Performance specification D 08: thermostatic mixing valves (healthcare premises)'.) See Table 2 for recommended devices and outlets.

Table 2 Recommended devices and outlets

Activity/area	Maximum recommended set delivery temperature (°C)	Type of device
Areas where TMV type 3 valves should be fitted		Type 3 thermostatic mixing valve
Showers and hair-wash facilities	41	
Unassisted baths	44	
Baths for assisted bathing	46 – to allow for the cold mass of the bath. NB – prior to patient immersion, water should be checked with a thermometer.	
Bidets	38	
Note: Bath fill temperatures of more than 44°C should only be considered in exceptional circumstances where there are particular difficulties in achieving an adequate bathing temperature. If a temperature of more than 44ºC is to be used, then a safe means of preventing access to the hot water should be devised to protect vulnerable patients.		

Wash-hand basins and sinks

Wherever wash-hand basins are installed, a mixed water temperature outlet is required: a risk assessment should be undertaken, which is overseen by the WSG, that considers the needs of patients and service-users to determine whether there is a scalding risk and whether additional protection is required (e.g. a type 1 with temperature stop, type 2 or type 3 mixing valve – see options below). **Hazard warning signs for scalding risk should be displayed if appropriate.**

For outlets not intended for hand-washing (e.g. sinks in kitchens, dirty utilities or cleaners' rooms), TMVs should not be installed. **All installations require a hot water hazard warning sign.** (The temperature could equate to the maximum temperature available from the calorifier.)

Note: Microbiological risks should also be considered for all installations.

Options:

1. Separate hot and cold taps

2. Mixed temperature outlet:

- Type 1 – a mechanical mixing valve with or without temperature stop (i.e. manually blended)
- Type 2 – a thermostatic mixing valve: BS EN 1111 and or BS EN 1287
- Type 3 – a thermostatic mixing valve with enhanced performance: HTM 04-01: Supplement – 'Performance specification D 08: thermostatic mixing valves (healthcare premises)'

Type 3 TMVs should have undergone third-party testing and certification to the requirements of HTM 04-01: Supplement – 'Performance specification D 08: thermostatic mixing valves (healthcare premises)'.

Notes:

1. Where installed, it is preferable that thermostatic mixing devices are fitted directly to the mixed temperature outlet or be integral with it, and be the method of temperature and flow control, i.e. the mixing device should not be separate nor supply water via a second tap or manual mixer since there will be many cases where draw-off of cold water will not occur. If a separate thermostatic device is used, it should be fitted as close to the outlet as possible, which should be a flow-only control. Where "T" type mixing valves are installed, they should be readily accessible for maintenance.
2. In the case of bidets with ascending sprays or a handle douche, which may be accidentally immersed, the water supply should be independently fed from storage with no draw-offs at a lower level (i.e. a break-tank arrangement). Appropriate backflow protection must be provided (see paragraphs 12.18–12.24).

3. Automatic taps (timed flow) can be considered as a result of a risk assessment and should be specified as appropriate for the conditions of use, either type 2 or 3. If the temperature is non-user adjustable, they should be supplied via a type 2 or 3 TMV set to 39–40ºC. The sensors should include a timer that can be adjusted to take account of the optimum washing time: this is particularly for scrub sinks. Sensors should be offset or positioned such as to reduce the risk of accidental contamination of the outlet and be positioned so that POU filters can be used. Facilities for overriding the sensors will be necessary. When a duty cycle setting exists, it should be activated to avoid stagnation. (If there is more than one tap/outlet, e.g. in the case of scrub sinks, then all should deliver water to avoid stagnation.)
4. In the case of dual-function delivery devices, i.e. bath/shower diverter, type 3 valves should deliver the temperature appropriate to each outlet e.g. bath max 44ºC or 46ºC, shower 41ºC. (Refer also to the commissioning procedure section in HTM 04-01: Supplement – 'Performance specification D 08: thermostatic mixing valves (healthcare premises)'.)
5. Taps, components and fittings should be removable and easily dismantled for cleaning and disinfection.
6. Where manual mixing devices with a temperature stop are installed, it is important to ensure that the normal maximum delivery temperature is controlled to safe limits. Installation, commissioning and maintenance should take account of the system's dynamic pressure and temperature changes, and the seasonal changes in incoming cold water temperatures.
7. This table does not cover birthing pools. (See "Areas this HTM does not cover" in Chapter 1.)

Showers

10.60 Showers with fixed heads are preferred for prevention of backflow (see paragraphs 12.18–12.24) and minimisation of contamination. Where flexible hoses and moveable shower outlets are provided, the outlet should not be capable of being accidentally immersed into a drain, WC or other potential source of contamination. They should be selected based on ease of cleaning, descaling and disinfection.

10.61 The flow of some showerheads can be adjusted by selecting different sets of nozzles (fine spray, pulsating flow etc); as this will exacerbate possible stagnation problems, they should not be installed in healthcare premises.

10.62 Thermostatic mixing valves should be accessible in such a way as to prevent damage to the shower installation, the supply pipework or the removable panels themselves in wet areas. Access for safe inspection and removal should be given high priority.

11 Building management systems

11.1 The continued safe operation of domestic hot and cold water systems requires a number of routine checks to be made by physical means using separate thermometric equipment. A number of the control parameters can, however, be continuously monitored by building management systems (BMS) even though routine checks will still be required for calibration purposes. Parameters that should be monitored are as follows:

a. incoming mains temperature (at the water meter), inlet, outlet, and surface water temperatures of cisterns and cold water feed tanks for hot water calorifiers;

b. temperatures for calorifier flow and returns, and the returns on each loop;

c. hot water service return temperatures on all primary loops;

Note

In non-recirculating hot and cold systems, at least two points, including the furthermost from the entry of the pipe into the department, should be monitored. In other departments, monitoring should be provided on a similar basis.

d. cold water service at furthermost point and in a location that demonstrates general temperature representation within the ward/department;

e. consideration should be given to the frequency, timing and monitoring of taps etc with automatic flushing devices.

11.2 In addition to temperature, the BMS should monitor pressurisation and circulating pumps and water treatment systems for fault conditions or change of status likely to result in a fault. There should be a documented procedure for regularly checking the BMS for such alarms.

12 Pipework installations

12.1 All hot and cold water pipework should be designed and installed in full accordance with the Water Supply (Water Fittings) Regulations 1999 and relevant parts of BS EN 805, BS EN 806-2 and BS 8558.

12.2 Within the system, it is essential to include facilities for measuring, regulating, isolating, venting, draining and controlling the flow of water. Regulating valves with built-in pressure tappings or orifice plates with manometer tappings will be required for the measurement of pressure drop, which enables the volume rates of flow to be determined. Care should be taken to ensure that regulating valves or orifice plates are sited well away from bends or fittings.

Sizing

12.3 Pipes should be capable of a rate of flow to satisfy the combined maximum demand of all the services to be supplied. All the maximum demands of the separate services may not occur simultaneously, and the actual combined maximum demand may be a proportion of the sum of the separate maximum demands, which will be determined by the number and character of the services.

12.4 Hot and cold water pipework should be sized using the procedure outlined in CIBSE's Guide G – 'Public health engineering'.

Pipe branches

12.5 Pipe branches should be designed with the aim of avoiding stagnation. As far as practical, the maximum length of any pipework between a terminal device and a recirculating system or a cold water distribution mains should be kept to a minimum; generally, the complete length of the spur should not exceed 3 m. The length is measured from the centre line of the circulation pipework to the point of discharge along the centre line of the pipework. These pipes should be insulated.

Routing of pipework

12.6 Pipework in buildings should be designed and routed:

- so that minimal heat transfer will occur between hot and cold or the surrounding environment (see also paragraph 9.2); and
- in a manner that will promote good turnover of water, particularly in cold water service systems.

12.7 All pipework should be accessible for inspection, maintenance and repair as far as is practicable. Ducts, trenches and chases containing pipework should be large enough to facilitate repairs.

Buried pipelines

12.8 Pipelines made of plastics are susceptible to hydrocarbons such as fuels and oils. These chemicals can travel through plastic pipes if they are nearby and contaminate the water supply, and it may take days, weeks or even months before a noticeable taste can be detected in the water supply. Whenever spills are reported, an assessment of services within the area should be undertaken (see WIS 4-32-19 and UKWIR's 'Guidance for the selection of water supply pipes to be used in brownfield sites').

12.9 Pipework distribution networks should be divided into sections by the provision of isolating valves in accessible locations to facilitate isolation for repairs, maintenance and flushing.

12.10 Underground mains need not be laid at unvarying gradients but may follow the general contour of the ground. As far as possible, however, they should fall continuously towards drain points and rise continuously towards the air vent. They should not rise above the hydraulic gradient; that is, there should always be a positive pressure, greater than atmospheric, at every point under working conditions. The gradient between air release and drainage valves should be not less than 1:500 rising in the direction of flow and not less than 1:200 falling in the direction of flow.

12.11 Underground pipes entering a building should do so with a cover of not less than 0.75 m below the external ground surface and should pass through the wall within a watertight built-in sleeve. The sleeve should be filled in around the pipe with a suitable material for a minimum length of 152 mm at both ends to prevent the ingress of water or vermin. External underground pipes should be at a depth, or otherwise sufficiently protected, to prevent damage by traffic and any consequent vibrations. A minimum depth under roadways of 1 m measured from the top of the pipe to the surface of the roadway is necessary. In other underground locations the depth should not be less than 0.75 m, subject to this depth being sufficient protection against frost (frost penetration depends on the nature of the subsoil and the ground surface). Freezing can occur at depths of up to 1.1 m (see paragraph 13.26). Local information on the prevalence of frost should be sought (see also paragraphs 13.25–13.29).

12.12 Marker tapes should be laid over the whole length of all underground water services pipework (see also the requirements in BS 1710). The tapes should be clearly marked with the description of the service and should be coloured blue and red for fire mains.

Vents and drains

12.13 Air-release valves should be provided at summits and drainage valves at low points between summits unless adequate provision is made for the discharge of air and water by the presence of service connections. Large-orifice air valves will discharge displaced air when mains are being charged with water. When air is liable to collect at summits under ordinary conditions of flow, small orifice air valves, which discharge air under pressure, may be required. “Double-acting” air valves having both large and small orifices should be provided where necessary. Air-valve chambers should be adequately drained to avoid the possibility of contamination.

12.14 Automatic air-release valves should be installed where accessible for maintenance. Installation in ceiling voids is not recommended.

12.15 Drain points should not discharge directly into a drain or sewer or into a manhole or chamber connected thereto without an appropriate air gap between the water system and the drain. This can be achieved with a Type AA air gap or an air-break-to-drain device in accordance with BS EN 1717 clause 9. Where a wash-out discharges into a natural watercourse, the discharge should at all times be well above the highest possible water level in the watercourse. Consent for this discharge may be required from the Environment Agency. In some cases it may be necessary for the wash-out to discharge into a watertight sump, which has to be emptied while in use by portable pumping equipment.

12.16 In order to minimise quantities of water that may collect in stub pipes at drain points, the length of such stub pipes should be kept to an absolute minimum. This relates in particular to drains from hot water calorifiers, storage cisterns and distribution pipework.

Valves

12.17 A clear indication should be given on all valves of the direction of rotation needed

to close the valve. Normal practice is to have clockwise closing when looking down on the valve.

12.18 Where blending valves have been installed at the end of a run of hot water pipework, consideration should be given to the inclusion of a drain valve adjacent to the mixer. This should be located upstream of the mixing valve so as to facilitate flushing out and routine temperature testing of the hot water without having to dismantle the blending valve.

Backflow protection and the prevention of contamination

12.19 In all cold water installations it is important that adequate protection be provided to all supplies against backflow. In a healthcare facility, there should be a high degree of protection not only to the water in the undertaker's mains, but also within the facility's installations to protect the patients and staff. Instances of water use in healthcare facilities where backflow is likely to be harmful to health include bidets, bedpan washers, dental spittoons and equipment, mortuary equipment, and water outlets located in laboratories.

12.20 In addition to backflow protection at all points of use, the whole installation protection should be provided as required by the Water Supply (Water Fittings) Regulations 1999.

12.21 Healthcare buildings and medical premises have been identified as involving Fluid Category 5 backflow risks (see Schedule 1 "Fluid Categories" from the Water Supply (Water Fittings) Regulations 1999), which are defined as points of use or delivery of water where backflow is likely to involve fluids contaminated with human waste or pathogens. Within healthcare facilities, water usage covers a wide range of applications, from domestic use by patients and staff to specialised use in operating departments and pathology laboratories, and with equipment such as bedpan washers and haemodialysis machines. Even within high-risk specialist areas such as pathology laboratories (see paragraph 13.22), further separation of water supplies may be required to protect water used for domestic uses from those high-risk applications. In addition, many apparently "commercial" usages may be classed as high-risk because they are for healthcare purposes (such as centralised laundries).

12.22 Where any doubt exists with regard to the level of protection required against water supply contamination, reference should be made to the Water Supply (Water Fittings) Regulations 1999 and guidance contained in the WRAS 'Water Regulations Guide', or to the water undertaker.

12.23 The Water Supply (Water Fittings) Regulations 1999 require the identification, by colour-coding or labelling, of all pipework carrying fluids other than wholesome water. This includes plumbed-in equipment used for diagnostic and treatment purposes (see BS 1710).

12.24 New systems should not include legs of pipework for potential future extensions to the system as these will create stagnant legs. Any alterations to existing systems – or where redundant pipework is found – should be cut back to the connection point; this includes replacing the branch 'T' with a straight coupling.

12.25 Certain departments such as pathology laboratories present particular risks of water contamination. Attention is drawn to section G15.24 in the WRAS 'Water Regulations Guide' on supplementing point-of-use protection by zone protection, where the pipes supplying a high-risk area can be given additional protection by installation of a secondary backflow protection device.

Frost protection

12.26 The Water Supply (Water Fittings) Regulations 1999 require that all cold water pipework and fittings be adequately protected against damage from freezing.

12.27 In the case of external pipework that is run underground, the Regulations require that consent be sought from the water supplier if pipes are to be run at depths of less than 0.75 m or greater than 1.35 m. Permission from the water undertaker should be sought if any deviation is required.

12.28 Particular care is required when routing pipework externally above ground or through unheated areas within buildings. The WRAS 'Water Regulations Guide' gives guidance on the minimum thickness of thermal insulating materials that should be applied in such cases (see the online calculation tool on the WRAS website).

12.29 Adequate provisions for isolating and draining sections of cold water distribution pipework will ensure that disruption caused by frost damage can be minimised.

12.30 For further guidance on frost protection, refer to the WRAS 'Water Regulations Guide'.

Maintaining cleanliness and hygiene

12.31 To prevent the risk of seeding the water system during construction and installation, care should be taken to prevent the ingress of contaminants and particulate matter into pipework, fittings and cylinders etc. Blanking flanges, plugs and caps should not be removed until connections need to be made. Open ends of pipes should be recapped when work ceases. Particular attention should be taken when pipes are passed through partitions etc and when transporting items from storage to installation locations.

13 Noise and vibration

Pump noise

13.1 Noise generated by centrifugal pumps will not cause problems if water velocity in the pipes and the speed of the pumps are low, for example about 1 m/s and 960 rpm respectively.

13.2 Care should be taken in locating water-boosting pumps within healthcare buildings to ensure that they will not cause interference to in-patient accommodation and other quiet zones.

13.3 Such interference may result from break-out noise from the boosting equipment, or noise transmitted through the pipework system or through the building structure. Pump noise may also result from cavitation caused by low suction head.

13.4 Where pumps are located close to sensitive areas, provision for noise and vibration reduction should be incorporated in the design. Such provision will include selection of quiet-running motors, vibration isolation of boosting equipment from pipework and structure and, if required, acoustic lining to the booster plant enclosure.

13.5 Guidance on recommended noise levels for various locations is given in CIBSE's Guide A – 'Environmental design'. See also HTM 08-01 – 'Acoustics'.

Other forms of system noise

13.6 Other forms of nuisance noise that may be generated by hot and cold water distribution systems are listed below:

a. noise from pipework due to excessive water velocity;

b. water hammer caused by rapid closure of valves or taps;

c. oscillation of the float of a float-operated valve;

d. tap washer oscillation;

e. noise caused by water discharging from float-operated valves into cisterns;

f. noise caused by thermal movement of pipes;

g. noise due to trapping of air within pipework, particularly on hot water systems.

13.7 Further details on the above sources of noise, including guidance on avoiding such noise problems, are given in the WRAS 'Water Regulations Guide'.

14 Water economy and energy conservation

Water

14.1 Hot and cold water distribution systems for healthcare buildings should be designed so as to minimise the use of water. The cold water distribution systems should incorporate an adequate number of water meters to allow for close monitoring of water consumption. Where practicable, consideration should be given to linking water meters to a building management system or an automatic metering system.

14.2 Measures to optimise water consumption – and yet avoid risk of stagnation – that should be considered at design stage include:

a. provision of automatic systems to control flushing of urinals;

b. use of showers rather than baths wherever practicable;

c. WC pans and flushing cisterns that use more than 6 L per flush are prohibited by Water Supply (Water Fittings) Regulations 1999;

d. control of water pressure to a level that is not excessive for the purpose required;

e. use of self-closing or non-concussive taps in appropriate circumstances;

f. locating warning pipes from cisterns and discharge pipes from relief valves in such a way that any discharge can be readily observed, and/or fitting alarms on such pipes.

14.3 Further guidance on the prevention of wastage of water is given in the WRAS 'Water Regulations Guide'. See also HTM 07-04 – 'Water management and water efficiency'.

Energy

14.4 Hot and cold water systems should be designed to operate by gravity as far as possible. Where water-boosting pumps are necessary, the pump motors should be selected to operate at maximum efficiency at the required duty.

14.5 The practice of pre-heating of the cold feed to calorifiers should not be carried out. The only time it is acceptable is when under all flow/demand conditions a temperature greater than 45°C can be guaranteed at the entry to the calorifier. Any pre-heater should have a low water capacity. Heat recovery/systems for pre-heating water for domestic purposes should not be installed in healthcare premises unless there are adequate fail-safe measures in place to ensure that the hot water distribution system is not compromised.

14.6 Further guidance on energy conservation in relation to hot and cold water systems is given in HTM 07-02 – 'Encode' (see also the Carbon Trust's website).

15 Installation, testing and commissioning

See also Chapter 11 on commissioning in HTM 04-01: Supplement – 'Performance specification D 08: thermostatic mixing valves (healthcare premises)'.

15.1 While testing and commissioning is regarded as a discrete activity, continuous monitoring is required throughout the installation to ensure that:

a. materials and equipment installed comply with the Water Supply (Water Fittings) Regulations 1999 and other British Standards, and are not otherwise unsuitable. For example, equipment has been assessed and shown mechanically and materially to be appropriate (for example, suitable approvals) for the intended purpose (see paragraph 1.15) and has been installed in accordance with any relevant conditions;

b. the work is done entirely within the specification for the scheme;

c. all the requirements of current legislation are met, both during construction of the installation and when it is completed, particularly with regard to the Health and Safety at Work etc. Act 1974.

Installation checks

15.2 The system should be regularly checked during installation to ensure that open pipes, valve ends, cylinder connections etc are sealed to prevent the ingress of dust/debris that could cause problems during commissioning and subsequent operation (see paragraph 12.30). Checks should also be made to ensure that lead solders are not being used.

Commissioning

15.3 Correct commissioning is vitally important for the satisfactory operation and long-term control of hot and cold water systems. Where buildings are to be occupied in stages, the systems should be commissioned in stages as occupation is anticipated. The design team should prepare a commissioning brief for use by the contractor's commissioning engineer which has been agreed as suitable for purpose by the WSG with input from specialist external advisers if necessary.

15.4 A water risk assessment and associated method statements should be prepared by the design team and contractors, and this should be agreed by the WSG before commissioning begins. As commissioning correctly is such an important step in ensuring the safety of the building for the rest of its life-cycle, estates departments should ensure competent staff are available for witnessing key stages.

15.5 The water system should be filled as late in the commissioning process as possible. The design team should consider using inert gas for pressure-testing when possible. The system should be flushed to remove all flux and debris before being filled with water as soon as possible, but within a maximum of 48 hours, to prevent biofilm development and corrosion. Wholesome water should be used for flushing. Treated water should be available for top-up as necessary during the commissioning process.

All strainers should be cleaned after flushing and before final filling.

15.6 After water has been introduced into the system, a flushing regime should be introduced to maintain the wholesomeness of the water content.

15.7 It is essential that the results of all checks and measurements are recorded in writing at the time they are made. Breaks in the continuity of commissioning operations are likely, and proper records will show the state of progress at any stage. It is most important that commissioning records are provided as part of the handover information.

15.8 The commissioning brief should specify fully and clearly the extent of the commissioning, the competencies of the personnel to be carrying out the process and the objectives which should be achieved, and should include:

a. full design data on temperatures, water flow rates and pressures;

b. plant and equipment data;

c. number of commissioning procedures for thermostatic mixing valves in accordance with Chapter 11 of HTM 04-01: Supplement – 'Performance specification D 08: thermostatic mixing valves (healthcare premises)';

d. drawings and schematics;

e. a list of test certificates to be provided.

15.9 The design team's attention is drawn to CIBSE's Commissioning Code W – 'Water distribution', which provides guidance on information that will be required by the commissioning engineers.

15.10 In the preparation of commissioning instructions for domestic hot and cold water services, design teams should ensure that their work is in accordance with up-to-date guidance.

15.11 The design team should prepare for inclusion in the contract documents a list of tests and measurements that are to be taken by the contractor and recorded by him/her. These should be witnessed by the contract supervising officer or project engineer on his/her behalf and he/she, if approved, will circulate the results, in accordance with the client's instructions.

15.12 The installation, on completion, should be operated by the contractor as a whole, and subjected to functional or performance tests as specified by the design team.

15.13 The commissioning manual should be prepared by the contractor and submitted to the client's commissioning adviser and the WSG (with support from their specialist adviser if required) for review before being issued in final form.

15.14 Typical schedules of checks and performance tests should be included in the commissioning manual together with record sheets. These should be amended and supplemented as the design team considers necessary.

15.15 Once the client's commissioning adviser is satisfied that the system meets the design intent, the final accordance record sheets should be completed. If performance is not acceptable, the matter should be dealt with in accordance with the contract requirements.

15.16 The supervising officer or project engineer, who should countersign any relevant test record documents, should witness commissioning and testing.

15.17 "As installed" record drawings, schematic diagrams, and operating and maintenance instructions should be supplied at the time of handover. Certified records of pressure-testing and disinfection should also be made available.

15.18 The whole commissioning procedure should be carried out under the guidance of a single authority, although the involvement of specialists or manufacturers may be required for specific items of plant.

15.19 Valid calibration certificates should be submitted and checked for all measuring equipment to be used by the commissioning engineers before the start of the commissioning phase.

15.20 The commissioning should be carried out in a logical and methodical manner.

15.21 The installation, on completion, should be operated by the contractor as a whole, and subjected to specified functional or performance tests.

15.22 Once the system meets the design intent, the final completion record sheet(s) should be completed. In the event of performance not being acceptable, the matter should be dealt with in accordance with the contract requirements.

Commissioning and testing checklists

15.23 The following is a summary of the key activities associated with pre-commissioning and commissioning of hot and cold water storage and distribution systems. The list is not intended to be comprehensive.

Note

Before water is introduced into any part of the system, checks should be carried out to determine that appropriate backflow prevention measures have been implemented (see paragraph 9.10).

Cold water installations

15.24 Pre-commissioning checks can be carried out on completion of the system installation, filling and pressure-testing.

15.25 Pre-commissioning checks and tests to be applied are as follows. Check that:

a. systems have been provided and installed in accordance with specification and drawings, and that the systems are charged with water, vented and free from leaks;

b. water storage cisterns are free from distortion and leaks, are properly supported and secured, are provided with correctly fitting covers, and are in accordance with the Water Supply (Water Fittings) Regulations 1999;

c. distribution pipework is rigidly supported, insulated, and incorporates adequate provisions for venting, draining, expansion, isolation and measurement of flow, temperature and pressure;

d. pipework systems have been pressure-tested;

Note

Except where otherwise specified, testing of underground pipelines should be carried out in accordance with the requirements of the Water Supply (Water Fittings) Regulations 1999.

e. pipework systems and storage/break-tanks are correctly identified and marked;

f. regulating valves and flow control devices operate freely;

g. water meter(s) is/are fitted correctly;

h. electrical isolation, cross-bonding and wiring of system components are installed in accordance with the current edition of BS 7671.

Hot water installations

15.26 Pre-commissioning checks can be carried out upon completion of system installation, filling and pressure-testing.

Note

Before water is introduced into any part of the system, checks should be carried out to determine that appropriate backflow prevention measures have been implemented (see paragraph 10.10).

15.27 Pre-commissioning checks and tests to be applied are as follows. Check that:

a. systems have been provided and installed in accordance with the specification and drawings;

b. the system is charged with cold water, vented, and free from leaks;

c. hot water storage vessels are free from leaks and are properly supported and secured;

d. distribution pipework is rigidly supported, insulated, and incorporates adequate provision for venting, drainage, expansion, isolation, and measurement of flow, temperature and pressure;

e. pipework systems, storage cylinders etc have been pressure-tested;

f. pipework systems, calorifiers and cisterns are correctly identified and marked;

g. regulating valves and flow control devices operate freely;

h. all control and regulating valves are labelled or marked to correspond with reference numbers on contract drawings;

i. electrical isolation, cross-bonding and wiring of system components is installed in accordance with the current edition of BS 7671;

j. up-to-date system schematics are displayed in a frame in the relevant plantroom.

Commissioning checks of hot and cold water systems

15.28 Upon satisfactory completion of the pre-commissioning checks, the systems should be cleaned, disinfected and flushed before refilling. Advice on cleaning and disinfection is given in HSG274 Part 2. (See also paragraphs 16.42–16.44 for guidance on the safe discharge of wastewater used during disinfection procedures.)

15.29 Commissioning checks and tests to be applied are as follows. Check that:

a. drain-down points flow when released and are free from leaks when shut, that air vents and release valves open correctly and are airtight when shut off, and that overflows run freely and discharged water does not cause flooding or damage;

b. float-operated valves function satisfactorily and are adjusted to achieve the correct water level;

c. all temperature and other controls are adjusted and calibrated to agreed design limits of system performance;

d. all electrical circuits are tested and the pump motor direction of rotation is correct, and that electrical controls and alarms function correctly;

e. operation of any safety or anti-flood device is satisfactory;

f. circulating and pressurisation pumps are free from excessive noise, vibration and leaks and that pressurisation vessels are filled to the correct water level;

g. expansion vessels where installed are filled to the correct water level;

h. control valves operate correctly and shut-off valves close tightly;

i. heat exchangers operate satisfactorily;

j. primary heating circuits are adjusted and regulated, and thermostatic settings are correct; and that bypass circuits and automatic control valves operate correctly;

k. remote and automatic control of pumps (if appropriate) is satisfactory, and there are no leaks at joints under maximum flow conditions;

l. the cold water and hot water circulating and distribution systems are vented and regulated;

m. thermostatic mixing devices and regulating valves are adjusted and set to desired values (TMVs require hot and cold water for testing and commissioning, and should be commissioned in accordance with Chapter 11 of HTM 04-01: Supplement – 'Performance specification D 08: thermostatic mixing valves (healthcare premises)');

n. all taps, mixers and outlets operate satisfactorily and that all strainers and shower outlets have been cleaned and are free from contamination;

o. water flow quantities at all plant items, regulating valves and flow-measuring valves are recorded;

p. mass flow rates from taps, main and other outlets in positions shown on contract drawings are satisfactory;

q. pressure drop at heat exchangers at full design demand flow is tested and recorded;

r. hydraulic balancing of hot water secondary circulation system is carried out to ensure that minimum temperatures are achieved in all parts of the circuit;

s. full load current of components does not exceed the recommended values;

t. the running current of components does not exceed the recommended values;

u. pump thermal overload trips are set.

Temperature testing

15.30 These tests should be performed and validated prior to contractual handover and bringing the system into use and when in occupation. Separate thermostatic measuring and recording equipment should be used, that is, independent of any building management system. It will be necessary to have systems fully operational and to simulate typical draw-off of water.

15.31 Tests should include:

a. measuring the incoming water temperature at the main water meter;

b. testing the inlet, outlet and surface water temperatures of cisterns and cold water feed/header tanks for the hot water calorifiers and water heaters. The temperature should be close to the water temperature of the incoming water;

c. testing the flow and return temperatures at connections to calorifiers and water heaters. These should not be less than 60°C and 50°C respectively;

d. testing the temperature in branches of hot water circulating systems installed in all departments to ensure that the system has been balanced, and that under "no draw-off" conditions 55°C is achieved in the circulating system at all outlets;

e. testing single cold water outlets and the cold water inlet to mixing valves to ensure temperature equilibrium below 20°C.

Sampling

15.32 The WSG should discuss and agree a sampling regime and appropriate parameters (physical, chemical and microbiological) depending on the intended use of the system and vulnerability of the patients. This should be agreed prior to tender.

15.33 Sampling should be carried out prior to any construction/refurbishment works and immediately prior to handover, but no sooner than 48 hours after disinfection. It is recommended that sampling is undertaken by an accredited organisation independent of the contractor.

Chlorine dioxide systems

15.34 Allowance should be made for the type of residual present in the incoming supply as part of the strategy for additional disinfection within premises. The dosage of chlorine dioxide should be proportional to the water flow and the dosing system should incorporate safeguards to prevent inadvertent overdosing. In the case of hot water distribution systems with calorifiers/water heaters operating conventionally (that is, at 60°C), there will be a tendency for chlorine dioxide to be lost by gassing off, especially if the retention time in a vented calorifier/water heater is long. In most cases, however, some concentration of total oxidant should be found in the hot water, although this should be far less than the 0.5 mg/L injected.

15.35 The required dose should be determined by incremental addition until it reaches a concentration that provides adequate preservation of water quality but should not exceed 0.5mg/L. The failsafe operation of the system plus any leak detection installed should be witnessed and verified.

Note 1

Initially during the commissioning process it may be necessary to maintain a higher dosage rate than 0.5mg/L.

Note 2

Excessive values of chlorine dioxide should be avoided subsequently since it can corrode copper and steel pipework and can also damage non-metallic pipework and component parts, particularly at higher temperatures.

15.36 Guidance on chlorine dioxide systems is given in HSG274 Part 2.

Copper and silver ionisation

15.37 Values of more than 0.2 mg/L copper and more than 0.02 mg/L silver are recommended at outlets to ensure effective control of *Legionella*. Analysis for silver and copper should be carried out by a UKAS-accredited laboratory.

15.38 Maintaining adequate silver/copper ion concentration in hard water systems can be difficult as a result of the build-up of scale on the electrodes potentially obstructing copper and ion release. Consequently more frequent checks will be necessary to ensure that the system is delivering adequate ion values. (The ionisation process of pH sensitive and dosing may need to be increased for pH values greater than 7.6.)

Note

The Water Supply (Water Quality) Regulations 2000 set a standard for copper of 2 mg/L, which must not be exceeded. However, there is currently no standard for silver used for domestic purposes. At the time of publication the European Union and WHO do not dictate any standards for silver as there is currently insufficient data for recommending a concentration limit. Equipment manufacturers generally recommend copper (0.2–0.8 mg/L) and silver (0.02–0.08 mg/L) ion concentrations to control *Legionella* effectively. See also paragraphs 5.18–5.20.

15.39 Where some of the outlets on the treated water systems are to be used for domestic purposes, regular water testing needs to be maintained to ensure that the copper concentration does not exceed 2.0 mg/L as Cu and the silver level does not exceed 0.1 mg/L as Ag at these outlets.

15.40 Guidance on silver and copper ionisation systems is given in HSG274 Part 2.

Other water treatment systems

15.41 A range of biocidal treatment systems are available, and further advice on their use is given in HSG274 Part 2.

Maintaining control of systems

15.42 After commissioning and prior to occupancy, it is essential to put in place measures to ensure that wholesome water and hot and cold water temperatures are maintained throughout the system. This will require regular flushing as determined by the WSG and associated risk assessments (see also clauses 2.40–2.52 in HSG274 Part 2).

Note

Once filled, systems should not be drained unless full disinfection is to be carried out prior to building occupancy and use. However, allowing water in newly installed capillary-jointed copper plumbing to stagnate can result in serious corrosion of the copper.

Discharge of wastewater used during disinfection procedures within buildings

15.43 Contaminated water from disinfection procedures that is run to waste, be it to a natural watercourse or sewer, can potentially result in a pollution hazard or affect the efficacy of a sewage treatment plant. It is therefore important that the appropriate consent to discharge is obtained prior to disposing of the contaminated water.

15.44 Where water from disinfection procedures is to be discharged into a watercourse or into a drain leading to a watercourse, consent to discharge should be obtained from the appropriate authority (the Environment Agency in England and Wales, the Scottish Environmental Protection Agency in Scotland, and the Department of the Environment for Northern Ireland in Northern Ireland).

15.45 Water from disinfection procedures may be classed as trade effluent and, prior to any discharge into a sewer or sewerage system, consent to discharge should be sought from the local water company that provides the sewage and trade effluent services to the site (sewerage undertaker). (See also page 33 of HBN 00-07 and also guidance from Water UK.)

Note

Dependent on the geographical location of the site with respect to the operational boundaries of water companies, the duties of the water undertaker and sewerage undertaker may be provided by two different companies.

16 Documentation

16.1 It is essential that a full report of all commissioning and testing activities is compiled and handed over to be incorporated within the operation and maintenance manuals.

16.2 These commissioning and testing records will be required so that subsequent maintenance and periodic checks can be made to ensure that the installation continues to operate as intended. Such information will include:

- results of temperature checks on the cold water supply;
- results of temperature checks on hot water circulating systems and trace-heated hot water installations; and
- commissioning and in-service test data for type 3 and type 2 TMVs (see Chapter 11 of HTM 04-01: Supplement – 'Performance specification D 08: thermostatic mixing valves (healthcare premises)').

The information should also include identification of, and test results for, sentinel taps.

16.3 Where continuous water treatment is installed, the commissioning records should include details of settings of the equipment, dosing rates and requirements for testing.

16.4 Operation and maintenance manuals should be in accordance with BSRIA's Building Applications Guide BG1/2007 – 'Handover O&M manuals and project feedback'.

16.5 As a minimum, for new installations or major refurbishment, the contract should require the following documents and drawings to be supplied:

a. full manufacturing details, including batch numbers of all pipes and fittings;

b. (in accordance with BS 8580) a risk assessment for the control of *Legionella*;

c. full records and certificates of pressure tests for all sections of pipework;

d. settings of all balancing valves, with readings of flow rates where applicable;

e. full details of each item of plant, including arrangement drawings and appropriate test certificates;

f. as-fitted drawings showing clearly the location of balancing valves, flows and settings, isolation valves, drain valves;

g. schematic drawings for installation in plantrooms showing all valves and items of plant;

h. full details of water treatment parameters and operating modes and settings;

i. full details of maintenance requirements;

j. detailed confirmation of disinfection procedures to BS EN 806 series (parts 1–5) and BS 8558 and results of post-disinfection microbiological analysis;

k. full records confirming that all materials and fittings hold WRAS or equivalent accreditation;

l. expected operational conditions of the water system (that is, expected pressures, expected temperatures, expected flow rate throughout the system as pressure drops will occur etc).

Appendix 1 Impact of water consumption on care pathways

Water figures per unit of healthcare activity are published by the NHS Sustainable Development Unit (NHS SDU):

http://www.sduhealth.org.uk/areas-of-focus/carbon-hotspots/pharmaceuticals/cspm/sustainable-care-pathways-guidance.aspx

Estates Return Information Collection (ERIC) data on total water consumption (litres per day per floor area) for each type of healthcare organisation can be found at: http://hefs.hscic.gov.uk/

Appendix 2 Overview of UK water legislation and regulation

The table below shows the principal acts and secondary legislation created to regulate the provision of public and private water supplies in the UK.

Legislation

Legislation	England	Northern Ireland	Scotland	Wales
Primary Legislation – Principal Acts	Water Industry Act 1991 (as amended)	The Water and Sewerage Services (Northern Ireland) Order 2006 (as amended)	Water (Scotland) Act 1980 (as amended) and Water Industry (Scotland) Act 2002	Water Industry Act 1991 (as amended)
Powers and Offences provided by the Principal Acts which can be used in relation Water Fittings Regulations enforcement	Water Industry Act 1991; Section 73 & 75	The Water and Sewerage Services (Northern Ireland) Order 2006; Articles 113 & 115	Water (Scotland) Act 1980; Schedule 4; Section 30(1)(a)& (b),& 30(2), & 31(1)	Water Industry Act 1991; Section 73 & 75
Secondary legislation – Public Water Supplies – Drinking Water Quality	The Water Supply (Water Quality) Regulations 2000 (as amended)	The Water Supply (Water Quality) Regulations (Northern Ireland) 2007 (as amended)	The Public Water Supplies (Scotland) Regulations 2014	The Water Supply (Water Quality) Regulations 2010
Secondary legislation – Public Water Supplies – Water Fittings	The Water Supply (Water Fittings) Regulations 1999 (as amended)	The Water Supply (Water Fittings) Regulations (Northern Ireland) 2009	The Water Supply (Water Fittings) (Scotland) Byelaws 2014	The Water Supply (Water Fittings) Regulations 1999 (as amended)
Secondary legislation – Private Water Supplies	The Private Water Supplies Regulations 2009 (as amended)	The Private Water Supplies Regulations (Northern Ireland) 2009 (as amended)	The Private Water Supplies (Scotland) Regulations 2006 and amended by The Water Quality (Scotland) Regulations 2010	The Private Water Supplies (Wales) Regulations 2010 (as amended)

The secondary legislation transposes into law the European Union Council Directive 98/83/EC on the quality of water intended for human consumption. Compliance with this Directive is the responsibility of the UK legislators (as a member state) with Defra providing representation as the regulatory authority.

Water Supply (Water Fittings) Regulations 1999 have been amended by:

- The Water Supply (Water Fittings) (Amendment) Regulations 1999 – SI 1506/1999
- The Water Act 2003 (Consequential and Supplementary Provisions) Regulations 2005 – SI 2035/2005
- The Construction Products Regulations 2013 – SI 1387/2013

Executive summary

Preamble

This current review and update of HTM 04-01 is intended to move users of the document towards a holistic management of water systems via Water Safety Groups (WSGs), Water Safety Plans (WSPs) and other initiatives.

This version draws together and updates the previous guidance and includes recommendations for the safe management of water systems, via the integration of the principle of WSGs and WSPs (first introduced in the HTM 04-01 *P. aeruginosa* addendum – published in March 2013), and how to manage and minimise the risks to health from various aspects, ranging from clinical risks, microbial and chemical contamination, changes to the water system, resilience of the water supply etc. It also introduces a stronger emphasis on staff competencies and the implementation of water hygiene awareness training.

Introduction

The development, construction, installation, commissioning and maintenance of hot and cold water supply systems are vital for public health. Healthcare premises are dependent upon water to maintain hygiene and a comfortable environment for patients and staff, and for treatment and diagnostic purposes.

Interruptions in water supply can disrupt healthcare activities. The design of systems should ensure that sufficient reserve water storage is available to minimise the consequence of disruption, while at the same time ensuring an adequate turnover of water to prevent stagnation in storage vessels and distribution systems.

This Health Technical Memorandum (HTM) gives comprehensive advice and guidance to healthcare management, design engineers, estate managers, operations managers, contractors and the supply chain on the legal requirements, design applications, maintenance and operation of hot and cold water supply, storage and distribution systems in all types of healthcare premises. It is equally applicable to both new and existing sites.

Aims of this guidance

The current review and update of HTM 04-01 is intended to move users of the document towards a holistic management of water systems via WSGs, WSPs and other initiatives.

It has been written to promote good practice for those responsible for the design, installation, commissioning, operation and maintenance of water services in healthcare premises, by:

- highlighting the need for robust governance and management;
- outlining the remit of the WSG and how this relates to the provision of safe water in healthcare premises;
- outlining key criteria and system arrangements to help stop the ingress of chemical and microbial contaminants and microbial colonisation and bacteria proliferation;
- illustrating temperature regimes for sanitary outlets to maintain water hygiene;
- ensuring the safe delivery of hot water;
- outlining how the correct selection of system components and correct use by occupants can help preserve the quality and hygiene of water supplies;

- providing a point of reference to legislation, standards and other guidance pertaining to water systems;
- providing a basic overview of possible potential waterborne pathogens;
- giving an overview of some of the different water systems (including components) and their safe installation, commissioning and operation and maintenance;
- providing typical system layouts and individual component location;
- providing information on thermostatic mixing valve configurations, appropriate usage and maintenance requirements;
- identifying key commissioning, testing and maintenance requirements for referral by designers, installers, commissioners, operators and management.

Controlling waterborne pathogens

The guidance gives comprehensive guidance on measures to control waterborne pathogens. While *Legionella* control is, in the main, associated with poor engineering configuration and maintenance, with no evidence of patient-to-patient or patient-to-outlet transfer, *P. aeruginosa* may be transferred to and from outlets and the water from both patients and staff. Suspected *P. aeruginosa* waterborne infections require additional investigations to determine the source and interventions from infection control specialists and microbiologists. Therefore, a temperature control regime is the traditional strategy for reducing the risk from *Legionella* and for reducing the growth and colonisation of other waterborne organisms within water systems. To prevent growth of *P. aeruginosa* and other waterborne pathogens, controls are necessary to manage the water system before and after the outlet.

As with all control measures, temperatures should be monitored at regular intervals to verify effective control.

Because of the complexity of hot and cold water distribution systems and the difficulty of maintaining a temperature control regime in some healthcare facilities, this guidance suggests that additional chemical, physical and other water control methods that have been shown to be capable of controlling microbial colonisation and growth may also be considered.

Main changes from the 2006 edition of HTM 04-01

- This 2016 edition of HTM 04-01 provides comprehensive guidance on measures to control waterborne pathogens such as *Pseudomonas aeruginosa Stenotrophomonas maltophilia, Mycobacteria* as well as *Legionella*.
- This edition has been updated to align with the Health and Safety Executive's (HSE's) recently revised Approved Code of Practice for *Legionella* (L8) and its associated HSG274 guidance documents.
- The Addendum to HTM 04-01 published in 2013 (and now Part C of HTM 04-01) introduced the concept of WSGs and WSPs. Part B of the HTM now includes updated guidance on the remit and aims of the WSG and WSP.
- New guidance has been included on the hygienic storing and installation of fittings and components and on the competency of installers/plumbers working on healthcare water systems. The guidance also outlines that any person working on water distribution systems or cleaning water outlets needs to have completed a water hygiene awareness training course. An example course outline is included.
- Guidance on sampling techniques for, testing for, and the microbiological examination of *Pseudomonas aeruginosa* samples – originally in the HTM 04-01 Addendum – is now included in Part B to complement similar guidance on *Legionella*.

Glossary and abbreviations

In addition to the definitions listed below, other definitions can be found in the Water Supply (Water Fittings) Regulations 1999; BS 6100; BS 8558; and BS EN 806.

Alert organisms: Alert organisms are microorganisms that have the potential to cause harm and disease in individuals and which can cause an outbreak of infection in a hospital environment. An alert organism is identified by the microbiology laboratory and referred to the infection prevention and control (IPC) team for assessment of possible healthcare-associated acquisition and to identify any possible environmental/equipment sources.

Augmented care units/settings – There is no fixed definition of "augmented care"; individual providers may wish to designate a particular service as one where water quality must be of a higher microbiological standard than that provided by the supplier. While this document provides broad guidance, the water quality required will be dependent on both the type of patient and its intended use. Most care that is designated as augmented will be that where medical/nursing procedures render the patients susceptible to invasive disease from environmental and opportunistic pathogens such as *Pseudomonas aeruginosa* and other alert organisms. In broad terms, these patient groups will include:

a. those patients who are severely immunosuppressed because of disease or treatment: this will include transplant patients and similar heavily immunosuppressed patients during high-risk periods in their therapy;

b. those cared for in units where organ support is necessary, for example critical care (adult paediatric and neonatal), renal, respiratory (may include cystic fibrosis units) or other intensive care situations;

c. those patients who have extensive breaches in their dermal integrity and require contact with water as part of their continuing care, such as in those units caring for burns.

Backflow – Flow upstream, that is in a direction contrary to the intended normal direction of flow, within or from a water fitting.

Biofilm: A biofilm is a complex layer of microorganisms that have attached and grown on a surface. This form of growth provides a niche environment for a wide range of microorganisms to interact and where the secretion of exopolysaccharides by bacteria will form an extracellular matrix for both bacteria and other unicellular organisms such as amoebae and flagellates to remain in a protected state.

Colony forming unit: Unit that gives rise to a bacterial colony when grown on a solid medium; this may be a single bacterial cell or a clump of cells.

Dead-leg – a length of water system pipework leading to a fitting through which water only passes infrequently when there is draw-off from the fitting, providing the potential for stagnation.

Flow straightener: A device inserted into the spout outlet of a tap to modify flow, take out turbulence and create an even stream of water.

Healthcare-associated infections (HCAI): encompasses any infection by any infectious agent acquired as a consequence of a person's treatment or which is acquired by a healthcare worker in the course of their duties.

Healthcare facility/building – all buildings: infrastructure, equipment, plant, embedded systems and related items that support the delivery of healthcare and services of all types, irrespective of their ownership or operation by third parties.

Healthcare organisations: organisations that provide or intend to provide healthcare services for the purposes of the NHS.

Legionellosis: a collective term for diseases caused by *Legionella* bacteria including the most serious Legionnaires' disease, as well as the similar but less serious conditions of Pontiac fever and Lochgoilhead fever.

Manual mixing tap – a tap that controls both the flow and temperature of water delivered.

Point-of-use (POU) filter: a filter with a maximal pore size of 0.2 µm applied at the outlet, which removes bacteria from the water flow.

Redundant pipework (also known as blind end): a length of pipe closed at one end through which no water passes.

Remediation: Any process that reduces the risk from harmful agents such as microorganisms.

Thermostatic mixing tap: a tap that controls the flow and by thermostatic means the temperature of water delivered.

Thermostatic mixing valve: valve with one outlet, which mixes hot and cold water and automatically controls the mixed water to a user-selected or pre-set temperature.

Transmission: Any mechanism by which an infectious agent is spread from a person or environmental source to a susceptible person.

Waterborne pathogen: microorganism capable of causing disease that may be transmitted via water and acquired through ingestion, bathing, or by other means.

Water outlet: (In this document) refers mainly to taps and showerheads, but other outlets, as indicated by risk assessments, may be considered important.

Water Safety Group (WSG): A multidisciplinary group formed to undertake the commissioning and development and ongoing management of the water safety plan (WSP). It also advises on the remedial action required when water systems or outlets are found to be contaminated and the risk to susceptible patients is increased.

Water safety plan (WSP): A risk-management approach to the safety of water that establishes good practices in local water distribution and supply. It will identify potential hazards, consider practical aspects, and detail appropriate control measures.

Water supply [to the healthcare facility]: The water supplied can be via:

- the mains water supply from the local water undertaker;
- a borehole (operated by the healthcare organisation as a private water supply);
- a combination of mains water and borehole supply;
- emergency water provision (bulk tankered water or bottled drinking water).

Water undertaker – the role of a water undertaker is defined in a number of sections of the Water Industry Act 1991.

Wholesomeness: standards of wholesomeness are defined in section 67 of the Water Industry Act 1991. Separate legislation for public and private supplies sets out the prescribed concentrations and values for water and are detailed in the following legislation: the Water Supply (Water Quality) Regulations 2000 for water from a public supply; or the Private Water Supplies Regulations 2009 for water from a private supply.

List of abbreviations

cfu – colony forming units

COSHH – Control of Substances Hazardous to Health [Regulations]

CQC – Care Quality Commission

DWI – Drinking Water Inspectorate

EA – Environment Agency

EPDM – ethylene propylene diene monomer

HBN – Health Building Note

HSE – Health & Safety Executive

HSG274 Part 2 – The Health & Safety Executive's technical guidance on the control of Legionnaires' disease in hot and cold water systems.

HTM – Health Technical Memorandum

MCA: milk cetrimide agar

MRD: maximum recovery diluent

POU – point-of-use

PWTAG – Pool Water Treatment Advisory Group

SHTM – Scottish Health Technical Memorandum

WRAS – Water Regulations Advisory Scheme

WSG – Water Safety Group

WSP – Water safety plan

0 Policy and regulatory overview: water safety and the healthcare estate

Introduction

0.1 The National Health Service (NHS) has a corporate responsibility to account for the stewardship of its publicly funded assets. This includes the provision, management and operation of an efficient, safe estate that supports clinical services and strategy.

0.2 This corporate responsibility is carried by all accountable officers, directors with responsibility for estates and facilities and their equivalents, chairs, chief executive officers and non-executive board members. Together they have a responsibility to enact the principles set out in this document, provide leadership and work together to implement the necessary changes to provide a safe, efficient high quality healthcare estate.

0.3 To achieve this, quality and fitness-for-purpose of the healthcare estate is vital. Health Technical Memorandum (HTM) 04-01 seeks to set out the quality of, and standards for, water safety in the healthcare estate.

0.4 A healthcare organisation's Water Safety Group (WSG) (see Part B) is pivotal in ensuring that decisions affecting the safety and integrity of the water systems and associated equipment do not go ahead without being agreed by them. This includes consultations relating to decisions on the procurement, design, installation and commissioning of water services, equipment and associated treatment processes.

0.5 The quality and fitness-for-purpose of the estate are assessed against a set of legal requirements and governance standards. Adhering to the guidance outlined in this HTM will be taken into account as evidence towards compliance with these legal requirements and governance standards.

Compliance of the healthcare estate

0.6 Principles related to the safety of healthcare estates and facilities are enshrined in the Health and Social Care Act 2008 (Regulated Activities) Regulations 2014, specifically Regulation 12(2)(h) and Regulation 15 of the Act.

Note

There are numerous other statutes and legal requirements that NHS organisations, supporting professionals, contractors and suppliers must comply with. These are covered in the respective Health Building Notes (HBNs), Health Technical Memoranda (HTMs) and the NHS Premises Assurance Model (NHS PAM).

Health and Social Care Act 2008 (Regulated Activities) Regulations 2014

0.7 Regulation 12(2)(h) decrees that registered providers must assess:

- the risk of, and prevent, detect and control the spread of, infections, including those that are health care associated.

0.8 Appropriate standards of cleanliness and hygiene should be maintained in premises used for the regulated activity. DH (2015) issued 'The Health and Social Care Act 2008 Code of Practice on the prevention and control of infections and related guidance' (the HCAI Code of Practice), which contains statutory guidance about compliance with regulation 12(2)(h) (see paragraphs 0.15–0.17).

0.9 Regulation 15 of the Act states that:

(1) All premises and equipment used by the service provider must be –

a. clean,

b. secure,

c. suitable for the purpose for which they are being used,

d. properly used,

e. properly maintained, and

f. appropriately located for the purpose for which they are being used.

(2) The registered person must, in relation to such premises and equipment, maintain standards of hygiene appropriate for the purposes for which they are being used.

Note

The "registered person" means, in respect of a regulated activity, the person who is the service provider or a registered manager in respect of that activity.

A "service provider" means a person registered with the CQC under Chapter 2 of Part 1 of the Health and Social Care Act 2008 as a service provider in respect of that regulated activity.

Regulator requirements

0.10 The CQC independently regulates all providers of regulated health and adult social care activities in England. The CQC's (2015) 'Guidance for providers on meeting the regulations' explains how to meet regulations 12(2)(h) and 15 outlined above.

0.11 Failure to comply with the Health and Social Care Act 2008 (Regulated Activities) Regulations 2014 and the Care Quality Commission (Registration) Regulations (2009) is an offence, and the CQC has a wide range of enforcement powers that it can use if a provider is not compliant. These include the issue of a warning notice that requires improvement within a specified time, prosecution, and the power to cancel a provider's registration, removing its ability to provide regulated activities.

Examples of governance and assurance mechanisms arising from primary legislation (not exhaustive)

NHS Constitution

0.12 The Health Act 2009 places a duty on bodies providing and commissioning NHS services to have regard to the NHS Constitution. The Health and Social Care Act 2012 further applied this duty to the new bodies created by that Act or by amendments to the 2012 Act.

0.13 The NHS Constitution "sets out rights to which patients, public and staff are entitled". It also outlines "the pledges which the NHS is committed to achieve, together with responsibilities that the public, patients and staff owe to one another to ensure that the NHS operates fairly and effectively".

0.14 It commits the NHS to ensuring "**that services are provided in a clean and safe environment that is fit for purpose, based on national best practice (pledge)".** In order to deliver on this pledge, the NHS should take account of:

- the NHS Premises Assurance Model (NHS PAM) – the NHS PAM identifies where the NHS Constitution needs to be considered and where assurance is required;

- national best practice guidance for the design and operation of NHS healthcare facilities (such as HBNs and HTMs).

The HCAI Code of Practice

0.15 A complex range of issues distinguishes healthcare environments from most other building types. One of the most important of these relates to the control of infection. Infection prevention and control teams should be consulted on any design decisions and a risk analysis conducted on the many issues of design involving water systems (see HBN 00-09 – 'Infection control in the built environment'). To manage and monitor the prevention and control of infections effectively, the HCAI Code of Practice requires a WSG and a water safety plan (WSP) to be in place.

0.16 The information outlined in HBN 00-09 follows the general principles given in the HCAI Code of Practice, which sets out criteria against which a registered provider will be judged on how it complies with Regulation 12(2)(h) of the Health and Social Care Act 2008 (Regulated Activities) Regulations 2014 on the prevention, detection and control of infections, particularly waterborne infections in relation to this document.

0.17 The law states that the HCAI Code of Practice must be taken into account by the CQC when it makes decisions about registration against the cleanliness and infection control requirement. The regulations also say that providers must have regard to the Code when deciding how they will comply with registration requirements. Therefore, by following the Code, registered providers will be able to show that they meet the requirement set out in the regulations. However, the Code is not mandatory. A registered provider may be able to demonstrate that it meets the regulations in a different way (equivalent or better) from that described in this document. The Code aims to exemplify what providers need to do in order to comply with the regulations.

Figure 1 illustrates how DH estates and facilities best practice guidance (such as the NHS PAM and HTMs) aligns with the statutory and policy framework. This guidance is fundamental to ensuring that NHS trusts are able to deliver on their commitments under the NHS Constitution and to comply with the CQC's fundamental standards.

Never events

0.18 NHS England's never events policy framework defines "never events" as serious, largely preventable patient safety incidents that should not occur if the available preventive measures have been implemented by healthcare providers. On the list of never events is scalding of patients. The risk of scalding for vulnerable patients (children and young people, older people, and disabled people) is a particular problem in healthcare premises. HTM 04-01 provides guidance on reducing the risk of scalding.

Health and safety legislation

0.19 In the UK, the control of *Legionella*e falls within the requirements of the Health and Safety at Work etc. Act. This Act also places duties on design teams, suppliers and installers to ensure that articles or substances for use at work are safe and without risks to health and that any information related to the article or substance is provided. The Management of Health and Safety at Work Regulations 1999 provide a broad framework for controlling health and safety at work. The Control of Substances Hazardous to Health Regulations 2002 (COSHH) provide a framework of actions designed to assess, prevent or control the risk from bacteria like *Legionella* and take suitable precautions.

0.20 The Health & Safety Executive's (HSE) (2013) Approved Code of Practice 'Legionnaires' disease: The control of *Legionella* bacteria in water systems (L8)' contains practical guidance on how to manage

and control the risks in water systems. The HSE has published complementary technical guidance in HSG274, which is split into three specific areas:

- Part 1 – evaporative cooling systems;
- Part 2 – hot and cold water systems; and
- Part 3 – other risk systems.

0.21 In addition, under the Reporting of Injuries, Diseases and Dangerous Occurrences Regulations (RIDDOR), there is a duty for employers to report any cases of legionellosis in an employee who has worked on hot and cold water systems that are likely to be contaminated with *Legionella*. Cases of legionellosis are reportable under RIDDOR if:

a. a doctor notifies the employer; and

b. the employee's current job involves work on or near cooling systems that are located in the workplace and use water; or work on water-service systems located in the workplace which are likely to be a source of contamination.

0.22 With regard to enforcement responsibilities, the HSE will take the lead with regard to incidents involving *Legionella*. See the Health and Safety Executive/Care Quality Commission/Local Government Association's (2015) 'Memorandum of understanding between the Care Quality Commission, the Health and Safety Executive and local authorities in England'.

Security

0.23 Accessibility to all plant and equipment should be limited to authorised personnel only (see NHS Protect's (2012) 'Guidance on the security and management of NHS assets').

Water regulations

0.24 As well as complying with the recommendations outlined in this document, the design and installation of the hot and cold water services, new or extended, in any healthcare premises should also comply with:

- the Water Supply (Water Fittings) Regulations 1999;
- Defra's guidance to the Water Supply (Water Fittings) Regulations;
- recommendations of the water suppliers in the Water Regulations Advisory Scheme's (WRAS) 'Water Regulations Guide'; and
- any other requirements of the local water undertaker.

Water Supply (Water Fittings) Regulations 1999

0.25 These Regulations set legal requirements for the design, installation, operation and maintenance of plumbing systems, water fittings and water-using appliances. They have a specific purpose to prevent misuse, waste, undue consumption or erroneous measurement of water and, most importantly, to prevent contamination of drinking water.

0.26 These Regulations apply in all types of premises supplied, or to be supplied, with water from a water undertaker. They apply from the point where water enters the property's underground pipe, to where the water is used in plumbing systems, water fittings and water-using appliances. However they do not apply in premises that have no provision of water from the public mains supply.

Water Supply (Water Quality) Regulations 2000

0.27 These Regulations cover the quality of water supplied by water undertakers for public distribution which is intended for domestic purposes; these purposes include drinking, cooking, food preparation, washing and sanitation. Water supplied meeting these quality requirements is referred to as wholesome water.

Private Water Supplies Regulations 2009

0.28 These Regulations cover private sources of water intended for human consumption including drinking, cooking, food preparation or other domestic purposes, such as boreholes and wells. Water meeting these quality requirements is referred to as wholesome water. These Regulations also place duties for monitoring and control of the quality of public water supplies where these are then further distributed to other users on separate premises by the water company's bill payer (this arrangement is often referred to as onward distribution).

0.29 Local authorities are the regulators for private water supplies and have a number of statutory duties under the Private Water Supplies Regulations.

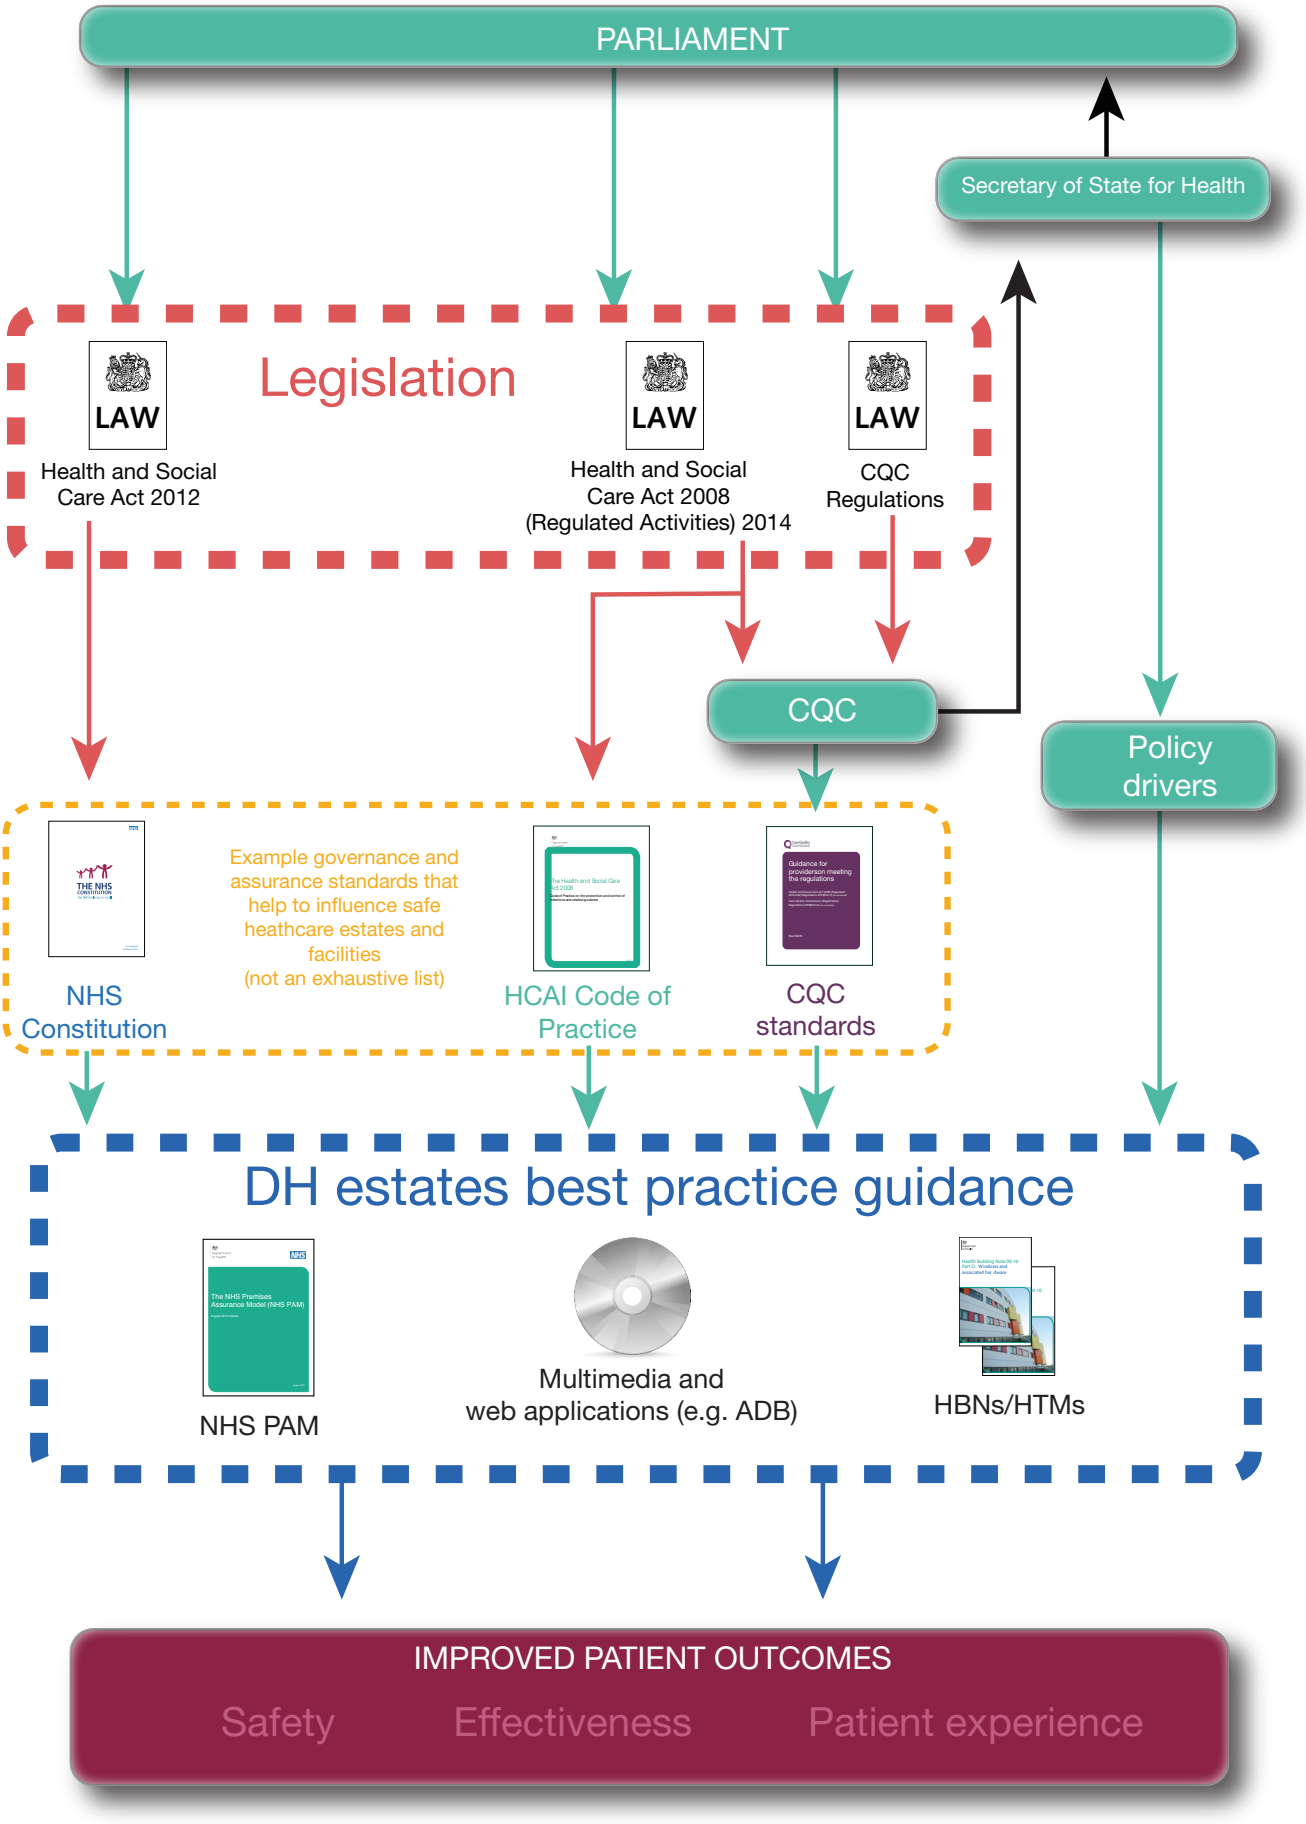

Figure 1 How best practice guidance on the safety and quality of healthcare estates and facilities fits in with the legislative and policy framework. (The statutes and mandatory requirements shown in this figure are not exhaustive. See Note after paragraph 0.6.)

1 Introduction

1.1 This edition of HTM 04-01 – 'Safe water in healthcare premises' supersedes HTM 04-01 – 'The control of *Legionella*, hygiene, "safe" hot water, cold water and drinking water systems' published in 2006. It is also based on the guidance given in HTM 04-01: Addendum '*Pseudomonas aeruginosa* – advice for augmented care units'. It has been revised to take account of revisions to the HSE's (2013) Approved Code of Practice L8 and technical guidance HSG274.

1.2 This HTM gives comprehensive advice and guidance to healthcare management, design engineers, estate managers, operations managers and infection control specialists on the legal requirements, design applications, installation, commissioning, maintenance and operation of hot and cold water supply, storage and distribution systems and associated equipment and systems in all types of healthcare premises. It is equally applicable to both new and existing sites.

1.3 In its new form, the document is divided in three parts. This part (Part B) covers operational management, including the control of *Legionella, P. aeruginosa* and other important waterborne pathogens. This document should be read in conjunction with Part A which outlines the principles involved in the design, installation, commissioning and testing of the hot and cold water supply, and storage and distribution systems for healthcare premises. Some variation may be necessary to meet the differing provision arrangements of the various water undertakers and complexity of distribution systems. Part C covers water safety in augmented care settings.

General

1.4 Current statutory legislation requires both "employers" and "employees" to be aware of their individual and collective responsibility for the provision of safe wholesome hot and cold water supplies, and storage and distribution systems in healthcare premises. Ultimate responsibility for management will fall to the statutory duty holder of the premises (see paragraph 1.8 for a definition of the statutory duty holder).

1.5 Healthcare premises are dependent on water to maintain hygiene and a comfortable environment for patients, visitors and staff, and for clinical and surgical care.

1.6 Intelligent design, construction, installation, commissioning and maintenance of hot and cold water supply systems to minimise the risks of waterborne illness are vital for public health.

1.7 Interruptions in water supply can disrupt healthcare activities. Procedures should be in place to minimise the consequence of disruption, while at the same time ensuring an adequate turnover of water to prevent stagnation in storage vessels and distribution systems (see paragraphs 2.16–2.17 in HTM 04-01 Part A and also HBN 00-07 – 'Planning for a resilient healthcare estate').

Duty holder

1.8 In this document, the statutory duty holder is either the employer or the person in control of the healthcare premises. Typically these could be the owner, chief executive, board of

directors, or other person who is ultimately accountable, and on whom the duty falls, for the safe operation of healthcare premises.

Shared premises

1.9 In estate management, it is increasingly common for there to be several duty holders in one building. In such cases, duties may arise where persons or organisations have clear responsibility through an explicit agreement such as a contract or tenancy agreement.

1.10 The extent of the duty will depend on the nature of that agreement. For example, in a building occupied by one leaseholder, the agreement may be for the owner or leaseholder to take on the full duty for the whole building or to share the duty. In a multi-occupancy building, the agreement may be that the owner takes on the full duty for the whole building. Alternatively, it might be that the duty is shared where, for example, the owner takes responsibility for the common parts while the leaseholders take responsibility for the parts they occupy. In other cases, there may be an agreement to pass the responsibilities to a managing agent. Where a managing agent is used, the management contract should clearly specify who has responsibility for maintenance and safety checks, including managing the risk from waterborne hazards.

1.11 Where there is no contract or tenancy agreement in place or it does not specify who has responsibility, the duty is placed on whoever has control of the premises or part of the premises.

Areas this HTM does not cover

1.12 Although many of this HTM's recommendations will be applicable, it does not set out to cover water supply for fire-fighting services nor water supply for technical, industrial or other specialist purposes, other than to indicate precautions that should be taken when these are used in association with domestic water services. The point at which a domestic activity becomes an industrial process has not been defined, and the applicability will need to be considered in each case.

1.13 This HTM does not cover wet cooling systems such as cooling towers. Guidance on these systems is given in HSE's Approved Code of Practice and guidance 'Legionnaires' disease: The control of *Legionella* bacteria in water systems (L8)' and HSG274 technical guidance Part 1.

1.14 While some guidance on other water-service applications is included, it is not intended to cover them fully. For:

- process waters used for laundries, see HTM 01-04 – 'Decontamination of linen in health and social care';
- endoscopy units, see HTM 01-06 – 'Decontamination of flexible endoscopes';
- primary care dental premises, see HTM 01-05 – 'Decontamination in dental practices';
- renal units, see HBNs 07-01 and 07-02, the Renal Association's guidelines, BS EN ISO 13959 and BS EN ISO 11663;
- sterile services departments, see HBN 13 – 'Sterile services department';
- hydrotherapy pools, see the PWTAG's 'Swimming pool water: treatment and quality standards for pools and spas';
- spa pools, see HSE/PHE's 'Management of spa pools: controlling the risks of infection';

Note

This document is currently being revised and will become HSG274 Part 4 – 'The control of *Legionella* and other infectious agents in spa pool systems'.

- birthing pools, see HBN 09-02 – 'Maternity care facilities' and PWTAG's 'Swimming pool water: treatment and quality standards for pools and spas'.

2 Governance and management responsibility

Note

Governance is concerned with how an organisation directs, manages and monitors its activities to ensure compliance with statutory and legislative requirements while ensuring the safety of patients, visitors and staff is not compromised.

To help achieve this, healthcare organisations need to ensure that sound policies are approved by the board of directors. These should:

- ensure safe processes, working practices and risk-management strategies are in place to safeguard all their stakeholders and assets in order to prevent and reduce harm or loss; and
- be backed up with adequate resources and suitably qualified, competent and trained staff.

2.1 This guidance should be applied to all healthcare premises, however small, where there is a duty of care under the Health and Safety at Work etc. Act 1974.

2.2 To ensure governance with regard to water safety, the duty holder will:

- identify and assess sources of risk;
- if appropriate, prepare a written scheme for preventing or controlling the risk;
- implement, manage and monitor precautions;
- keep records of the precautions;
- appoint a competent person with sufficient authority and knowledge of the installation to help take the measures needed to comply with the law.

2.3 To implement the above legal duties in a healthcare organisation, the duty holder should appoint a WSG to undertake the commissioning, development, implementation and review of a WSP. The aim of the WSG is to ensure the safety of all water used by patients/residents, staff and visitors, and to minimise the risk of infection associated with waterborne pathogens. This is supported by the HCAI Code of Practice (see paragraphs 0.15–0.17), which recommends that management and monitoring arrangements should ensure that a WSG and WSP are in place.

2.4 The WSP should demonstrate that any person on whom the statutory duty falls has fully appreciated the requirement to provide an adequate supply of hot and cold water of suitable quality. Though compliance with this guidance may be delegated to staff or undertaken by contractors, accountability cannot be delegated. The WSG should ensure that appropriate expertise and competence is available to ensure the delivery of safe water for all uses throughout the organisation. This group should have clearly identified lines of accountability up to the CEO and board. For membership of the group, see paragraphs 6.5–6.6.

2.5 The WSG should include persons who are fully conversant with the design principles and requirements of water systems and should be fully briefed in respect of the cause and effect all waterborne hazards.

2.6 The WSP is a holistic approach to manage water for all uses (including diagnostic and treatment purposes) so that it is safe for all users including those most at risk of waterborne infections as a consequence of their illness or treatment (see paragraphs 6.16–6.22).

2.7 All regular tests and checks set out in the WSP should be carried out even if they cause minor disruption to healthcare services, and comprehensive records should be maintained in accordance with the healthcare organisation's management policy.

2.8 A risk assessment forms an integral component of the WSP and is a legal requirement to identify potential hazards (which may be microbial, chemical or physical) in the system, risks of infection to patients, staff and visitors, and other indicators of water quality (for example, taste, odour, flavour and appearance if intended for drinking). See paragraphs 6.23–6.26 for typical examples of issues to consider in the risk assessment.

2.9 The risk assessment should be carried out by a competent person or persons. If the provision of risk assessments is contracted to an external organisation, it is recommended that those engaged to carry out any risk assessments associated with water safety should be able to demonstrate to the WSG their experience and competence in assessing specific risks from microbiological, chemical and physical hazards on the specific healthcare population. They should also be able to give advice on how to manage the systems/equipment to minimise the risks etc. It is the responsibility of the WSG to determine the method of demonstrating this competence. Core requirements including accredited training and personal examples of recent water safety risk assessments in the healthcare sector presented orally and/or by interview should be considered options. Detailed knowledge and expertise requirements of the risk assessor(s) are provided in the World Health Organization's (WHO) (2011) 'Water safety in buildings'.

2.10 The risk assessor(s) should be given access to competent assistance from the client. This may be in the form of:

- engineering and building expertise;
- as-fitted drawings and schematic diagrams;
- clinical expertise;
- knowledge of building occupancy and use including vulnerability of patient groups;
- bespoke equipment plus policies, procedures and any protocols (for example cleaning of wash-hand basins and disposal of clinical effluent etc).

2.11 In addition access should be made available to all required areas (and associated systems and equipment) unless deemed inaccessible by legislation (for example areas that contain asbestos).

2.12 For *Legionella* risk assessments, contractors should be able to demonstrate a full understanding of, and work to, BS 8580. In addition to guidance provided above, the documents below should also be referenced in relation to the specification, procedures and general requirements for completing robust and fit-for-purpose water safety risk assessments:

- HSG274 Part 2 (2014) – 'The control of *Legionella* bacteria in hot and cold water systems'.
- BS 8580 – 'Water quality: risk assessments for *Legionella* control – Code of Practice'.
- BSRIA's (1999) FMS 4/99 – 'Guidance and the standard specification for water services risk assessment'.
- BSRIA's (2015) BG 57/2015 – 'Legionnaires' disease – risk assessment'.

2.13 Management procedures should ensure that compliance is continuing and not notional. The prime purpose of the assessment is to be able to demonstrate that the WSG is aware of

all the relevant factors that may pose a risk of waterborne infection, that effective corrective or preventive action has been implemented, and that monitoring is in place to ensure the plans are effective in controlling the risk.

2.14 Healthcare organisations should be aware of the legal duty to notify the water undertaker when it is proposed to carry out works on any systems conveying water from the public water supply (see the WRAS website).

Note

Water undertakers can carry out a fittings inspection to ensure that work has been properly carried out and that the public water supply remains protected for work carried out.

3 Statutory requirements

3.1 It is the responsibility of the duty holder to ensure that their premises comply with all statutes.

3.2 Duty holders have an overriding general duty of care under the Health and Safety at Work etc. Act 1974. Therefore, they should ensure that the water supply, storage and distribution services are installed and operated within the terms of the following legislation.

Health and Safety at Work etc. Act 1974

3.3 Employers have a general duty under the Health and Safety at Work etc. Act 1974 to ensure, so far as is reasonably practicable, the health, safety and welfare of patients, visitors and staff and the public who may be affected by workplace activities.

3.4 These duties are legally enforceable, and the HSE has successfully prosecuted employers including health organisations under this statute. It falls upon owners and occupiers of premises to ensure that there is a management regime for the proper design, installation and maintenance of plant, equipment and systems. Failure to have a proper system of working and adequate control measures can also be an offence even if an outbreak of, for example, Legionnaires' disease or other such incident has not occurred.

The Management of Health and Safety at Work Regulations 1999

3.5 These regulations provide a broad framework for controlling health and safety at work. They require every employer to make a suitable and sufficient assessment of all risks to health and safety of employees and the public caused by work activities, and require employers to have access to competent help in applying the provisions of health and safety law. In addition to *Legionella* and other waterborne pathogens, other risks from a hot and cold water distribution system include deterioration of water quality, scalding at hot water outlets and danger due to pipe bursts at excessive pressures.

Control of Substances Hazardous to Health (COSHH) Regulations 2002

3.6 These regulations provide a framework of actions designed to control the risk from a range of harmful substances including waterborne pathogens such as *Legionella* and the chemicals that may be used to control the growth of microorganisms in water supplies. Employers have a duty to assess the risks from exposure to these substances to ensure that they are adequately controlled.

Public Health (Infectious Diseases) Regulations 1988

3.7 The Public Health (Infectious Diseases) Regulations 1988 require that a properly appointed officer inform the chief medical officer for England or for Wales, as the case may be, of any serious outbreak of any disease that to his/her knowledge has occurred in the district.

Note

Appendix 2.3 of HSE's *Legionella* technical guidance HSG274 Part 2 (2013) contains further advice and guidance on communication and cooperation with the consultant in communicable disease control (CCDC), and on arrangements for support of the CCDC and for this person to have access to provider units including healthcare organisations.

Water Supply (Water Quality) Regulations 2000

3.8 The Water Supply (Water Quality) Regulations 2000 apply to water supplied by a water undertaker to any premises that are used for domestic purposes such as drinking, cooking, personal hygiene, washing or food production.

Note

Two additional sources of advice on drinking water quality are:

a. the director of public health;

b. WHO's 'Guidelines for drinking water quality'.

Private Water Supplies Regulations 2009

3.9 These regulations cover private sources of water such as boreholes and wells intended for human consumption including drinking, cooking, food preparation or other domestic purposes. These regulations also place duties for monitoring and control of the quality of public water supplies where these are then further distributed to separate premises by the bill payer other than the water undertaker or licensed water supplier (often referred to as onward distribution).

Food Safety Act 1990

3.10 The Food Safety Act 1990 covers water used for food preparation or food manufacture and also includes water used for drinking. The Food Safety and Hygiene (England) Regulations 2013 are also relevant.

The Health and Safety Executive's (4th edition) Approved Code of Practice L8 2013

3.11 The HSE's (2013) Approved Code of Practice L8 (4th edition) came into effect on 7 November 2013 and is supported by the technical guidance (HSG274 Parts 1–3). It replaced the earlier publication entitled 'Legionnaires' disease: The control of *Legionella* bacteria in water systems – Approved Code of Practice and guidance' (L8 3rd edition). The onus is on the duty holder to demonstrate that procedures in place are as good as, or better than, those required by L8.

3.12 The Approved Code of Practice L8 has a special legal status. If a person or organisation is prosecuted for a breach of health and safety law and it is proved that they did not follow the provisions of the Code, they will need to show that they have complied with the law in some other equally effective way or a court will find them at fault. Health and safety inspectors seek to secure compliance with the law and may refer to this guidance.

3.13 Compliance with HSG274 will satisfy the Approved Code of Practice L8.

3.14 The health service, with responsibility for the wider aspects of public health and the operation of healthcare premises, is expected to be particularly vigilant.

3.15 The incidence of healthcare-associated waterborne illness including Legionnaires' disease is relatively low, but cases and outbreaks are considered to be avoidable. Management, operators and contractors should be aware that incidents or outbreaks cause widespread concern, especially if associated with healthcare premises. Investigation of these outbreaks has shown that they are generally related to poor training, flaws in system design, poor commissioning and risk assessments, defects and breakdowns. However, by far the greatest contributors to outbreaks of Legionnaires' disease are poor or inappropriate maintenance and control procedures and ineffective communication and systems management.

Water Supply (Water Fittings) Regulations 1999

3.16 These regulations set legal requirements for the design, installation, operation and maintenance of plumbing systems, water fittings and water-using appliances. They have a specific purpose to prevent misuse, waste, undue consumption or erroneous measurement of water and, most importantly, to prevent contamination of drinking water. These regulations are enforced by the local water undertaker.

3.17 These regulations apply in all types of premises supplied, or to be supplied, with water from a water undertaker. They apply from the point where water enters the property's underground pipe, to where the water is used in plumbing systems, water fittings and water-using appliances. However they do not apply in premises that have no provision of water from the public mains supply.

3.18 These regulations are set out – along with the Department for Environment, Food and Rural Affairs' (Defra) guidance on the regulations and the water industry's recommendations for fulfilling these provisions – in the 'Water Regulations Guide' published by the Water Regulations Advisory Scheme (WRAS).

British and European Standards

- The BS EN 805 series covers design and installation requirements for systems and components outside buildings.
- The BS EN 806 series covers installations inside buildings conveying water for human consumption.
- BS 8558 provides UK-specific complementary guidance to the BS EN 806 series of standards, replacing BS 6700.
- BS 1710 is the British Standard specification for identification of pipelines and services.
- PD 855468 – 'Guide to the flushing and disinfection of services supplying water for domestic use within buildings and their curtilages'.
- BS 8551 – 'Provision and management of temporary water supplies and distribution networks (not including provisions for statutory emergencies). Code of practice'.
- BS 8554 – 'Code of practice for the sampling and monitoring of hot and cold water services in buildings'.
- BS 7592 – 'Sampling for *Legionella* bacteria in water systems. Code of practice'.

4 *Legionella*: overview

Source of the bacteria

4.1 *Legionella* bacteria are ubiquitous in both the natural and constructed aquatic environment and are widespread in natural freshwater including rivers, lakes, streams and ponds and may also be found in damp soil.

4.2 Airborne dispersal may occur when aerosols or droplet nuclei are created. There is a strong likelihood of low concentrations of *Legionella* existing in all open water systems including those of building services; therefore, the main emphasis should be on preventing *Legionella* from multiplying in water systems in healthcare premises.

Ecology

4.3 The following factors have been found to influence the colonisation and growth of *Legionella*:

a. Water temperature between 20°C and 45°C will promote growth.

b. Areas of poor flow, stagnation or inappropriate components.

c. Biofilms play an important role in harbouring and providing favourable conditions in which *Legionella* can grow. Biofilms in water systems are heterogeneous and will consist of bacteria, fungi, algae, protozoa, debris and corrosion products. Nutrients can be provided to the biofilm from the incoming water, particularly where there is increased turbidity and also from scale, sediment, corrosion products, trapped organic and inorganic molecules supplied by the flowing water and a range of surface materials.

d. *Legionella* are unable to grow in sterile water as they require other microorganisms for growth. *Legionella* have also been shown to proliferate rapidly in association with some waterborne protozoa including amoebae.

e. Water fittings, pipework and materials used in the construction of water systems can encourage the growth of waterborne pathogens. Water quality can deteriorate within the system and in components such as terminal fittings, particularly when utilisation is low. Pipework downstream of thermostatic mixing valves may pose a particular problem as the lower temperature can encourage the growth of waterborne pathogens.

Epidemiology

4.4 Legionnaires' disease is often described as an atypical acute pneumonia of rapid onset often with gastrointestinal symptoms, which can confuse the diagnosis. Legionnaires' disease is predominantly caused by inhalation of *L. pneumophila* serogroup 1, which is the commonest cause of Legionnaires' disease accounting for around 85% of cases within the EU (see the European Centre for Disease Prevention and Control's (ECDC) website). However, other non-*pneumophila* species have also been shown to cause disease in

hospitals. Pontiac fever is a self-limiting form of legionellosis which usually requires no treatment. Outbreaks of Pontiac fever have been associated with patients showering.

4.5 The risk of healthcare-associated legionellosis depends on a number of factors such as:

- the presence of *Legionella* in sufficient numbers (see also paragraph 4.15);
- conditions suitable for multiplication of the organisms (for example temperatures between 20°C and 45°C);
- source of nutrients (for example scale, sludge, rust, protozoa, and other available organic carbon, bacteria and biofilms);
- a means of creating and disseminating aerosols (a typical droplet size of <5 µm can be inhaled deep into the lungs) that contain viable *Legionella* (potential sources, for example, include showers and most other water draw-offs that are capable of creating an aerosol);

Note

Some cases of Legionnaires' disease in healthcare premises have been associated with aspiration of contaminated ingested water rather than inhalation of aerosols.

- the presence of people who may have compromised immune or respiratory systems or have other risk factors that increase their susceptibility to *Legionella* infection.

4.6 Many, if not all, of these factors are likely to be encountered in healthcare premises.

Control measures

See also:

- paragraphs 5.11–5.16 on management of control;
- Chapter 4 in Part A on water treatment and control programmes for hot and cold water systems.

4.7 A temperature control regime is the traditional means of controlling *Legionella* in hot and cold water services. Hot and cold water systems should be maintained to keep cold water, where possible, at a temperature below 20°C, and to keep hot water stored at 60°C and distributed so that it reaches the outlets at 55°C within one minute. Owing to the complexity of hot and cold water systems found in healthcare facilities and the difficulty of maintaining a temperature control regime at all times, in all areas, chemical and other water treatments that have been shown to be capable of controlling microbial colonisation and growth may need to be considered as an additional control measure.

4.8 Validation of treatment systems is important to ensure that the design and operation of a new or modified system is effective. Ongoing verification by operational monitoring is essential to ensure that the control measures remain effective. The monitoring of treatment programmes should demonstrate that they are working within legislation and the established guidelines, and are effective in controlling the target waterborne pathogens. The frequency of monitoring and test procedures will vary according to the method selected.

4.9 The use of biocides requires meticulous monitoring and their use can have an effect on water quality including taste and odour.

4.10 Where biocides are used, risk assessments (which have been agreed with the WSG) should identify at-risk patient groups (and/or equipment) to ensure there are no unforeseen consequences for patients (for example, patients in neonatal units and renal units).

Route of infection

4.11 The principal route of infection for Legionnaires' disease is through inhalation of the bacteria into the lungs via aerosols. The risk rises with increasing numbers of inhaled bacteria. Aspiration of contaminated drinking water into the airways has also been described as a mode of transmission of Legionnaires' disease. Aspiration can be a significant source of legionellosis in certain vulnerable patients including those using nasogastric tubes, stroke patients, those taking sedatives and narcotics, and those with motor neurone disease. Sucking ice made from contaminated water has been linked to some nosocomial cases of Legionnaires' disease.

Aerosol generation

4.12 Contaminated water presents a risk when dispersed into the air as an aerosol with smaller aerosols (<5 µm diameter) remaining airborne for longer, penetrating deeply into the lungs (alveoli). However, larger droplets can evaporate and still contain several organisms. Amoebic vacuoles, typically 3 µm, may contain many *Legionella* and potentially provide an infectious dose.

4.13 Water services are capable of generating aerosols from the process of water splashing on to wash-hand basins, sinks, and baths, in shower cubicles and when flushing toilets. Equipment that uses or is cleaned by water should be assessed for its potential to produce aerosols both in normal and abnormal (for example during maintenance) operating conditions.

Number of infectious bacteria

4.14 The number of organisms that cause infection has not been reliably determined and is likely to vary from person to person.

4.15 Two factors determine the number of bacteria deeply inhaled:

a. The concentration of bacteria in the air is determined both by the concentration of bacteria in the water and by the amount of contaminated water dispersed into a given air volume. The concentration of live bacteria in the air reduces rapidly with distance from the source; however this depends on the humidity and temperature.

b. The duration of exposure to the contaminated air:

   i. exposure in a shower is usually limited to a few minutes, while exposure in a bath is much longer;

   ii. the risk increases with the number of *Legionella* in the air, the respiratory rate of the individual and the length of time the person is exposed. The chances of *Legionella* infections occurring increase with the number and susceptibility of people exposed.

Susceptibility of individuals

4.16 While previously healthy people may develop Legionnaires' disease, there are a number of factors that increase susceptibility:

a. increasing age, particularly over the age of 50 (children are rarely infected);

b. men are approximately three times more likely to be infected than women (this may change with altered smoking habits);

c. existing respiratory disease that makes the lungs more vulnerable to infection;

d. illnesses and conditions such as cancer, diabetes, kidney disease or alcoholism, which weaken the natural defences;

e. smoking, particularly heavy cigarette smoking, because of the probability of impaired lung function;

f. patients who are immunocompromised as a result of illness or treatment (for example, those on immunosuppressant drugs that inhibit the body's natural defences against infection).

5 *Pseudomonas aeruginosa* and other waterborne pathogens: overview

Ecology

5.1 *P. aeruginosa* is a Gram-negative bacterium, commonly found in wet or moist environments. It is commonly associated with disease in humans with the potential to cause infections in almost any organ or tissue, especially in patients compromised by underlying disease, age or immune deficiency. As a pathogen the significance of *P. aeruginosa* is exacerbated by its resistance to antibiotics, virulence factors and its ability to adapt to a wide range of environments and nutrients.

5.2 *P. aeruginosa* thrives in relatively nutrient-poor environments such as water systems at a range of different temperatures and can exist as planktonic cells in water or as biofilms where mixed populations of bacteria are bound to surfaces. Biofilms can become detached to contaminate the water phase or flow.

Transmission

5.3 *P. aeruginosa* is an opportunistic pathogen that can colonise and cause infection in patients who are immunocompromised or whose defences have been breached (for example, via a surgical site, tracheostomy or indwelling medical device such as a vascular catheter). In most cases, colonisation will precede infection. Some colonised patients will remain well but can act as sources for colonisation and infection of other patients. As a microorganism that is often found in water, the more frequent the direct or indirect contact between a susceptible patient and contaminated water, and the greater the microbial contamination of the water, then the higher the potential for patient colonisation or infection.

5.4 Contaminated water in a healthcare setting can transmit *P. aeruginosa* to patients through the following ways:

- direct contact with the water through:
  - ingesting;
  - bathing;
  - contact with mucous membranes or surgical site; or
  - through splashing from water outlets or basins (where the flow from the outlet causes splashback from the surface);
- inhalation of aerosols from respiratory equipment, devices that produce an aerosol or open suctioning of wound irrigations;
- medical devices/equipment rinsed with contaminated water;
- indirect contact via healthcare workers' hands following washing hands in contaminated water, from surfaces contaminated with water or from contaminated equipment such as reusable wash-bowls or refillable spray cleaning bottles.

Source

5.5 It is generally accepted in the case of *Legionella* that the source of bacteria in hot and cold water systems is the incoming water supply and that it becomes a problem where there is a failure of the recommended control measures (for example, maintenance of

temperatures or water treatment regimes). In contrast to *Legionella*, the origin of *P. aeruginosa* is less certain and its presence is particularly evident within the last two metres before the point of discharge.

5.6 Devices fitted to, or close to, the tap outlet (for example mixing valves, solenoids or outlet fittings) may exacerbate the problem by providing the conditions and nutrients that support microbial growth (for example, appropriate temperatures, a high surface-area-to-volume ratio or a high surface area for oxygenation of water, and leaching of nutrients from materials such as ethylene propylene diene monomer (EPDM)). The source, therefore, could be:

- the incoming water supply from the water provider;
- the water supply within the building (both from the storage and distribution system), usually within biofilms;
- the wastewater system (see Breathnach et al. 2012); or
- via external retrograde contamination from:
  - clinical areas due to the discarding of patient secretions or where medical equipment may have been washed in the wash-hand basin;
  - outlet users where hands may have been contaminated by *P. aeruginosa*;
  - poor hygiene or processes during cleaning, resulting in contamination from the drain or surrounding environment to the outlet fitting;
  - splashback from contaminated drains;
  - contaminated cloths/mops etc.

5.7 Given this variety, the challenge for the WSG is to risk-assess operational practices in an attempt to minimise contamination from any of these sources.

Mycobacteria

5.8 Non-tuberculous mycobacteria have been associated with healthcare outbreaks worldwide. These outbreaks usually involve sternal wound infections, plastic-surgery wound infections or post-injection abscesses.

5.9 Mycobacterial infections in patients undergoing dialysis treatment have also been reported. Other infections have been attributed to the transmission of *Mycobacterium chimaera* from contaminated heater cooler units used in theatre during cardiothoracic surgery (see also paragraph 8.23).

Stenotrophomonas

5.10 There are at least 14 species of *Stenotrophomonas*; the most important waterborne pathogen is *Stenotrophomonas maltophilia.* This is an emerging opportunistic environmental pathogen that causes healthcare-associated infections and is found in aqueous habitats including water sources. *S. maltophilia* is an organism with various molecular mechanisms for colonisation and infection, and can be recovered most notably from the respiratory tract of cystic fibrosis patients with *P. aeruginosa*. Its habits within the healthcare environment are very similar to *P. aeruginosa;* however, it is more heat-sensitive and will not grow above 40°C. Good temperature management should reduce the risk of colonisation. It has been associated with the colonisation of taps/tap water, sinks/sink traps, showers, hydrotherapy pools, ice-makers, disinfectant solutions, haemodialysers, nebuliser chambers, humidifier reservoirs, bronchoscopes and ventilator circuits. *S. maltophilia* isolated from tap water has been shown to be responsible for the colonisation/infection of five neonates in a neonatal intensive-care unit. Where clinical results indicate water may be a vector in the transmission of *Stenotrophomonas* spp., then water sampling should be carried out as per *P. aeruginosa* (see Appendix E).

Other emerging pathogens of concern in healthcare

Other organisms may have particular pathogenicity in certain circumstances. Specialist microbiological advice should be sought until their management and control within heathcare can be documented more fully.

Management of control

5.11 Management of water systems to reduce the risk of waterborne pathogens is vital to patient safety. It requires surveillance and maintenance of control measures including temperature control, usage, cleaning and disinfection measures as identified within the risk assessment and WSP for both hot and cold water systems.

5.12 To prevent the growth of waterborne pathogens, controls are necessary to manage the water system before and after the outlet.

5.13 The WSG should ensure that estates and facilities staff have up-to-date accurate records and drawings/diagrams showing the layout and operational manuals of the whole water system. Estates and facilities staff should have received adequate hygiene training (see paragraphs 6.29–6.30) and be fully aware of the extent of their responsibilities to prevent microbial contamination of plumbing components (see paragraphs 1.21–1.26 in HTM 04-01 Part A). There should be strict adherence to the recommendations in HSG274 Part 2.

5.14 The WSG should also ensure that infection prevention and control (IPC) teams have received adequate training and that there is compliance with national evidence-based guidelines for preventing healthcare-associated infections. Best practice advice relating to clinical wash-hand basins should be followed to minimise the risk of contamination of surfaces, outlets and drains due to waterborne pathogens (see Chapter 3 in HTM 04-01 Part C).

5.15 IPC teams and WSGs should continue to monitor clinical isolates of waterborne pathogens including the presence of *P. aeruginosa* in risk-assessed augmented care units as an alert organism and be aware of possible outbreaks or clusters of infection with this microorganism.

5.16 The HCAI Code of Practice sets out the criteria against which a registered provider's compliance with the requirements relating to cleanliness and infection control will be assessed by the Care Quality Commission. It also provides guidance on how the provider can interpret and meet the registration requirement and comply with the law. Regulations 12 and 15 state that providers should provide and maintain a clean and appropriate environment in managed premises that facilitates the prevention and control of infections (see paragraphs 0.15–0.17).

6 Operational management

Introduction

6.1 Healthcare organisations have an explicit duty under the Health and Safety at Work Act etc. 1974 to assess and manage the risks posed by water systems on their premises. In accordance with the HCAI Code of Practice (see paragraphs 0.15–0.17), the healthcare organisation's chief executive is responsible for having systems in place to manage and monitor the prevention and control of infection. These systems should make use of WSPs and risk assessments to consider how susceptible patients are at risk from their environment and from others. Ensuring these elements are in place will assist the organisation to fulfil its duties in relation to the provision of safe water systems. A programme of audit should be in place to ensure that key policies and practices are being implemented appropriately. This will inform the organisation's assurance framework.

6.2 Each healthcare organisation, through its WSG and WSP, should be able to demonstrate that they have suitable governance, competence and accountability arrangements in place to deliver safe water in healthcare premises.

The Water Safety Group (WSG)

6.3 The WSG is a multidisciplinary group formed to oversee the commissioning, development, implementation and review of the WSP. The aim of the WSG is to ensure the safety of all water used by patients/residents, staff and visitors, to minimise the risk of infection associated with waterborne pathogens. It provides a forum in which people with a range of competencies can be brought together to share responsibility and take collective ownership for ensuring it identifies water-related hazards, assesses risks, identifies and monitors control measures and develops incident protocols.

Note

Where estates and facilities provider services are part of a contract (including PFI), it is essential that these providers participate fully in all those aspects of estate and facilities management that can affect patients. This includes responding to specific requests from the IPC team and WSG, which may be in addition to relevant guidance and documentation.

6.4 The WSG should have clearly identified lines of accountability up to the duty holder. The roles, responsibility and accountability of the WSG should be defined (see Chapter 2).

6.5 The group should ensure that there is the appropriate expertise available to ensure that all elements of the WSP are fully implemented. This will require assurance from installers, maintainers and users with regard to the safety of all water used by patients/residents, staff and visitors, to minimise the risk of infection associated with waterborne pathogens. The WSG may typically comprise personnel who:

- are familiar with all water systems and associated equipment in the building(s) and the factors that may increase risk of

infection from *Legionella, P. aeruginosa* and other waterborne pathogens (that is, the materials and components, the types of use and modes of exposure, together with the susceptibility to infection of those likely to be exposed);

- have knowledge of the particular vulnerabilities of the at-risk population within the facility; as part of its wider remit, the WSG should include representatives from areas where water may be used in therapies, medical treatments or decontamination processes where exposure to aerosols may take place.

6.6 This would normally involve representation from estates (operations and projects), infection control, medical microbiology, nursing, augmented care, housekeeping/ support services, an Authorising Engineer/ independent adviser, medical technical officers, specialist users of water (such as renal units and departments offering aquatic therapy), and sterile services departments (SSDs). See Figure 2 for an example structure and see also the Note under paragraph 6.3.

6.7 As and when required, the local security management specialist (LSMS) should provide a security management input. The LSMS should be consulted in any vulnerability and risk assessments being undertaken, to ensure that the security of the water systems is fully considered and proportionate security measures are implemented.

6.8 The WSG should be led and chaired by a person who has appropriate management responsibility, knowledge, competence and experience. Where required, it may appoint in writing an independent professional adviser/ Authorising Engineer (Water) with a brief to provide services in accordance with this HTM and the HSE's technical guidance HSG274 Part 2.

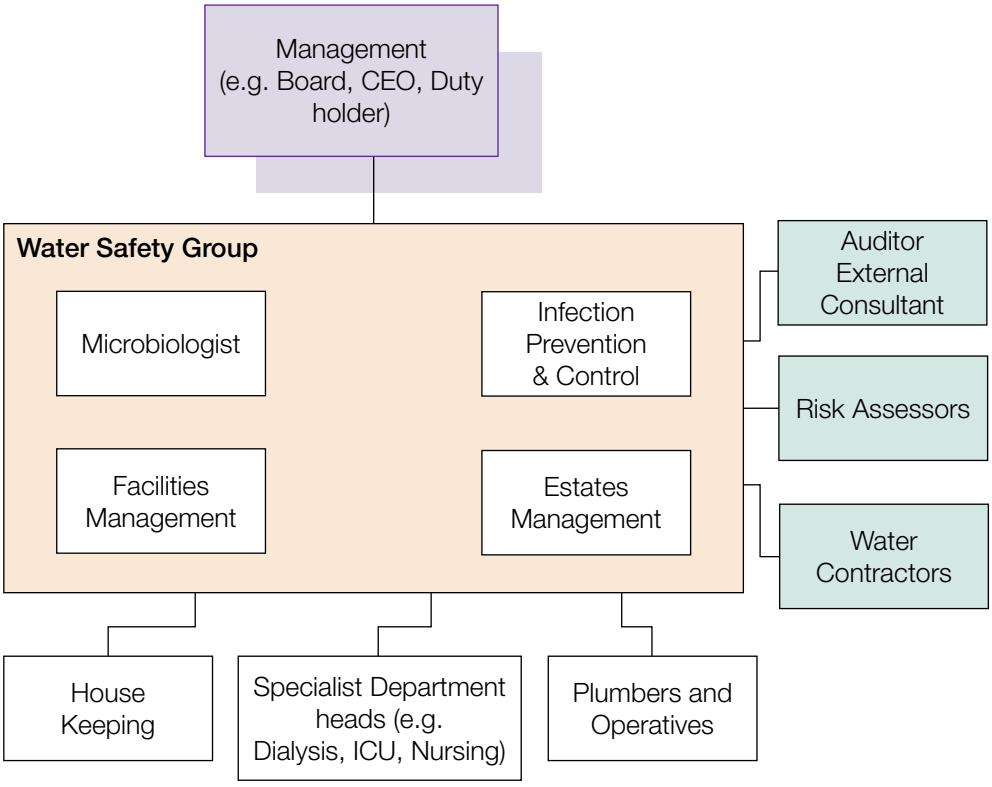

Figure 2 Example WSG structure

Remit of the WSG

6.9 The following is a typical list of tasks assigned to the WSG:

- to work with and support the IPC team;
- to ensure effective ownership of water quality management for all uses;
- to determine the particular vulnerabilities of the at-risk population;
- to review the risk assessments;
- to ensure the WSP is kept under review including risk assessments and other associated documentation;
- to ensure all tasks indicated by the risk assessments have been allocated and accepted;
- to ensure new builds, refurbishments, modifications and equipment are designed, installed, commissioned and maintained to the required water standards;
- to ensure maintenance and monitoring procedures are in place;
- to review clinical and environmental monitoring data;
- to agree and review remedial measures and actions, and ensure an action plan is in place, with agreed deadlines, to ensure any health risks pertaining to water quality and safety are addressed;
- to determine best use of available resources;
- to be responsible for training and communication on water-related issues;
- to oversee water treatment with operational control monitoring and to provide an appropriate response to out-of-target parameters (that is, failure to dose or overdosing of the system);
- to oversee adequate supervision, training and competency of all staff;
- to ensure surveillance of both clinical and environmental monitoring.

6.10 Detailed minutes of the group meetings should be recorded, distributed promptly and retained in accordance with the management policy to demonstrate good management, appropriate and timely actions and good governance.

6.11 The WSG should always act in an appropriate and timely manner. Individual responsibilities should not be restricted by the need to hold formal meetings.

6.12 Episodes of colonisation or infection of patients that could be related to the water system should be referred by the IPC team to the chair of the WSG for any additional action to be determined.

6.13 The WSG should review any proposed or existing developments associated with the water supply and distribution system to ensure that they:

- minimise the risk to patients/service-users, especially those treated in augmented care settings;
- are compliant with all extant legislation and DH policy and guidance.

6.14 All systems and equipment that use water to which patients, staff and visitors could be exposed should be approved by the WSG. When buying equipment, assurance should be sought from the manufacturer regarding safety for patients and service-users.

6.15 The WSG will need to ensure that decisions affecting the safety and integrity of the water system do not proceed without its agreement.

Water safety plans (WSPs)

6.16 To assist with understanding and mitigating risks associated with waterborne hazards in distribution and supply systems and associated equipment, healthcare organisations should develop a WSP, which provides a risk-management approach to the safety of water and establishes good practices in local water usage, distribution and supply

(see Figure 3). It will identify potential water-related hazards, consider practical aspects and detail appropriate control measures. The content of a WSP will depend on the size and complexity of the healthcare organisation's water system. The plan will include governance arrangements related to the management of water safety. See paragraph 6.21 for a list of elements that the WSP should incorporate.

6.17 Those organisations with existing robust water management policies for waterborne hazards will already have in place much of the integral requirements for developing a WSP.

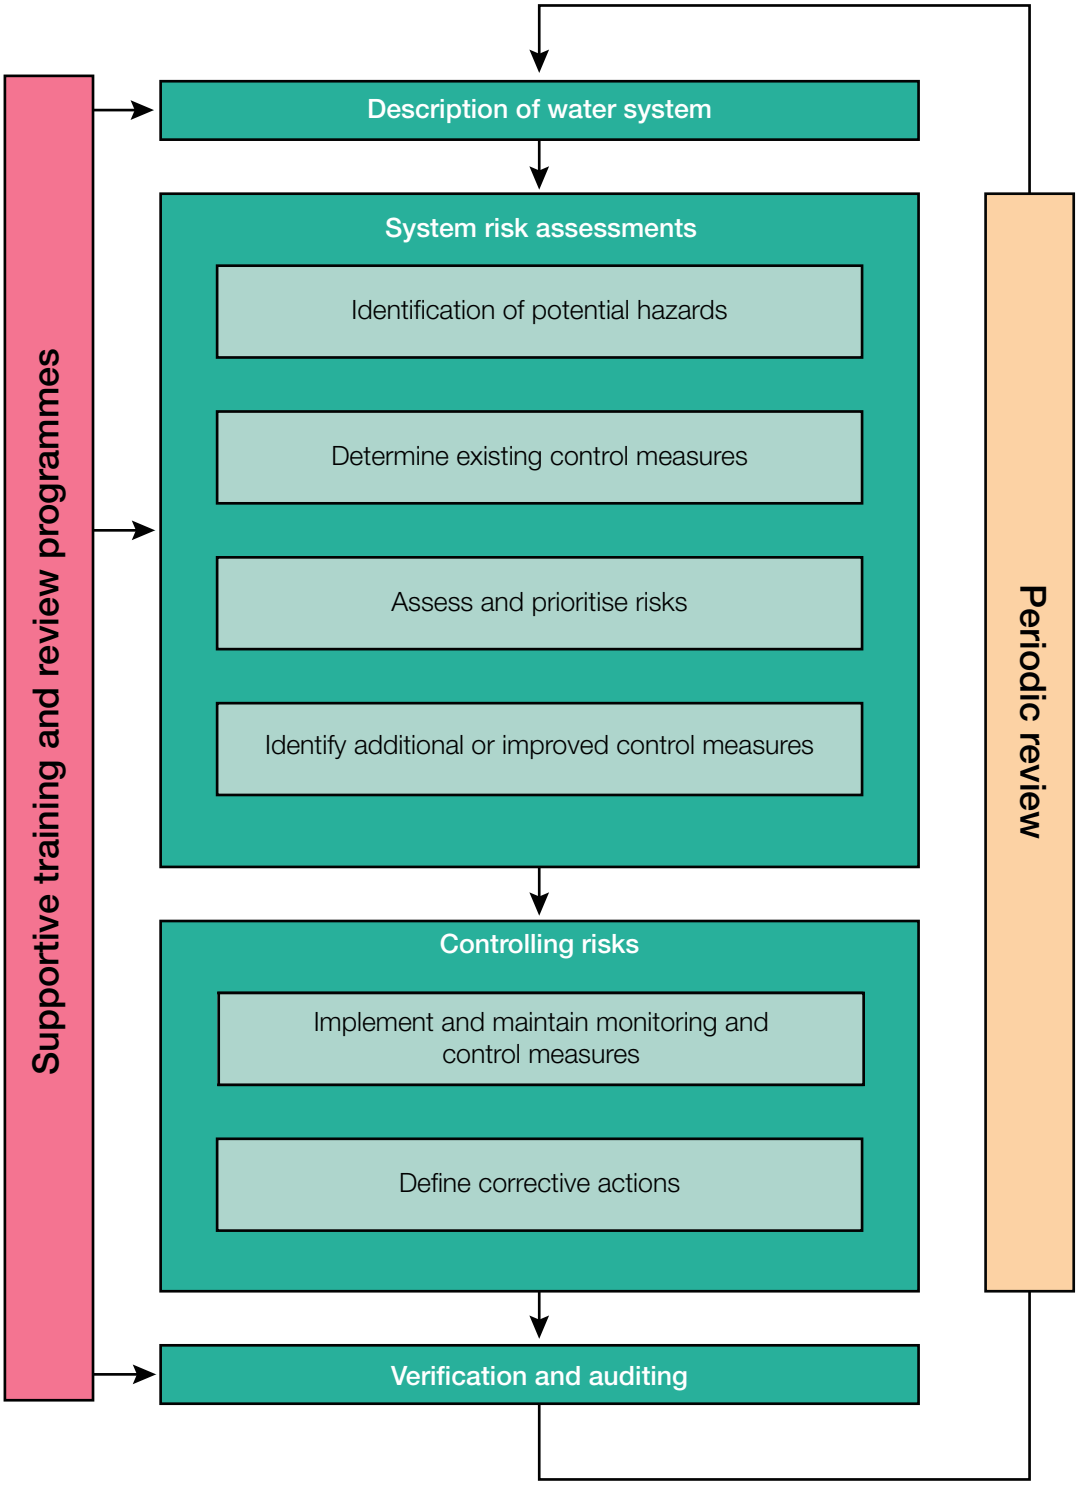

Figure 3 Documentation of management procedures (adapted from Figure 4.1 in WHO's 'Water safety in buildings')

6.18 The WSP is a living document. It should be kept under continual review and ensure the adequate assessment and control of the risks from a wide range of waterborne pathogens. It should be a standing agenda item at WSG meetings.

6.19 The first step in the development of a WSP is to gain a comprehensive understanding of the water system, including the range of potential hazards, hazardous events and risks that may arise during storage, delivery and use of water. It may require an understanding of the quality and management of the water as provided and how that water is used. Fundamental to this and any subsequent investigation or review is the provision and availability of accurate records. Schematic diagrams are useful for assisting understanding of how entire water systems operate; however, more advanced drawings (as-built) are often needed in complex buildings. The WSP should also be cross-referenced to the healthcare organisation's security management strategy and business continuity plan.

6.20 WSPs include the need to:

- assess the risks that may be posed to patients (including those with particular susceptibility), staff and visitors;
- put into place appropriate management systems to ensure the risks are adequately controlled;
- ensure there are supporting programmes, including communication, training and competency checks.

6.21 With respect to physical, chemical and microbiological hazards, the WSP should incorporate:

- a clinical risk assessment to identify those settings where patients are at significant risk from waterborne pathogens;
- an engineering and bacterial risk assessment of all water systems;
- operational monitoring of control measures and record-keeping methodology;
- information on the age and condition of the water distribution system and materials of construction (as different materials hold differing risks and react differently to chemicals);
- links to clinical surveillance;
- early warnings of poor or unsuitable water quality (for example, taste, odour, flavour and appearance if intended for drinking);
- plans for the sampling and microbiological testing of water in identified at-risk units (see Chapter 10 and Appendices E and F);

Note

Appendix F has been developed to provide technical guidance for a range of laboratories, including NHS, Public Health England (PHE) and commercial laboratories that have the capability and capacity to undertake water sampling and testing.

- adequate supervision, training and competency for all levels of staff including housekeeping staff and those employed by facilities management organisations;
- communication and documentation;
- appropriate design, installation, commissioning and maintenance of all components and equipment;
- remedial actions to be taken to remedy high counts for *P. aeruginosa* and *Legionella* and other relevant pathogens where appropriate;
- adjustments to clinical practice until remedial actions have been demonstrated to be effective;
- regular removal/cleaning/descaling or replacement of the water outlets, hoses and thermostatic mixing valves (TMVs) and other components where risk assessment necessitates;

- amendments when changes are carried out including new builds, refurbishments and recently decommissioned clinical departments or units;
- amendments made when changes are made at the annual review.

6.22 The WSP should identify potential alert organisms and microbiological hazards caused by *Legionella*, *P. aeruginosa* and other relevant pathogens, consider practical aspects and detail appropriate control measures.

Risk assessments

6.23 The risk assessments that inform the WSP should identify potential hazards caused by *Legionella*, *P. aeruginosa* and other relevant pathogens, chemicals, temperature and events that may arise during supply, storage, delivery, maintenance and use of water in healthcare facilities.

6.24 Once potential hazards and hazardous events have been identified, the severity of risk needs to be assessed so that priorities for risk management can be established. The risk assessment needs to consider the likelihood and severity of hazards and hazardous events in the context of exposure (type, extent and frequency) and the vulnerability of those exposed. Although many hazards may threaten water quality, not all will represent a high risk. The aim should be to distinguish between high and low risks so that attention can be focused on mitigating risks that are more likely to cause harm (see BS 8580 for guidance on *Legionella* risk assessments). Typical examples of issues to consider may include the following:

- governance and accountability;
- the susceptibility of all who may be exposed to water (including ice) used for diagnosis and treatment;
- scalding risk and the appropriate installation of TMVs;
- failure to maintain necessary hot and cold system supply temperatures;
- clinical practice where water may come into contact with patients and their invasive devices;
- the appropriate cleaning of the environment and equipment;
- the disposal of blood, body fluids and patients' wash-water;
- the maintenance and cleaning of wash-hand basins and associated taps, specialist baths and other water outlets;
- suitable siting and installation of wash-hand basins including the appropriate positioning of soap and antimicrobial hand-rub dispensers;
- change in use (for example, clinical area changed to office accommodation or vice-versa) due to refurbishment or operational necessity;
- other devices that increase/decrease the temperature of water (for example, ice-making machines, water chillers) which may not be appropriate where patients are at particular risk such as in augmented care settings;
- engineering assessment of water systems, including appropriate design, installation, commissioning, maintenance and verification of the effectiveness of control measures (see also the Water Supply (Water Fittings) Regulations 1999);
- infrequently used outlets;
- previous risk assessment, current control measures and documentation;
- policies and procedures;
- the unnecessary use of flexible hoses and any containing inappropriate lining materials;
- sampling, monitoring and testing programmes that needs to be put in place;
- backflow protection;
- safe access to equipment;

- prevention of unauthorised access to equipment;
- education and training.

6.25 Situations will arise where venous catheter sites and surgical wounds may become contaminated from water outlets such as showers. Similarly the practice of soaking leg ulcers or syringing ears may require consideration of the microbiological quality of water used and will require local assessment.

6.26 The likelihood of hazardous events is influenced by the size and complexity of the water system and can be exacerbated by poor or overcomplicated design, construction, commissioning, operation and maintenance.

Staff training and competence

6.27 The WSG should implement a programme of staff training to ensure that those appointed to devise strategies, carry out control measures and undertake associated monitoring are appropriately informed, instructed and trained. They should also be assessed as to their competency. It is also essential that they have an overall appreciation of the practices affecting water hygiene and safety, and that they can interpret the available guidance and perform their tasks in a safe and technically competent manner.

6.28 The WSG should review the competence of staff on a regular basis, and refresher training should be given; records of training attendance need to be maintained. Although training is an essential element of ensuring competence, it should be viewed within the context of experience, knowledge and other personal qualities that are needed to work safely. Competence is dependent on specific needs of individual installations and the nature of risks involved.

Water hygiene training

6.29 Individuals to whom tasks have been allocated (supervisors and managers as well as operatives) need to have received adequate training in respect of water hygiene and microbiological control appropriate to the task they are responsible for conducting. The training and competence assessment should be clearly defined and should include those responsible for simple housekeeping tasks such as outlet flushing and the cleaning of wash-hand basins, through to maintenance staff and up to individuals who define strategy and develop procedures.

6.30 It is important that any person working on water distribution systems or cleaning water outlets should have completed a water hygiene awareness training course so that they can gain an understanding of the need for good hygiene when working with water distribution systems and water outlets, and of how they can prevent contamination of the water supply and/or outlets.

Water hygiene training

As part of helping to ensure the delivery of safe wholesome water at all outlets and preventing contamination, which may lead to healthcare-associated infections, it is recommended that healthcare organisations implement a water hygiene training scheme.

Consideration should also be given to integrating a health screening element into the training to help ensure those undergoing the training are not carriers of any waterborne diseases on the date of training and are aware of their responsibilities towards the water supply. It is important that individuals are aware of their duty to protect the health of patients, staff and visitors and that they are responsible for ensuring that they inform their line manager if they come into contact with any disease that has the potential to cause harm.

The course should encompass the following topics (not exhaustive):

- organisational governance arrangements in relation to water hygiene and safety;
- familiarisation with local policies/ procedures in relation to the management and provision of water hygiene and safety;
- information on prominent waterborne pathogens and their consequences;
- the ways in which water distribution systems, water outlets, components and any associated equipment can become contaminated;
- the responsibilities of individuals to prevent the contamination of the water distribution system and water outlets and assisting in ensuring control measures in place are effective;
- how the safety of water can be maintained by good hygiene practices;
- when not to work with water intended for domestic purposes;
- system design;
- components/accessories (taps, TMVs);
- disinfection and cleaning equipment/ materials;
- how to store and handle pipes;
- organisation-specific control measures;
- the impact of getting it wrong;
- role of persons being trained;
- personal hygiene along with dealing with clothing, footwear, cleaning equipment/materials, tools and storage when considering water hygiene (as applicable to each role).

Management of water safety risks and issues

6.31 Identified water safety risks and issues should be assessed, prioritised and included on a risk register for discussion and management by the WSG and advice given on when these should be escalated to senior management/board level. Consideration should also be given to the potential and known threats from unauthorised access to the water supply for malicious purposes (see also NHS Protect's (2012) guidance on the security and management of NHS assets).

6.32 When the risks have been identified, an action plan needs to be developed with defined roles and responsibilities, and agreed

timescales to minimise these risks. The action plan should include:

- appropriate remedial actions, monitoring details and schedules for validation that show the remedial actions are effective and subject to ongoing verification (completion dates should be defined);
- any training and competency issues required to ensure compliance with this guidance.

Advice on exposure of augmented care patients to *P. aeruginosa* is covered in HTM 04-01 Part C.

Documentation

6.33 All records pertaining to the risk assessment and action plan should be held and managed by the WSG.

Safe hot water temperature

6.34 See paragraphs 10.57–10.59 in HTM 04-01 Part A for guidance on safe water temperatures and delivery devices. See also HSE's 'Managing the risks from hot water and surfaces'.

6.35 To reduce the risk of scalding, thermostatic mixing devices are required for specific hot water outlets (see Table 2 in HTM 04-01 Part A). A scalding risk assessment is necessary to establish the need and type of device to be installed.

6.36 As with any safety device, routine checks will be essential to ensure continued satisfactory operation (see Chapter 11 of HTM 04-01: Supplement – 'Performance specification D 08: thermostatic mixing valves (healthcare premises)'). Such devices, however, should not be a substitute for caution. For example, when performing assisted bathing, it is often necessary to set the delivery temperature to a higher level than that normally considered safe to allow for the cooling effect of large baths that are required.

6.37 Before lowering or assisting patients into the bath, the water temperature must be checked with a thermometer to ensure that it has fallen to a safe value.

Utilisation

6.38 One of the critical factors affecting the quality of water within hot and cold water distribution systems is the extent of utilisation.

6.39 Where stagnation occurs or utilisation is low, cold water temperature can increase significantly and approach the range that is conducive to the growth of a variety of waterborne pathogens such as *Legionella*. Where hot and cold water is mixed, further opportunities arise for deterioration in water quality.

6.40 TMVs should not be installed in series with mixing taps (thermostatic or manual) (see also paragraphs 6.52–6.58 on maintenance practice).

6.41 The WSG needs to ensure that there is good liaison between the estates officers/ maintenance providers and clinicians to ensure that the water services are sufficiently used.

6.42 HSG274 Part 2 recommends that generally, for infrequently used outlets, flushing is carried out once a week but that in healthcare facilities the risk assessment, as agreed by the WSG, may indicate a higher frequency, and water draw-off should form part of the daily cleaning process. The procedure for such practice should be fully documented and covered by written instructions.

6.43 Monitoring of water usage on a building-by-building basis can indicate when usage falls and the risk increases. Reductions in normal usage patterns should be investigated and remedial measures introduced following investigations by the WSG.

Note

Regular flushing applies to all infrequently used outlets. The use of portable temperature-monitoring devices may assist in identifying where additional flushing is necessary.

Temporary closure of wards/ departments

6.44 During the temporary closure of wards or departments, a flushing regime should be instigated to maintain system hygiene. Flushing should be continued until stable temperatures are achieved. Advice and guidance is also provided in BSI's PD855468.

6.45 Alternatively, when this is impracticable, or should the temporary closure become permanent, it should be disconnected from the rest of the system, ensuring there are no dead-legs. Before reconnecting, the system should be recommissioned and disinfected in accordance with Chapter 15 of HTM 04-01 Part A.

Leak detection/water conservation

6.46 It is essential to regularly check systems and all components for signs of leakage; for example, a tap left dripping can waste in excess of 14,000 L of water each year. Particular attention should be given to WCs as leakage appears as a dribble at the back of the pan, which often goes undetected.

6.47 Consumption should be monitored; if it increases for no apparent reason, this may indicate a leak. Wet or soggy patches of ground may identify underground leaks, for example areas of greenery that are more lush than their surroundings.

6.48 Where water conservation measures are to be considered, a risk assessment should be undertaken to ensure there is no detrimental impact that may cause stagnation or low water usage in the existing water or drainage systems.

6.49 For further guidance, see HTM 07-04 – 'Water management and water efficiency'.

Water treatment undertaken by the local water undertaker

6.50 Local water undertakers use different types of water treatment, which may include the use of chloramine, and add additional compounds such as fluoride. It is recommended that regular contact is maintained with the local water undertaker to keep up to date with changes that may affect water quality or other operational changes affecting the premises.

Energy management

6.51 Efforts should be taken to minimise energy consumption without compromising water safety management. An effective maintenance plan will also contribute to this. Further guidance is given in HTM 07-02 – 'EnCO_2de'.

Maintenance practice

Note

See also Chapter 11 in HTM 04-01: Supplement – 'Performance specification D 08: thermostatic mixing valves (healthcare premises)'.

6.52 Healthcare organisations should ensure that all personnel that work on water systems can demonstrate competence and have been inducted in local procedures, which should include safe water hygiene practices (see paragraphs 6.29–6.30).

6.53 There are legal, operational and economic reasons for introducing good maintenance practice. There is a legal requirement under the Water Supply (Water Fittings) Regulations 1999 to maintain water fittings to comply with the regulations. It sets a requirement to protect and preserve water quality for the safety of patients, staff and visitors. Complying with the law is

generally given the highest priority and is the minimum requirement that must be satisfied. Chapter 3 lists specific statutes that must be complied with. Additional advice is provided in BS EN 806-5 and BS 8558.

Note

BS EN 806-5 and complementary guidance in BS 8558 covers the operation and maintenance of water systems, in which a number of aspects are covered:

- operation;
- interruptions to operation and disconnection;
- resumption of supply;
- damage and faults (change in water quality, insufficient water supply, noise emission);
- alterations, extensions and refurbishment;
- accessibility of installation components;
- maintenance.

6.54 Regulations require notification to the water undertaker of any proposed changes and additions to the water supply system in the premises. Before making any changes, a risk assessment should be carried out and audited by an independent assessor. Further details can be found on the WRAS website.

6.55 Maintenance is required to achieve optimum economic life and maintain maximum operational efficiency of the plant.

6.56 There should be a risk assessment to decide the appropriate type of maintenance (for example scheduled, corrective or condition-based) for the different items of plant. The following should be considered:

a. Would a breakdown of a particular service during working, or outside normal, hours pose a risk to patient safety and wellbeing?

b. How long can a breakdown of particular plant be tolerated?

c. What cost can be justified to avoid breakdown of particular plant such as standby pumps, dosing pumps etc?

d. The availability of suitable spares.

6.57 If response to failure is critical for certain items of plant, the maintenance organisation will require a planned strategy of calling out skilled staff to achieve an agreed response time and to minimise the interval between breakdown and the diagnosis and repair of the plant.

6.58 The approach for healthcare premises should be based on that of planned preventive maintenance (PPM) as any failure in the water services would be seriously detrimental to the provision of healthcare. The PPM programme and any subsequent amendments should be agreed by the WSG (see also Chapter 5 on maintenance in HTM 00 – 'Policies and principles of healthcare engineering').

Maintenance responsibility

6.59 A maintenance manager should be given responsibility for implementation of a risk-based operational maintenance strategy. These responsibilities will include:

a. the provision of adequately trained and supervised labour (see also paragraph 6.30 on water hygiene training);

b. clear definitions of the equipment and services to be maintained, together with the procedures to be carried out on them;

c. monitoring of the quality of the work carried out to ensure that it is consistently acceptable;

d. the identification of appropriate resources and the implementation of financial control procedures.

Note

The maintenance manager should ensure that risk assessments have been carried out for all maintenance activities, and be particularly aware of any specific risks associated with hot and cold water installations (for example, hazards associated with gaining access to cisterns, the discharge of large volumes of hot water to enable the inspection of calorifiers and hot water storage vessels, and the possibility that these may have become colonised by *Legionella*).

Contract maintenance

6.60 The increasing complexity of building services equipment has resulted in a growing reliance on contractors for the provision of maintenance services. The decision to use either a contractor or in-house staff should be taken in the light of local circumstances.

6.61 Contracts between contractors and healthcare organisations should clearly define the responsibilities of both parties. See Chapter 2 of HBN 00-08 – '(Estatecode) Part B: Supplementary information for Part A' for further guidance. BSRIA's BG3: 'Maintenance for building services' also provides advice on aspects to be considered when obtaining contract maintenance.

6.62 All staff who work on or with water systems should have the necessary qualifications, regulatory knowledge, competence and experience needed to complete safely and effectively their specific tasks. Each individual should have a full understanding of their role and the impact of their actions on patient care (see also paragraph 6.30 on water hygiene training).

6.63 Only installers with the appropriate qualifications, regulatory knowledge and competence should be used to install and maintain water installations. There are seven Approved Contractors' Schemes (APHC, Aplus, CIPHE, Snipef, Taps, WaterMark and WIAPS) authorised through the Water Supply (Water Fittings) Regulations 1999. In addition to plumbing installers, four schemes (Aplus, Taps, WaterMark and WIAPS) operate sector memberships for specialist areas of work covering external water services (below-ground pipe etc), catering equipment and point-of-use (chilled-water) equipment.

6.64 The WaterSafe register holds details from all seven Approved Contractors' Schemes for businesses that have registered plumbing installers.

6.65 A recognised benefit to using an Approved Contractor (including sector installers) is they can carry out some work without the need to provide advanced notification to the water undertaker, and their work will be certified upon completion. A "work completed" certificate issued by a WaterSafe-recognised plumber provides a defence for property owners who are challenged by a water undertaker enforcing the Water Supply (Water Fittings) Regulations 1999 or during legal proceedings.

Maintenance brief

6.66 The maintenance manager requires a brief that is in line with all the requirements of the WSP and approved by the WSG. This will include (among others):

a. the scope of work;

b. budgeting – overall and single item limits;

c. level of reliability;

d. response time required to correct faults;

e. criteria for quality of service, works and equipment;

f. reporting procedure;

g. accountability and responsibility;

h. energy-saving policy;

j. health and safety policy;

k. environmental and sustainability factors.

6.67 The above requirements are necessary regardless of whether the work is carried out by contractors or in-house staff.

Performance monitoring

6.68 This involves the regular inspection of systems and records, which should be in such detail as to enable the WSG to form an opinion regarding compliance with the agreed criteria.

6.69 If a contractor is commissioned to carry out maintenance but in-house expertise is not available to monitor their performance, it may be necessary to seek advice from an independent professional adviser (this may be available from a neighbouring healthcare organisation). Using another maintenance contractor in a monitoring role could lead to a conflict of interest.

6.70 Performance monitoring should establish that:

a. the required level of service is met;

b. all the required plant is being maintained;

c. system performance is being maintained (that is, by the implementation of microbial sampling and temperature/biocide-level-monitoring regimes);

d. maintenance is being carried out to the agreed standard;

e. correct replacement parts are being used;

f. the agreed spares stocks are being held on site;

g. records are being correctly maintained;

h. the agreed standards, number of staff, and number of visits are being achieved;

i. plant is being operated to achieve optimum energy usage;

j. health and safety requirements are being complied with;

k. only agreed subcontractors with the appropriate knowledge and competence are being employed (see paragraphs 6.60–6.65);

l. the client and typical users of the building are satisfied;

m. invoices accurately reflect the work carried out, including materials expended;

n. breakdowns do not occur too often;

o. adequate consideration is being given to the potential environmental impact of contractors' actions, for example disposal of lubricants, chemicals, worn parts etc that cannot be recycled.

Monitoring systems

6.71 Where monitoring systems are provided to assist in the management of hot and cold water systems, they should be subject to a routine maintenance and calibration regime. Systems should be in place to ensure all set alarms should be responded to in a timely manner.

Emergency action

6.72 Contingency plans should be available in the event of the following:

a. A power or energy interruption or a plant failure resulting in the temperature control strategy or the delivery of effective control measures being maintained as designed.

b. A water supply failure that could last beyond the period for the designed storage capacity.

Note

The WSG should ensure that plans are in place for the supply and distribution of alternative safe water for drinking to vulnerable patients and those unable to collect supplies from distribution points within the healthcare facility. This will include the use of sterile water if appropriate.

c. Monitoring and sampling results that indicate patient safety may be compromised unless remedial action is undertaken with immediate effect.

d. Emergency action in the event of a case or an outbreak of a healthcare-associated waterborne infection (see also Appendix B for action to take on an outbreak of legionellosis).

e. Tampering and sabotage of the water supply which could impact on patient and staff safety.

6.73 Guidance on temporary supplies is provided in BS 8551.

Note

Under the Security and Emergency Measures Direction, water suppliers should liaise with healthcare authorities to develop emergency plans to maintain supplies for domestic purposes to healthcare premises.

These plans may include:

- Adequate storage cistern capacity and distribution arrangements within the healthcare facility to provide minimum volumes of water at the outset of a major incident to maintain hygiene and health for an initial period until other temporary arrangements can be introduced.
- The provision of facilities to connect to, and distribute water from, temporary storage cisterns such as pillow tanks at key locations within the site. Ground-level storage cisterns will require provision of booster pumps to either lift the water to existing storage cisterns or distribute it directly through existing or temporary site water mains.
- The provision of connection points to existing storage cisterns at suitable locations for delivery of emergency supplies of water, for example from tankers.
- Plans for the supply and distribution of alternative safe water for drinking to vulnerable patients and those unable to collect supplies from distribution points within the healthcare facility.

Data management and record-keeping

6.74 Given the amount of data that must be managed to facilitate the effective management of large and complex water systems, it is recommended that electronic data management tools be utilised to facilitate the intelligent use of data for the WSG to easily monitor trends and analyse chemical and microbiological parameters.

6.75 It is essential to have comprehensive operational manuals for all items of plant that include requirements for servicing, maintenance tasks and frequencies of inspection.

6.76 This information should be kept together with all commissioning data.

6.77 Documentation should also be drawn up as part of the health and safety file for the healthcare facility.

6.78 As a minimum, the following items should be recorded:

a. the names and positions of those responsible for conducting risk assessments, and managing and implementing the WSP;

b. the significant findings of risk assessments;

c. details of the procedures including sufficient detail to identify that the work was completed correctly and when the work was carried out; and

d. results of any monitoring inspection, test or checks carried out.

6.79 Records should be kept for at least five years unless they are required to be kept longer by the organisation's data management policy.

As-fitted drawings

6.80 The availability of accurate as-fitted drawings is essential for the safe operation of hot and cold water service systems and to inform the risk assessment. The drawings will be necessary to perform the temperature control checks on the systems and will assist in identifying any potential problems with poor hot water circulation and cold water dead-legs where flow to infrequently used outlets can be low. Such information should identify all key components in the installations, for example water meters, cisterns, filtration equipment (where fitted), calorifiers, and the location of isolating valves in the systems. Drawings should be kept up to date and amended when any changes are made to the system.

Schematic drawings

6.81 Separate schematic drawings should be prepared and displayed such that all plant items, control valves etc can be identified. A schematic diagram is an important tool to inform the risk assessment process. These are not formal technical drawings and are intended to be easy-to-read without specialised training or experience. While providing only an indication of the size and scale, they allow someone unfamiliar with the layout of a system to understand the positions and connections of the relevant components quickly. Drawings should be kept up to date and amended when any changes are made to the system.

Note

All drawings should be available to each person working on the systems and while conducting risk assessments.

6.82 In addition to drawings, there should be comprehensive schedules of outlets, lists of sentinel taps (outlets), other outlets to be tested (frequency as per the WSP) and other components in the system.

Asset register

6.83 The WSG should ensure that an accurate record of all assets relating to the hot and cold water distribution systems is set up and regularly maintained. They should also ensure that records of all maintenance, inspection and testing activities are kept up-to-date and properly stored.

6.84 The asset register should be designed to provide the following information:

a. an inventory of plant and water-associated equipment;

b. a basis for identifying plant details;

c. a basis for recording the maintenance requirements;

d. a basis for recording and accessing information associated with maintenance;

e. a basis for accounting to establish depreciation and the provision needed for plant replacement;

f. information for insurance purposes.

6.85 When completing records, it is essential that there is an audit trail in place indicating the individual concerned and dates/times where appropriate.

6.86 Further information on the monitoring of performance and effectiveness in carrying out maintenance tasks can be found in CIBSE's Guide M – 'Maintenance engineering and management'.

7 Description of systems, operational considerations and requirements

Source of supply

7.1 See Chapter 2 in HTM 04-01 Part A for comprehensive guidance and information on sources of water supply.

7.2 If supplies are taken from local boreholes or wells etc, the water should be tested to comply with the requirements of the Private Water Supplies Regulations 2009. The results of all analyses should be kept and recorded. Private supplies should be registered with the local authority.

Temperature control regime

7.3 A temperature control regime is the traditional strategy to control *Legionella* and other waterborne pathogens. This will require monitoring on a regular basis. Frequencies are listed in Table 1.

Note

The flow temperature of hot water out of the calorifier should be a minimum of 60°C. It should be a minimum of 55°C on flow and returns to all outlets and at the start of the hot water return. It should be a minimum of 50°C at the final connection to the calorifier.

7.4 Whereas many of the checks will, of necessity, require the use of separate thermometric equipment, some of the temperature checks can be carried out by continuous monitoring such as sensors and reporting systems (optionally linked to a building management system (BMS)).

Where a BMS is used, it will be essential to ensure that regular calibration and physical tests are performed in accordance with the manufacturer's instructions.

7.5 More extensive use of automatic sensors and reporting systems should be considered for surveillance of systemic temperature profiling. Sensors should be located throughout the whole hot and cold water systems to ensure they give representative temperature values.

Biocide regimes

Note

Any biocidal treatment is likely to adversely affect the lifecycle of the installation.

7.6 In addition to maintaining a temperature control regime, there may be occasions where additional biocidal treatment is required for the effective control of *Legionella* and other waterborne pathogens. However, the selection of a suitable treatment is complex and depends on a number of parameters. Moreover the chosen biocide needs to be properly managed. This is particularly the case with cold water services compared with hot water services where, with the benefit of circulation, water is returned to the calorifier/water heater and is then pasteurised. However, it should be taken into consideration that effective concentrations of some biocides are difficult to achieve in hot water systems due to gassing off. For water intended for consumption, the biocide concentrations must not exceed prescribed concentrations for drinking water.

7.7 The WSG should be actively involved in the decision-making process and should involve consultation with the water undertaker to ensure the suitability of biocidal products for their intended application.

For further information on biocidal treatment, see Chapter 4 of HTM 04-01 Part A. For ongoing checks, see HSG274 Part 2.

Metal contamination

7.8 See Chapter 5 in HTM 04-01 Part A.

Water softening

7.9 See Chapter 6 in HTM 04-01 Part A.

Filtration

7.10 See Chapter 7 in HTM 04-01 Part A for guidance on point-of-entry filtration. See paragraphs 7.45–7.49 and paragraph D22(k) in Appendix D and also Chapter 4 in HTM 04-01 Part A for guidance on POU filtration.

Metering

7.11 Metered data should be logged and recorded by an automatic metering system (see also HTM 07-04 – 'Water management and water efficiency'). Where water meters are installed in below-ground meter chambers, the chambers should be kept clean of debris and water; this will enable quick and accurate reading of the meters.

7.12 Meters should be periodically checked to ensure that they are operating and providing accurate readings.

7.13 Meters, other than the water undertaker's meter, should be removed at such intervals as recommended by the manufacturer for cleaning and renewal of worn parts and should be tested for accuracy and disinfected prior to replacement.

7.14 Meters should ideally provide a pulse output that can be monitored by a BMS, but if not should be read on a regular basis (monthly) and consumption monitored. Data from the meter should be reviewed over time for anomalies (typically low or high consumption rates). Graphical methods may be beneficial. Where it is desirable to connect to the water undertaker's meter, its authorisation must be gained in advance.

7.15 Consumption should be checked against the utility bill and any discrepancies investigated.

Water storage

7.16 For general information on water storage, see Chapter 8 in HTM 04-01 Part A.

7.17 The Water Supply (Water Fittings) Regulations 1999 and relevant parts of BS EN 806 and BS 8558 specify minimum standards for cold water storage cisterns to ensure that the stored water is retained at a wholesome standard suitable for domestic use. It is necessary to minimise stagnation and stratification of the stored water. A nominal 12 hours' total on-site storage capacity is recommended. The quantity of the water stored should be carefully assessed in relation to the daily requirement so that a reasonable rate of turnover is achieved. The storage capacity should be reduced where it is known or established that it is excessive and where it is practicable to do so.

7.18 All cold water storage cisterns and cold feed cisterns should be examined at least annually or more frequently if the risk assessment dictates, paying particular attention to the presence of foreign objects, biological material and excessive corrosion. On completion of the examinations, the cisterns should be cleaned, if required, and any remedial work carried out. Before the cisterns and system are put back into use, they should be disinfected in accordance with the procedure detailed in chapter 2 of HSG274 Part 2. Where consideration is being given to the removal of a storage cistern, a

full assessment of the downstream system is needed to ensure any consequential impacts are properly understood. These may include, but not be limited to, changes in pressure for pipes or equipment and any backflow prevention protection the cistern may have been providing.

7.19 Any chemicals or biocidal products used in the cleaning or maintenance of cisterns should be flushed from the cistern before it is put back into use. See Chapter 4 in HTM 04-01 Part A.

7.20 Cistern insulation should be checked to ensure that it is adequately positioned and in good condition.

7.21 Float-operated valves should be checked to ensure that they are securely fixed and set to achieve a correct water level in accordance with the Water Supply (Water Fittings) Regulations 1999.

7.22 Overflow/warning pipes should be checked to ensure that they maintain a steady fall (which ensures they will drain freely) and that they are clear and correctly routed to give an obvious visual alarm of an overflow condition. A weatherproof label fixed adjacent to the warning pipe identifying the tank and its location, together with the person/department to be contacted in the event of a discharge, will contribute to a quick and accurate defect report which could then be acted upon, so minimising water wastage (consideration to the provision of high- and low-level alarms linked to the BMS should also be given – see Chapter 8 in HTM 04-01 Part A). When connected to drain, they should comply with BS EN 1717.

7.23 A schematic drawing illustrating typical piping and valve arrangements for dual-cistern installations is shown in Figure 3 of HTM 04-01 Part A.

Pressurisation/supply pumps

7.24 Where two or more pumps are installed for pressurising systems, automatic control should be provided to prevent stagnation. The automatic control should also ensure all pumps are brought into operation at a regular frequency (for example, weekly) as determined by the risk assessment.

7.25 The maintenance carried out on this type of equipment should be in accordance with the manufacturer's recommendations.

Cold water distribution system

7.26 The design and installation of the cold water distribution system should comply with the Water Supply (Water Fittings) Regulations 1999 and relevant parts of BS EN 806-2 and BS 8558 (see Chapter 9 of HTM 04-01 Part A for further information).

7.27 The control of water temperature in the cold water service will essentially rely on good insulation and water turnover. Maintaining regular movement of cold water in sections prone to stagnation and guarding against excessive heat gain are effective control measures for *Legionella* and other waterborne pathogens. Special attention should be given to the maintenance and monitoring of these systems.

Notes

1. For the control of *Legionella* and other waterborne pathogens, 20°C is the quoted upper value above which multiplication of *Legionella* in particular begins to take place (see Chapter 4). It should be noted that during extremes of weather, environmental factors can influence the incoming water temperatures, particularly where water is provided from surface-water sources.

2. Where automatic flushing of urinals is used, their careful location and connection to the water system can be effectively used to assist in water turnover. When used, devices having a duty cycle should be set to flush as deemed necessary by the WSG. Information from water quality programs could be used to determine appropriate timeframes. Note that automatic flushing devices should not be located in accommodation used by patients who may become distressed by the noise.

7.28 Schematic diagrams (or as-built drawings) of the system with numbered and labelled valves reduce confusion and save time in trying to identify appropriate isolating valves and other system components.

7.29 Checks and actions should be carried out to show that:

a. the system components show no sign of leakage or corrosion or limescale;

b. the system insulation is in good condition;

c. the system filters have been changed and/or cleaned in accordance with manufacturers' recommendations. Regularly check and clean strainers;

d. all isolating valves have periodically been worked through their full range of travel;

e. every water outlet complies with the backflow protection requirements of the Water Supply (Water Fittings) Regulations 1999.

Drinking water

7.30 If separate drinking water supplies are provided, reference should be made to paragraphs 9.11–9.13 in HTM 04-01 Part A, and subject to a risk assessment consideration should be given to their removal.

Notes

1. Current guidance does not draw a distinction between drinking and general cold water services, and separate systems are no longer recommended. The installation of separate drinking water supplies has been standard policy. But in many cases where such systems have been installed, the quality of drinking water (particularly at infrequently used draw-offs, for example wash-rooms) has generally been inferior to that of the general cold water supply.

2. Softeners using salt-regenerated ion-exchange resins increase the sodium content of the water during softening, and this may be undesirable for children and infants (including the making up of babies' bottles) and anyone on strict salt-restricted diets.

Hot water storage and distribution

7.31 Hot water services should be designed and installed in accordance with the Water Supply (Water Fittings) Regulations 1999 and relevant parts of BS EN 806-2 and BS 8558. The hot water system may be of either the vented or the unvented type (see Chapter 10 of HTM 04-01 Part A for further information).

7.32 To control possible colonisation by waterborne pathogens including *Legionella*, it is essential to maintain the temperature within the hot water circulating system. To some extent, if properly maintained, the calorifier/water heater will provide a form of barrier to microbial growth. The minimum flow temperature of water leaving the calorifier/water heater should be 60°C.

7.33 The minimum water temperature at the connection of the return to the calorifier/water heater should be 50°C. To achieve the required circulating temperatures, it will be necessary to maintain the balance of flows to individual pipe branches and draw-off points.

7.34 Calorifiers should be subjected to regular procedures that include the following:

- Inspection, cleaning and maintenance at least annually, or as indicated by the rate of fouling.
- Quarterly drain flushing to minimise the accumulation of sludge. This may be extended to annual draining if, during inspection, it is found that there is little accumulation of debris.
- Whenever dismantled for statutory inspection, or every year in the case of indirect calorifiers, calorifiers should be thoroughly cleaned to remove sludge, loose debris and scale.
- Whenever a calorifier is taken out of service, it should be refilled, drained, refilled again and the entire contents brought up to, and held at, the nominal operating temperature of 60°C for at least an hour.
- The calorifier should remain isolated until the procedure is completed. When bringing calorifiers back on line, it is important that service valves are opened slowly to avoid any disturbance of sediment debris. Calorifiers that are to be taken out of service for more than a few days should be drained and should not be refilled until ready to return to service. The drain valve should be left open while the calorifier is out of use.
- Where it is known or established that gross over-capacity exists in a calorifier, and where it is practicable to do so, it should be replaced by a calorifier of the appropriate size.

Note

Full-flow (spherical/ball-type) isolating valves should be specified to avoid clogging. The drain from the gully should be of sufficient size to take the flow from the calorifier drain.

7.35 Hot water circulating pumps should be of adequate performance to ensure a minimum available temperature at draw-off points of 55°C and an absolute minimum of 50°C at the return connection to the calorifier. It is undesirable to have standby pumps owing to stagnation risks. If, however, an existing installation includes a standby pump and it is impracticable to remove it from service, it should be automatically controlled so that each is regularly brought into operation as determined by the risk assessment.

7.36 It is not permissible to shut down the pumped circulation. To do so will lead to the loss of the required system temperatures.

7.37 Electrical trace-heating is not recommended except for very small systems and those existing systems that would be difficult to rectify. Where it has been retained, it should be checked routinely (at least monthly) to ensure that it maintains the water temperature above 55°C. Care should be taken to ensure there are no cool spots. Consideration should be given to monitoring the temperatures by means of a BMS (sensors should be located at the most distal points).

Note

Dead-leg lengths should be as short as practicable; that is, the trace-heating should be taken up to the draw-off or mixing device. The continuity of the trace-heating should be monitored to avoid localised failure.

Instantaneous water heaters for single or multi-point outlets

7.38 These devices usually serve one draw-off only and are either electrically or gas-heated. In essence:

a. the flow rate is limited and is dependent on the heater's hot water power rating;

b. where restricted rates of delivery are acceptable, the heater can deliver continuous hot water without requiring time to reheat;

c. they are susceptible to scale formation in hard water areas where they will probably require frequent maintenance;

d. this form of hot water heating should only be considered for smaller premises or where it is not economically viable to run hot water distribution to a remote outlet;

e. they should be monitored to ensure they operate above 55°C (see Table 1).

Pressure and expansion vessels

7.39 Pressure and expansion vessels should be subject to routine inspection and maintenance as recommended by the manufacturer. Where practicable, these should be flushed through with wholesome water and purged to drain. If replaceable, bladders or diaphragms should be changed according to the manufacturer's guidelines or as indicated by the risk assessment.

Safe hot water delivery devices

7.40 Thermostatic mixing devices should only be installed where a risk assessment indicates their need. For guidance on applications and for a list of the types of mixing devices used, see Table 2 in HTM 04-01 Part A.

7.41 It is essential to check the temperature settings and operation of water mixing devices regularly (see manufacturers' instructions, the checklist at paragraph 7.53, and Chapter 11 in HTM 04-01: Supplement – 'Performance specification D 08: thermostatic mixing valves (healthcare premises)'). Other maintenance, where required, should be strictly in accordance with the manufacturer's instructions. Local water quality will influence the maintenance frequency for any installation.

7.42 All pipework supplying existing thermostatic mixing taps should be inspected to ensure that there is no preceding TMV supplying water to the hot port of the tap (see Figure D3 in Appendix D).

Notes

1. In existing installations, it may be necessary to install inline strainers. See the checklist at paragraph 7.53 for maintenance checks.

2. When bathing, or assisting patients, healthcare staff must always check the water temperature with a thermometer.

Showers

7.43 Disinfection of showerheads and angle-valve strainers has only a short-lived effect on microbial colonisation and growth. Manual cleaning to remove scale and other deposits or replacement of disposable showers should be carried out as based on the risk assessment. Traditionally this has been a quarterly task but the water quality and evidence base will influence the risk assessor's decision of the actual frequency implemented. Regular flushing of showers reduces microbial growth, but counts can significantly increase if regular flushing should cease. The most effective management of showers will be achieved by the removal of unnecessary ones and the regular use of others. Where showers are removed, it is important to cut back and remove all associated pipework (see paragraph 7.50 on the removal of redundant pipework).

7.44 It is important to note the distinction between self-purging and self-draining showers. Self-purging showers can be an effective Legionella control procedure, while self-draining showers can support the proliferation of *Legionella*.

Note

Adjustable showerheads are not recommended in healthcare facilities. See paragraph 10.61 in HTM 04-01 Part A.

Point-of-use filtration

7.45 Point-of-use (POU) filtration should be considered and agreed by the WSG only as an interim safeguard where control measures have been ineffective, prior to and during engineering remedial works, during periods of plumbing refurbishments and maintenance works, and where additional protection is required for vulnerable patients. Continuous long-term use of POU filters is not recommended, except where there is no effective alternative. The WSG should review their continued use and ensure an action plan is created and enacted to make certain they are changed at the intervals specified by the manufacturer.

7.46 Where POU filters are installed as a temporary measure while appropriate remedial work is carried out, they should be changed in accordance with the manufacturers' recommendations, typically at least once a month. Once removed for whatever reason, a replacement filter should be fitted. When changing filters, it is recommended that sampling of water quality takes place at outlets identified as sentinel points before refitting a replacement filter. It is essential to ensure that – where filters are to be used – they are constructed of the appropriate materials (see paragraph 3.1 in HTM 04-01 Part A).

7.47 Where POU filters are to be used, the backflow protection requirements need to be maintained in accordance with the Water Supply (Water Fittings) Regulations 1999. This may require additional backflow protection or modification of the system. In addition, sufficient activity space should be maintained to enable the outlet to be used without contaminating the filter.

7.48 Where filters are in place, follow manufacturers' instructions for cleaning, or they should be wiped clean as part of the basin/sink cleaning protocol as agreed by the WSG.

7.49 Where point-of-use filters are no longer required, the outlet connection should be flushed, cleaned and disinfected to remove any accumulated biofilm.

Removal of redundant pipework and services

7.50 In existing systems or during refurbishments, water systems should be inspected to identify redundant pipework (often referred to as blind ends) or services. In such cases, pipework should be cut back to the connection point including replacing the branch T with a straight coupling to ensure all redundant pipework is removed and to eliminate any opportunity for stagnation to occur.

Cleaning and disinfection

7.51 At some stage during the occupancy and use of a building, it is possible that the hot and cold water systems could become contaminated with waterborne pathogens. Should this be the case, the WSG may wish to consider cleaning and disinfection of part of the, or the entire, system. Advice may be found in HSG274 Part 2 and BSI's PD855468. See also Chapter 4 in HTM 04-01 Part A for guidance on the impact of treated water on materials and components.

Note

Whenever disinfection is planned, liaison with specialist departments (such as renal units and neonatal units) should take place.

Summary checklist for hot and cold system water systems

7.52 A summary checklist for hot and cold water systems is shown on the following pages (adapted from HSG274 Part 2 by kind permission of the HSE). For every operation that is undertaken, a method statement needs to be prepared and followed to ensure the stages are completed safely and effectively.

7.53 In Table 1 the suggested frequencies of inspecting and monitoring the hot and cold water systems will depend on their complexity and the susceptibility of those likely to use the water, and are for guidance only. The risk assessment should define the frequency of inspection and monitoring depending on the type of use and user and particularly where there are adjustments made by the assessor to take account of local needs. The water quality and evidence base will influence the risk assessor's decision.

Table 1 Checklist for hot and cold water systems (adapted from HSG274 Part 2)

Service	Action to take	Frequency (see paragraph 7.53)
Calorifiers	Inspect calorifier internally by removing the inspection hatch or using a borescope, and clean by draining the vessel. The frequency of inspection and cleaning should be subject to the findings and be increased or decreased based on conditions recorded	Annually, or as indicated by the rate of fouling
	Where there is no inspection hatch, purge any debris in the base of the calorifier to a suitable drain Collect the initial flush from the base of hot water heaters to inspect clarity, quantity of debris and temperature	Annually, but may be more frequent as indicated by the risk assessment or result of inspection findings
	Check calorifier flow temperatures (thermostat settings should modulate as close to 60°C as practicable without going below 60°C) Check calorifier return temperatures (not below 50°C).	Monthly
Hot water services	For non-circulating systems: take temperatures at sentinel points (nearest outlet, furthest outlet and long branches to outlets) to confirm they are at a minimum of 55°C within one minute	Monthly
	For circulating systems: take temperatures at return legs of principal loops (sentinel points) to confirm they are at a minimum of 55°C. Temperature measurements may be taken on the surface of metallic pipework	Monthly
	For circulating systems: take temperatures at return legs of subordinate loops; temperature measurements can be taken on the surface of pipes, but where this is not practicable, the temperature of water from the last outlet on each loop may be measured, and this should be greater than 55°C within one minute of running. If the temperature rise is slow, it should be confirmed that the outlet is on a long leg and not that the flow and return has failed in that local area	Quarterly (ideally on a rolling monthly rota)
	All HWS systems: take temperatures at a representative selection of other points (intermediate outlets of single pipe systems and tertiary loops in circulating systems) to confirm they are at a minimum of 55°C to create a temperature profile of the whole system over a defined time period	Representative selection of other sentinel outlets considered on a rotational basis to ensure the whole system is reaching satisfactory temperatures for *Legionella* control
POU water heaters (no greater than 15 litres)	Check water temperatures to confirm the heater operates at 55°C, or check the installation has a high turnover	Monthly–six monthly, or as indicated by the risk assessment
Combination water heaters	Inspect the integral cold water header tanks as part of the cold water storage tank inspection regime; clean and disinfect as necessary. If evidence shows that the unit regularly overflows hot water into the integral cold water header tank, instigate a temperature-monitoring regime to determine the frequency, and take precautionary measures as determined by the findings of this monitoring regime	Annually
	Check water temperatures at an outlet to confirm the heater operates at 55°C	Monthly

Service	Action to take	Frequency (see paragraph 7.53)
Cold water storage cisterns	Inspect cold water storage cisterns and carry out remedial work where necessary	Annually
	Check the cistern's water temperature remote from the ball valve and the incoming mains temperature. Record the maximum temperatures of the stored and supply water recorded by fixed maximum/minimum thermometers where fitted	Annually (summer) or as indicated by the temperature profiling
Cold water services	Check temperatures at sentinel taps (typically those nearest to and furthest from the cold cistern, but may also include other key locations on long branches to zones or floor levels). These outlets should be below 20°C within two minutes of running the cold tap. To identify any local heat gain, which might not be apparent after one minute, observe the thermometer reading during flushing	Monthly
	Take temperatures at a representative selection of other points to confirm they are below 20°C to create a temperature profile of the whole system over a defined time period. Peak temperatures or any temperatures that are slow to fall should be an indicator of a localised problem	Representative selection of other sentinel outlets considered on a rotational basis to ensure the whole system is reaching satisfactory temperatures for *Legionella* control
	Check thermal insulation to ensure it is intact, and consider weatherproofing where components are exposed to the outdoor environment	Annually
Showers and spray taps	Dismantle, clean, descale and disinfect removable parts, heads, inserts and hoses where fitted	Quarterly or as indicated by the rate of fouling or other risk factors, e.g. areas with high-risk patients
POU filters	Record the service start date and lifespan or end date and replace filters as recommended by the manufacturer (bacterial-retention filters should be used primarily as a temporary control measure while a permanent solution is developed, although long-term use of such filters may be needed in some healthcare applications)	According to manufacturer's guidelines
Base exchange softeners	Visually check the salt levels and top up salt, if required. Undertake a hardness check to confirm operation of the softener	Weekly, but depends on the size of the vessel and the rate of salt consumption
	Service and disinfect	Annually, or according to manufacturer's guidelines
Multiple-use filters	Backwash and regenerate as specified by the manufacturer	According to manufacturer's guidelines

Service	Action to take	Frequency (see paragraph 7.53)
Infrequently used outlets	Consideration should be given to removing infrequently used showers, taps and any associated equipment that uses water. If removed, any redundant supply pipework should be cut back as far as possible to a common supply (e.g. to the recirculating pipework or the pipework supplying a more frequently used upstream fitting) but preferably by removing the feeding 'T' Infrequently used equipment within a water system (i.e. not used for a period equal to or greater than seven days) should be included on the flushing regime Flush the outlets until the temperature at the outlet stabilises and is comparable to supply water and purge to drain Regularly use the outlets to minimise the risk from microbial growth in the peripheral parts of the water system, sustain and log this procedure once started	Weekly, or as indicated by the risk assessment
TMVs	Where integral, inspect, clean, descale and disinfect any strainers or filters associated with TMVs. To maintain protection against scald risk, TMVs require regular routine maintenance carried out by competent persons in accordance with the manufacturer's instructions. There is further information in paragraphs 2.152–2.168 of HSG274 Part 2.	Annually or on a frequency defined by the risk assessment, taking account of any manufacturer's recommendations
Inline strainers	Where fitted, inspect, clean, descale and disinfect any strainers or filters associated with TMVs or other sensitive equipment.	Annually or on a frequency defined by the risk assessment, taking account of any manufacturer's recommendations
Pressurisation and expansion vessels	Where practical, flush through and purge to drain. Where removable, bladders or diaphragms should be changed according to the manufacturer's guidelines or as indicated by the risk assessment	Monthly–six monthly, as indicated by the risk assessment
Biocidal treatment systems	Check the dosing and control system operation including alarms Measure the treatment parameters to establish the required values are being achieved at representative outlets including sentinel outlets **Note:** Consider 24-hour automatic monitoring for biocidal treatment on large or complex systems	Weekly Weekly Validation and calibration of the automatic monitoring system should be carried out at the frequencies recommended by the manufacturer

8 Other operational considerations

8.1 The WSG need to identify other waterborne hazards (the list below is not exhaustive but provides examples).

8.2 Waterborne pathogens including *Legionella* may colonise other areas where droplets of contaminated water of a size suitable for deep inhalation are generated. Such aerosol-generating plant and equipment should not be installed next to patient accommodation or air inlets. Some patients may be particularly susceptible to infection (see also HSG274 Part 3).

Vending, chilled-water and ice-making machines

8.3 See paragraphs 9.24–9.27 in HTM 04-01 Part A for guidance on installation of this equipment.

8.4 Where equipment is hand-filled, there should be clear instructions on the water used; it should be hygienically collected and decanted into the equipment from a clean vessel.

8.5 Chilled-water drinking fountains normally include a reservoir to assist in the cooling cycle; if machines are turned off, water quality can deteriorate. Provision of bottle dispensers should be approved only by the WSG. Where carbon filters and/or UV are fitted, these should be maintained as per the manufacturer's instructions. Additional cleaning to ensure adequate hygiene of nozzles etc should be put in place as recommended by the WSG.

Note

Proprietary water containers for water dispensing machines should be returned to the supplier.

8.6 Ice machines should not be placed in augmented care units. Where ice is needed for treatment purposes, it should be made using water obtained through a microbiological POU filter or boiled water in sterile ice trays or ice bags.

8.7 Ice should not be allowed to stagnate in an ice-making machine's storage bin, but should be changed frequently. Appropriate cleaning and hygienic procedures, agreed by the WSG, including the cleaning and disinfection of scoops etc should be put in place. For guidance on infection-control precautions with regard to ice-making machines, see HBN 00-09 – 'Infection control in the built environment'.

8.8 Maintenance for ice-making machines should be carried out in accordance with the manufacturer's recommendations. Care should be taken to ensure that the water supply to the ice-making machine is not subjected to heat gain.

Portable/room humidifiers

8.9 Designs should not include the use of "portable" or "room" self-contained humidifiers (having a water supply that is sprayed/atomised into the room space). In clinical/patient areas the decision to use this type of humidifier should rest with the IPC team. See also Safety

Notice NHSE SN(96)06 – 'Evaporative type cooling fan'.

Non-wholesome water storage

8.10 Non-wholesome water is sometimes stored for emergency use (for example for fire-fighting purposes). These systems should have an appropriate backflow prevention device in accordance with the Water Supply (Water Fittings) Regulations 1999. They should be considered by the risk assessment and the WSG.

Deluge showers

8.11 Deluge showers (sometimes called emergency showers) are intended for use in an emergency where a staff member or a patient has suffered external chemical contamination. Similarly, there may be other special outlets used for personal emergencies, for example eyebaths. These should not be installed on the end of lines. They should be dismantled, descaled and disinfected regularly in accordance with the risk assessment, and should be flushed in accordance with the recommendations in HSG274 Part 3.

Trolley wash procedures

8.12 High-pressure hoses will generate aerosols and have been associated with causing cases and outbreaks of Legionnaires' disease. The contamination of the aerosol can be reduced if the water supply is taken from a wholesome water system via a suitable air gap giving fluid category 5 protection – typically an air gap of Type AA or AB, which requires a break tank and booster pump to provide adequate pressure to the washing equipment. Procedures should be put in place to flush to drain before use, and to disinfect them if they have been out of use for a prolonged period.

Lawn sprinklers and garden (or similar) hoses

8.13 In certain conditions, lawn sprinklers may retain stagnant water in the pipework/hose supplying the sprinkler head; they may also produce an aerosol spray. The pipework may be installed underground or via a flexible hose over ground. In either case it is very unlikely that they can be completely drained down after use or when not required; at certain times in the year the retained water may be at temperatures suitable for the colonisation by, and multiplication of, *Legionella* and *P. aeruginosa*. There is evidence linking cases of Legionnaires' disease with permanently installed systems that use underground supply plumbing. Irrigation systems and hoses for these purposes should be supplied via backflow prevention devices giving fluid category 5 protection – typically an air gap of Type AA or AB, which requires a break tank and booster pump to provide adequate pressure to the irrigation nozzle or hose outlet. A risk assessment should be undertaken prior to use to minimise the risk by implementing suitable control measures.

8.14 Hoses used for filling of remote equipment or mobile units should be of materials suitable for use with wholesome water systems and should be drained, capped between uses and kept in cool conditions. They should be disinfected (by immersing in hypochlorite) before use.

Vehicle-washing plant

8.15 Vehicle washing is carried out either using a hand-held pressure spray or by a frame wash that consists of a bay containing a rectangular pipework frame fitted with several high-pressure sprays. In the latter case, this equipment should be flushed regularly. Pressure washers and frame washers should be supplied via backflow prevention devices giving fluid category 5 protection – typically an air gap of Type AA or AB, which requires a break tank and booster pump to provide adequate pressure to the outlets. See the

Water Management Society's 'Managing the risk of legionnaires' disease in vehicle-washing systems W046-5'.

8.16 Permanent hard-standing areas for vehicle-washing purposes should have an even surface to avoid ponding and have a slope or dish to a suitable drain.

Decorative internal and external water features

8.17 Internal ornamental water features (for example a water cascade in the main entrance hall) are susceptible to airborne contamination and are not recommended.

External water features

8.18 Ornamental fountains have been implicated in cases of legionellosis. External water features should not be situated under trees where fallen leaves or bird droppings may contaminate the water. Exposure to high winds should be avoided as they can disperse spray beyond the immediate confines of the basin/pond. The apex of the water column/jet should not exceed the distance to the nearest edge of the basin/pond for the same reason. An overflow/outlet to a suitable drain should be provided for easy emptying and cleaning. Where possible, a permanently installed freshwater supply pipe with topping-up device should be provided. Their provision should be subject to a risk assessment and approval by the WSG, and appropriate action is required to minimise the risk. Any top-up supply from a wholesome water supply should be supplied via backflow prevention devices giving fluid category 5 protection – typically an air gap of Type AA or AB.

8.19 A risk assessment should be undertaken prior to use to minimise the risk by implementing suitable control measures.

Wet fire and automatic sprinkler systems

8.20 Wet fire protection systems have been implicated in outbreaks of legionellosis. All hose reels, sprinkler systems and wet risers should be isolated from the potable water supply by a method permitted by the Water Supply (Water Fittings) Regulations 1999. Many fire authorities are not in favour of local fire-fighting, preferring early professional intervention. It may, therefore, be possible to remove hose reels, thus avoiding their hazards. (Any redundant pipework should be cut back to the connection point including replacing the branch 'T' with a straight coupling.)

8.21 Fire-fighting systems should be included within risk assessments. See FPA Technical Briefing Note – '*Legionella* and firefighting systems' for further guidance.

Patient contact equipment (for example respiratory nebulisers, humidifiers)

8.22 Patient contact equipment (such as respiratory nebulisers and humidifiers) should be used, drained, cleaned, rinsed, and dried strictly in accordance with the manufacturer's recommendations and agreed by the WSG. They should always be allowed to dry thoroughly before use. See also Chapter 3 in HTM 04-01 Part C, which should be applied to all healthcare settings.

Heater cooler units used in cardiac surgery

8.23 Heater coolers units (HCU) are used in cardiopulmonary bypass operations and for extracorporeal membrane oxygenation or extracorporeal life support, and their function is to regulate the temperature of the blood perfusing the patient using water in the HCU tanks to indirectly raise or lower the patient's body temperature. There have been a number of outbreaks and fatalities due to the presence

of *Mycobacterium chimaera* in the HCUs that has resulted in endocarditis, surgical site infection and disseminated infection possibly via the aerosol route. HCUs should be operated and decontaminated according to the manufacturer's instructions, and their use should be subject to a risk assessment that should be approved by the WSG.

Flowers and plants

8.24 Consideration should be given to providing specific facilities for regularly disposing of wastewater and compost outside in-patient accommodation. This should not be provided in dirty utilities.

Buried pipelines

8.25 Pipelines made of plastics are susceptible to hydrocarbons such as fuels and oils. These chemicals can permeate through plastic pipes if they are nearby and contaminate the water supply, and it may take days, weeks or even months before a noticeable taste can be detected in the water supply. Whenever spills are reported, an assessment of services within the area should be undertaken. See also paragraphs 12.8–12.16 in HTM 04-01 Part A.

8.26 Where there is a risk of hydrocarbon contamination of the supply, barrier pipe can be used instead. This is a double-layer plastic pipe with a barrier layer (usually aluminium) in between.

Other risk systems

8.27 Further guidance on other risk systems is given in Appendix 3.1 of HSG274 Part 3.

9 Microbiological monitoring

9.1 Where there are taste or odour problems, microbiological monitoring for total viable counts (TVCs) may be considered necessary. However, routine microbiological monitoring for TVCs is not recommended as there is no direct association with TVCs and the presence of waterborne pathogens.

9.2 If performed, TVCs may be used to analyse trends. Counts taken before and after disinfection (samples at least 48 hours post-disinfection) can give an indication of the efficacy of a disinfection procedure.

9.3 All microbiological measurements should be by approved methods and/or be carried out by United Kingdom Accreditation Service (UKAS)-accredited laboratories for the method being used. Dip slides are not acceptable on hot and cold water systems.

See also the Standing Committee of Analysts' 'Microbiology of drinking water – Part 7' for methods suitable for TVCs.

10 Testing for *Legionella*

10.1 *Legionella* monitoring should be carried out where there is doubt about the efficacy of the control regime or where the recommended temperatures, disinfectant concentrations or other precautions are not consistently achieved throughout the system. The WSG should use risk assessments to determine when and where to test, which may include the following circumstances:

a. When storage and distribution temperatures do not achieve those recommended and systems are treated with a biocide regime, testing should be carried out monthly, although that frequency may be altered depending on the results obtained.

b. In systems where the temperature or biocidal control regimes are not consistently achieved, weekly checks are recommended until the system is brought under control, after which the frequency of monitoring can be reviewed.

c. When a nosocomial outbreak is suspected or has been identified.

d. Where there are at-risk patients with increased susceptibility.

Legionella bacteria (cfu/L)	Action required
Not detected or up to 100	The primary concern is protecting susceptible patients, so any detection of *Legionella* should be investigated and, if necessary, the system resampled to aid interpretation of the results in line with the monitoring strategy and risk assessment.
>100 and up to 1000	Either: If the minority of samples are positive, the system should be resampled. If similar results are found again, a review of control measures and a risk assessment should be carried out to identify any remedial action necessary, or If the majority of samples are positive, the system may be colonised, albeit at a low level. An immediate review of control measures and a risk assessment should be carried out to identify any other remedial action required. Disinfection of the system should be considered.
>1000	The system should be resampled and an immediate review of the control measures and a risk assessment should be carried out to identify any remedial actions, including possible disinfection of the system. Retesting should take place three days following systemic chemical or thermal disinfection and at frequent intervals thereafter until a satisfactory level of control is achieved as agreed by the WSG.

10.2 As a minimum, samples should be taken as follows:

- from the cold water storage and the furthermost outlet from the tank;
- from the calorifier flow, or the closest tap to the calorifier, and the furthermost tap on the hot water service circulating system;
- additional samples should be taken from the base of the calorifier where drain valves have been fitted;
- additional random pre- and post-flush samples may also be considered appropriate where systems are known to be susceptible to colonisation in line with BS 7592 guidance;
- methods should be in accordance with BS 7592.

10.3 Analysis of water samples for *Legionella* should be performed in UKAS-accredited laboratories with the current ISO standard methods for the detection and enumeration of *Legionella* included within the scope of accreditation. These laboratories should take part in a water microbiology proficiency testing scheme (such as that run by PHE or an equivalent scheme accredited to BS EN ISO 17043). Alternative quantitative testing methods may be used as long as they have been validated using BS EN ISO 17994 and meet the required sensitivity and specificity. The laboratory should also apply a minimum theoretical mathematical detection limit of ≤100 *Legionella* bacteria/litre sample.

10.4 Action following *Legionella* sampling in hot and cold water systems is given in the following flowcharts (see Figures 4–6).

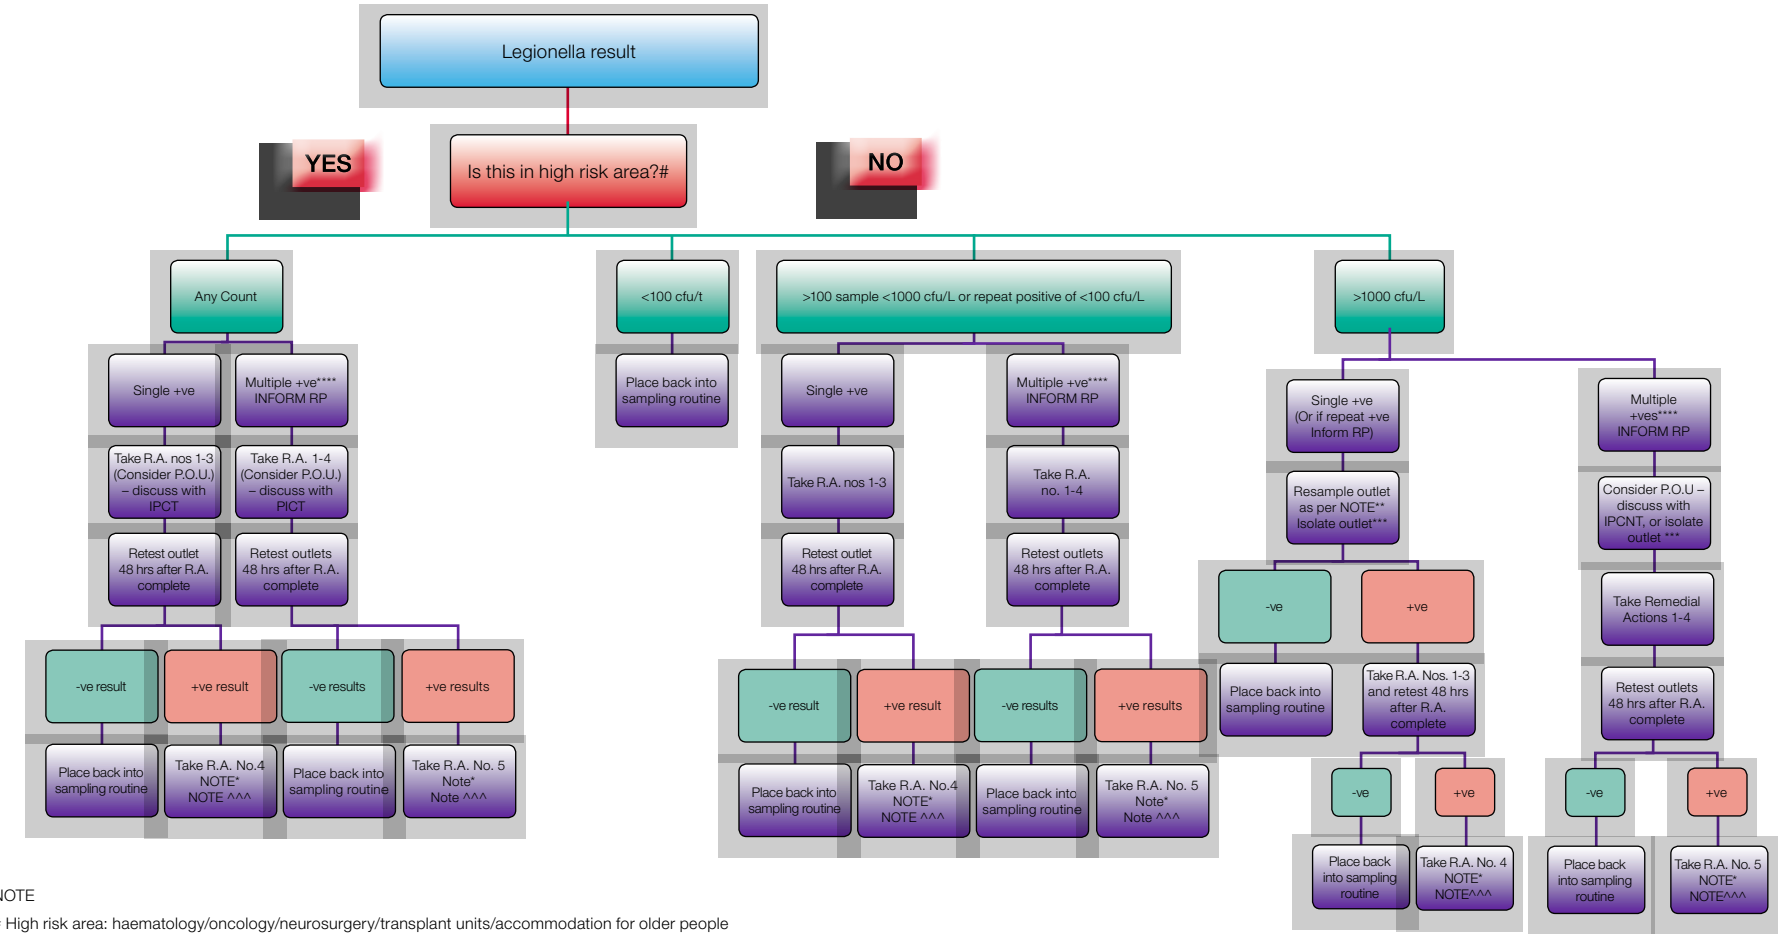
Note

Figures 4–6 are given as examples of a range of various methods that may be used. Individual conditions will dictate which procedure is appropriate and therefore the charts can be adapted accordingly.

Legionella bacteria (cfu/l)	Results from Pre-flush samples	Systemic results (Post-flush samples)
	Pre-flush samples tend to be an indicator of local conditions and if detected will often require Post-flush samples in order to determine that the contamination is local and not systemic.	Post-flush samples (or multiple positive samples) may be an indication that the whole water systems is contaminated and that controls are not effective.
Legionella not detected	Continue with current control scheme	
***Legionella* From detection to 100**	Action required • The detection limit for Legionella by culture methods was historically 100cfu/L, at present laboratories may be able to report to levels of 20cfu/L or less. This can cause confusion over what level should bring about corrective actions. The primary concern is protecting susceptible patients, so any detection of legionella should be investigated and, if necessary, the system resampled to aid interpretation of the results in line with the monitoring strategy and risk assessment.	
100- less than 1000	Action required • Identify remedial actions, Investigate:– o Usage frequency o Outlet for corrosion and scale o local heat gain, o Local Dead ends o Cross flow between hot and cold and vice versa, o Localised failure of the HWS return • It may be appropriate to immediately resample to indicate if initial remedial actions have been effective. The locations should then be resampled after 3 to 6 months to confirm any actions taken have remained effective. In addition to the above, and if the outlet is served by a TMV: • Review the need for the TMV taking into account the relative risks of scalding. Remove the TMV if considered appropriate • If the TMV is to remain, clean and disinfect the TMV, the outlet and the strainers on both cold and hot feeds. • Identify any flexible hoses (particularly after the TMV) and consider replacement, avoiding the use of flexible hoses where practicable.	Action required Whilst low numbers are unlikely to pose a risk to the general population, • Review immediately the system control measures and risk assessment • Identify remedial actions, Investigate: - o Check for any hot water backflow via the calorifier cold feed pipes o Calorifier discharge via open vents to the cold tank. o Failure of HWS to operate at target temperatures o Over capacity or under usage • Cleaning & Disinfection of the entire system should be considered • It may be appropriate to confirm effective disinfection, any required microbiological samples should be taken between two and seven days after the system is treated. (Samples taken immediately after a disinfection process might give false negative results). • The water system should then be resampled regularly to confirm any actions taken have remained effective.
1000-10,000	Action required • In addition to the above • Review immediately the local control measures and risk assessment to identify any required remedial action (dead ends etc) • Cleaning and Disinfection of the outlet should be undertaken – (especially showers and spray taps) • If a shower (spray outlet) cannot be taken out of use, consider installing point of use microbiological filters on all affected showers. • It is likely to be appropriate to resample, between two and seven days after, to indicate if initial remedial actions have been effective. • The locations should then be resampled (e.g. 1 to 3 months) to confirm any actions taken have remained effective.	Action required • In addition to the above • Cleaning & Disinfection of the entire system is likely to be required. • To confirm effective disinfection microbiological samples should be taken between two and seven days after the system is treated. (Samples taken immediately after a disinfection process might give false negative results).

Legionella bacteria (cfu/l)	Results from Pre-flush samples	Systemic results (Post-flush samples)
	Pre-flush samples tend to be an indicator of local conditions and if detected will often require Post-flush samples in order to determine that the contamination is local and not systemic.	Post-flush samples (or multiple positive samples) may be an indication that the whole water systems is contaminated and that controls are not effective.
>10,000	Action required • In addition to the above. • Take immediate measures to prevent exposure from this outlet until remedial measures are taken and shown to be effective. • If the outlet cannot be taken out of use, install a point of use microbiological filter on all affected outlets. • Resample, between two and seven days after, to indicate if initial remedial actions have been effective. • The locations should then be regularly resampled to confirm any actions taken have remained effective.	Action required • In addition to the above. • Take immediate measures to prevent exposure from all outlets fed by the system until remedial measures are taken. • Clean & Disinfect the entire system as soon as possible.

Figure 4 Action levels following *Legionella* sampling in hot and cold water systems. Example 1



NOTE

High risk area: haematology/oncology/neurosurgery/transplant units/accommodation for older people

* If all remedial actions are exhausted and there is no improvement in results, then take remedial action No. 6.

** Take additional samples pre and post from adjacent areas on same loop based on worst case scenario (Low usage outlets).

*** Remedial Action should occur 48 hours after isolation.

**** More than one positive on same loop in the system.

^^^ More frequent sampling is required

- Remedial Actions (R.A.)
  1. Review control measures e.g. temperatures flow and return and local, CLO_2 levels, investigate if outlets are being used and/or flushing regime in place
  2. Consider changing outlet i.e. shower head and hose or tap as appropriate
  3. WHB – TMV change/consider removal
  4. Full investigation of the plumbing system including dead leg invesitgation, flexible connections, has there been remedial works in the area, has anything changed
  5. Consider Installation of standalone ClO_2 Unit
  6. Consultation/inform WSG

RP = Responsible person

Figure 5 Action levels following *Legionella* sampling in hot and cold water systems. Example 2

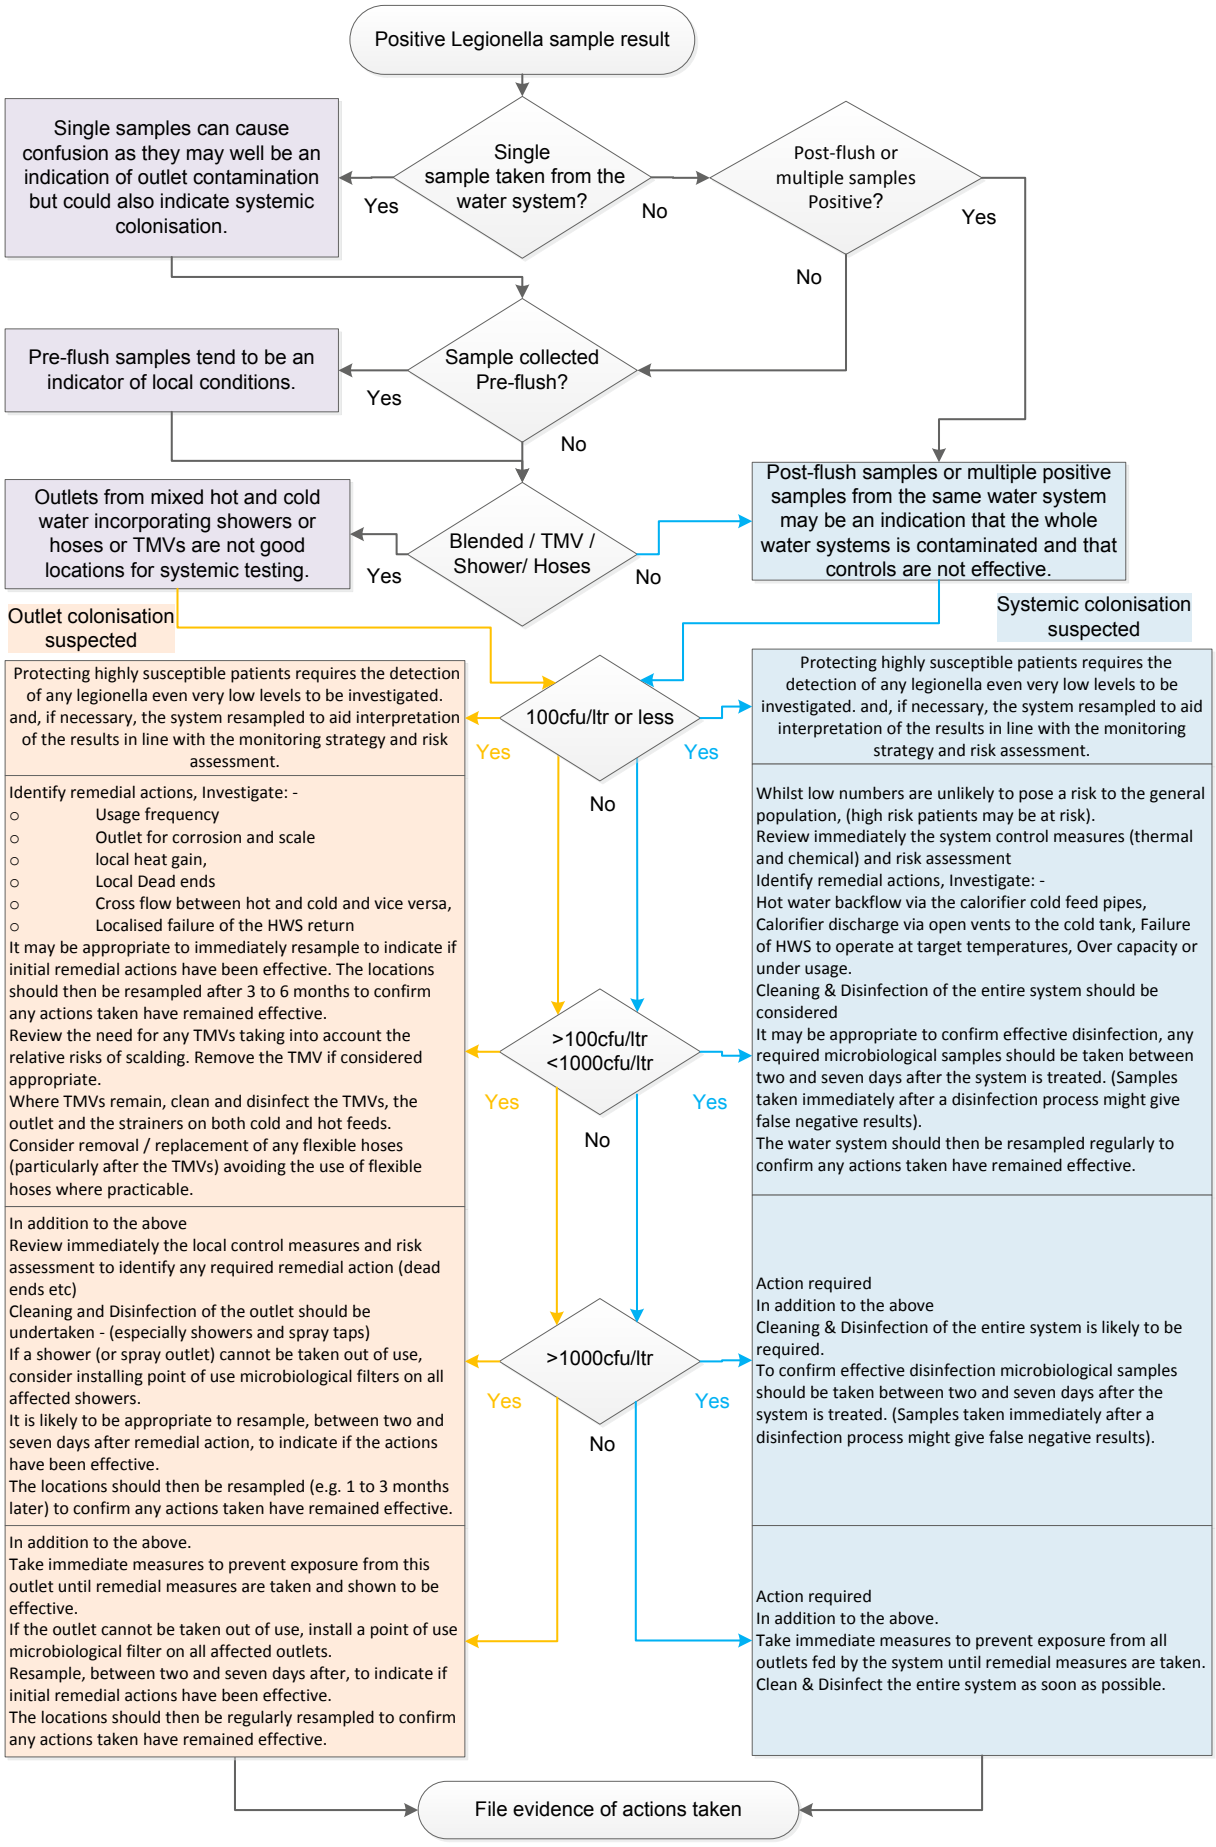


Figure 6 Action levels following positive result

Appendix A Examples of the use of water within a healthcare facility and water quality types

A1. All water and water systems in healthcare facilities should be risk-assessed according to their intended use and patient immune status taking into account any identified inherent hazards within the facility and the quality of the water supply to the systems being assessed. The assessment of risk should take account of the most vulnerable population likely to be exposed to each potential source.

A2. Examples of different categories of water for differing uses are shown in Table A1.

Note

The hazards and their occurrence will depend on the quality of source water. Therefore the associated risks should be calculated taking into account local conditions.

Table A1 Examples of water quality parameters for different applications in healthcare

Healthcare area	Application	Physical, chemical or microbial quality indicators	Water quality parameters given in:	Particular hazards (based on an assessment for each system)	See also
All settings	Wholesome water for drinking, cooking, food preparation and washing	Physical: Odour, colour, taste Chemical: Heavy metals, nitrates, orthophosphates, pesticides, surfactants Biological: Coliform bacteria, *E. coli, enterococci*	Water Supply (Water Quality) Regulations http://www.dwi.gov.uk/stakeholders/legislation/wqregs2007cons.pdf tables A and B. Where private water supplies are also used, see The Private Water Supplies Regulations 2009 http://www.dwi.gov.uk/stakeholders/legislation/pwsregs2009.pdf		DWI guidance and codes of practice Details of recommended sampling procedures are given in the Microbiology of Drinking Water https://www.gov.uk/government/uploads/system/uploads/attachment_data/file/316769/MoDW-2-232.pdf and BS EN ISO 19458.

Appendix B Action in the event of an outbreak of legionellosis

B1. In England and Wales, Legionnaires' disease is notifiable under the Health Protection (Notification) Regulations 2010. Under these regulations, registered medical practitioners must report cases of Legionnaires' disease to the Proper Officer. These regulations also require human diagnostic laboratories to notify PHE of cases of Legionnaires' disease identified by laboratory testing.

B2. An outbreak is defined as two or more cases where the onset of illness is closely linked in time (weeks rather than months) and location and where there is epidemiological evidence of a common source of infection, with or without microbiological evidence. An outbreak control team should always be convened to investigate outbreaks. It is the responsibility of the Proper Officer to declare an outbreak. The Proper Officer, appointed by the local authority, is often a consultant in communicable disease control (CCDC) within the local PHE centre health protection team.

B3. The local PHE centre health protection team has established incident plans to investigate major outbreaks of infectious diseases including legionellosis.

B4. The HSE or local environmental health officers (EHOs) may be involved in the investigation of outbreaks, their aim being to pursue compliance with health and safety legislation. The local authority, Proper Officer or EHO acting on their behalf will make a site visit to carry out a public health risk assessment, often with the relevant officer from the enforcing authorities (the HSE or the local authority) for health and safety reasons. Any infringements of relevant legislation may be subject to a formal investigation by the appropriate enforcing authority.

B5. There are published guidelines on the PHE website for the investigation and management of incidents, clusters and outbreaks of Legionnaires' disease.

B6. If the hot and cold water system is implicated in an outbreak of Legionnaires' disease, the WSG may wish to consider cleaning and disinfection of part of the, or the entire, system. Advice may be found in HSG274 Part 2.

C1. A unique identification is required for each outlet/mixing device as well as identification of its type.

C2. At commissioning, hot and cold water pressures also need to be measured and recorded for each mixing device together with all the test parameters from the in-service tests in HTM 04-01: Supplement – 'Performance specification D 08: thermostatic mixing valves (healthcare premises)'. This allows supply conditions to be reassessed in the future if outlet temperatures have changed.

Appendix D Testing for *P. aeruginosa*

D1. *P. aeruginosa* may be present within the water storage, distribution and delivery systems and also in the water supplied to the healthcare facility.

D2. The sampling protocol (Appendix E) is intended to help healthcare providers establish whether the water in augmented care units is contaminated with *P. aeruginosa* and, if it is, to help locate its origin and to monitor the efficacy of remedial measures.

D3. *P. aeruginosa* contamination is generally found in the last two metres of the point of water delivery; therefore pre-flush samples should be collected to assess the highest risk to outlet users and at-risk patients.

D4. Biofilm will constantly be released as clumps or free-floating individual cells (planktonic forms).The concentration of planktonic bacteria will build up over time when the water is stagnant, but will be diluted as water is used and flows through the pipework or tap containing the biofilm.

D5. Water outlets can give very different results and may be negative if water from the tap has been used before a sample is collected.

D6. The first water to be delivered from the outlet (pre-flush sample) should be collected to assess the microbial contamination in the last two metres of pipework.

D7. To maximise the recovery of these free-floating planktonic bacteria, water samples should be taken:

a. during a period of, preferably, no use (at least two hours or preferably longer); or

b. low use.

D8. If water flows over a biofilm containing *P. aeruginosa* located in the last two metres, planktonic bacteria arising from that biofilm will be diluted and a subsequent sample will give low bacterial counts. If contamination is upstream in the system, this will not affect bacterial counts, which may actually increase.

D9. The sample obtained after allowing water to flow from an outlet is referred to as a “post-flush” sample (see paragraphs E12 and E13 in Appendix E). Comparison of counts from pre-and post-flush samples can help locate the source of the *P. aeruginosa*. If a pre-flush sample gives a high count, subsequent paired pre- and post-flush samples should be tested to help locate the source of the contamination.

D10. In order to be able to carry out the appropriate microbiological examinations on a sample and provide a meaningful interpretation of test results, it is essential that samples are collected in the correct manner using the correct equipment and that the sampling protocol in Appendix E is adhered to.

D11. Protocols for microbiological examination of samples are provided in Appendix F.

Where to sample water outlets

D12. The water outlets to be sampled should be those that supply water which:

- has direct contact with patients;
- is used to wash staff hands; or
- is used to fill or clean equipment that will have contact with patients as determined by risk assessment.

When and how to sample water outlets

D13. The outlets identified above should be sampled to provide an initial assessment of contamination levels. There is no need to sample all taps that are due to be sampled on the same occasion; samples can be taken in batches on separate occasions. It may assist the receiving laboratory if the sampling schedule is agreed beforehand (see Figure D1 and also Appendix F).

Interpretation of *P. aeruginosa* test results

D14. If test results are satisfactory (not detected), there is no need to repeat sampling for a period of six months unless there are changes in the water distribution and delivery systems components or system configuration (for example, refurbishments that could lead to the creation of dead-legs) or occupancy.

D15. However, the WSG could indicate that water sampling is required within six months if there are clinical evidence-based suspicions that the water may be a source of patient colonisation or infection (that is, with *P. aeruginosa* or another potentially waterborne pathogen).

D16. If tests show counts of 1 to 10 cfu/100 mL, the WSG should risk-assess the use of water while simultaneously retesting the water outlet (see Figure D1 and Note below).

D17. If test results are not satisfactory (>10 cfu/100 mL), further sampling along with an engineering survey of the water system could be used to identify problem areas and modifications that may be implemented to improve water quality.

D18. After such interventions, the water should be resampled (see Figure D1 for suggested frequencies).

Note

Figure D1 gives an example of sampling frequencies. Sampling may be undertaken more frequently according to the risk assessment. It is important that samples are taken as described in Appendix E to avoid false negative results.

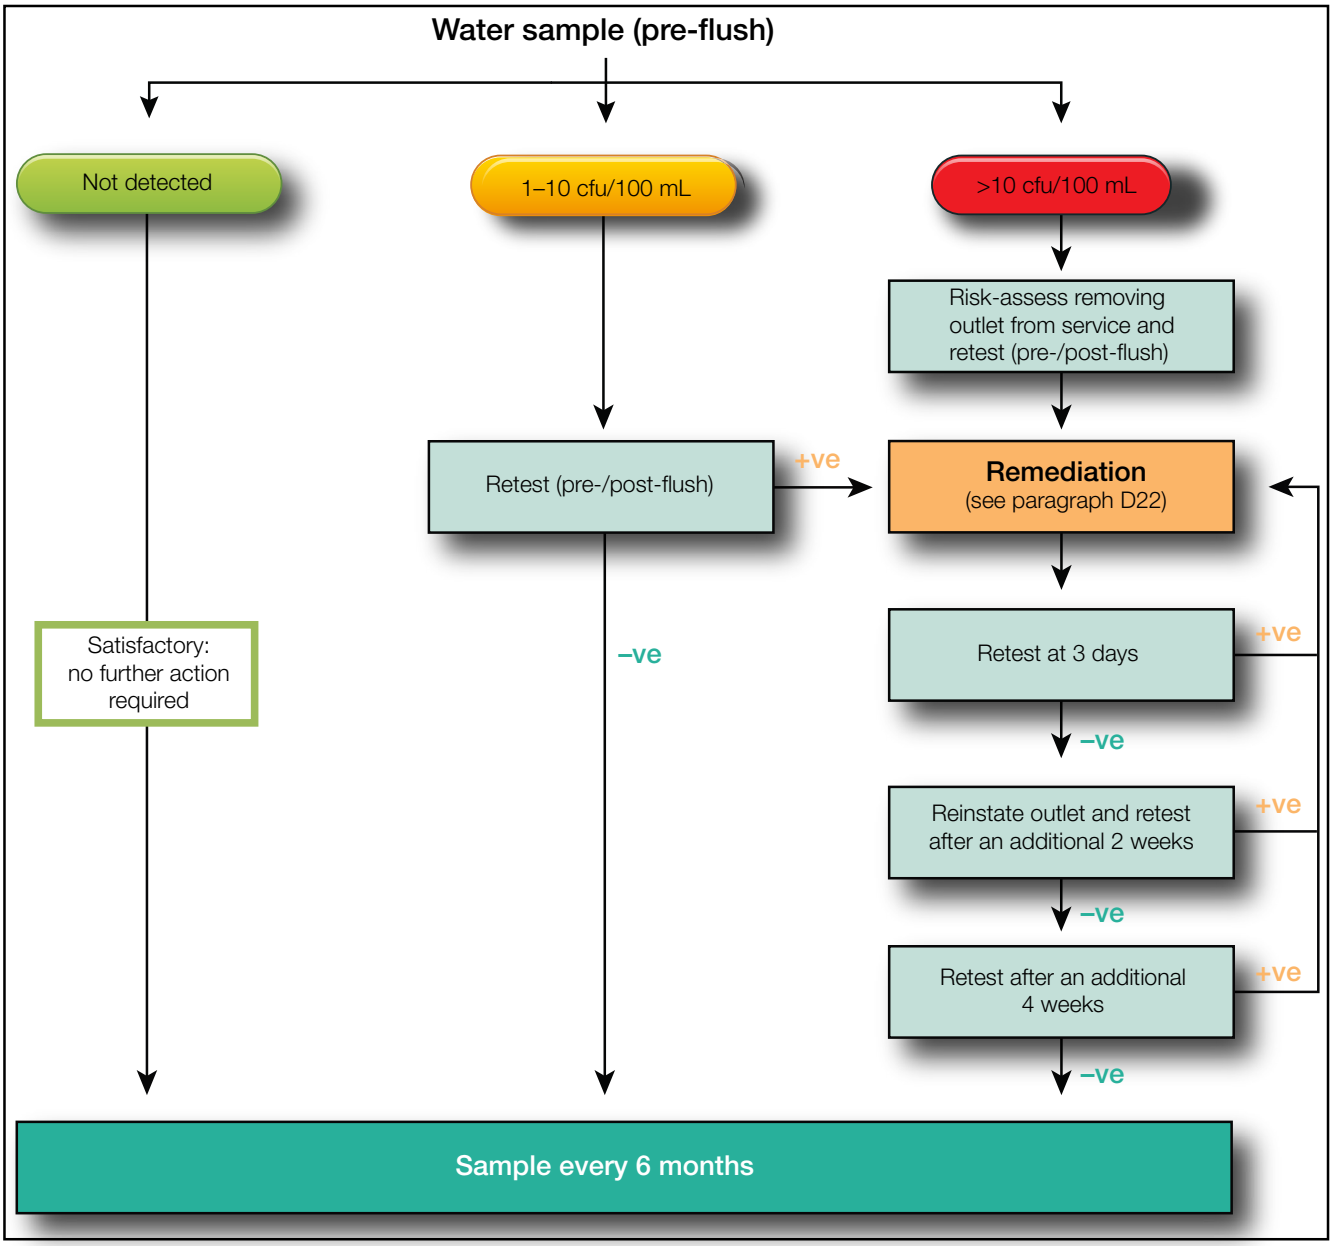

Figure D1 Summary of suggested water sampling and testing frequencies

Interpretation of pre- and post-flush counts

D19. High counts in pre-flush samples but with low counts or none detected at post-flush could indicate that areas/fittings at or near the outlets are the source of contamination (see Table D1).

- A few positive outlets, where the majority of outlets are negative, would also indicate that the source of contamination is at or close to the outlet.
- If both pre- and post-flush samples from a particular outlet are >100 cfu/100 mL and other nearby outlets have no or low counts, this shows that the single outlet is heavily contaminated, despite the high post-flush count. This could be explored by testing dilutions of pre- and post-flush water samples from this outlet or by using an extended flush such as for five minutes prior to post-flush sampling or by taking a post-flush sample after disinfection of the outlet as occurs with *Legionella* post-flush sampling.

Table D1 Interpretation of pre- and post-flush counts

High *P. aeruginosa* pre-flush count (>10 cfu/100 mL) and low post-flush count (<10 cfu/100 mL)	Suggestive of a local water outlet problem
High *P. aeruginosa* pre-flush count (>10 cfu/100 mL) and high post-flush count (>10 cfu/100 mL)	Suggestive of a problem not related to a local water outlet but to a wider problem within the water supply system

Note

Overlaying sample results onto schematic drawings of the system may help to identify the source of contamination and locations for additional sampling.

D20. If the sampling indicates that the water services are the problem, then most outlets would possibly be positive and other points in the water system could then be sampled to assess the extent of the problem (see Table D1).

D21. Figure D2 provides a summary of the sampling procedure and interpretation of results for *P. aeruginosa*.

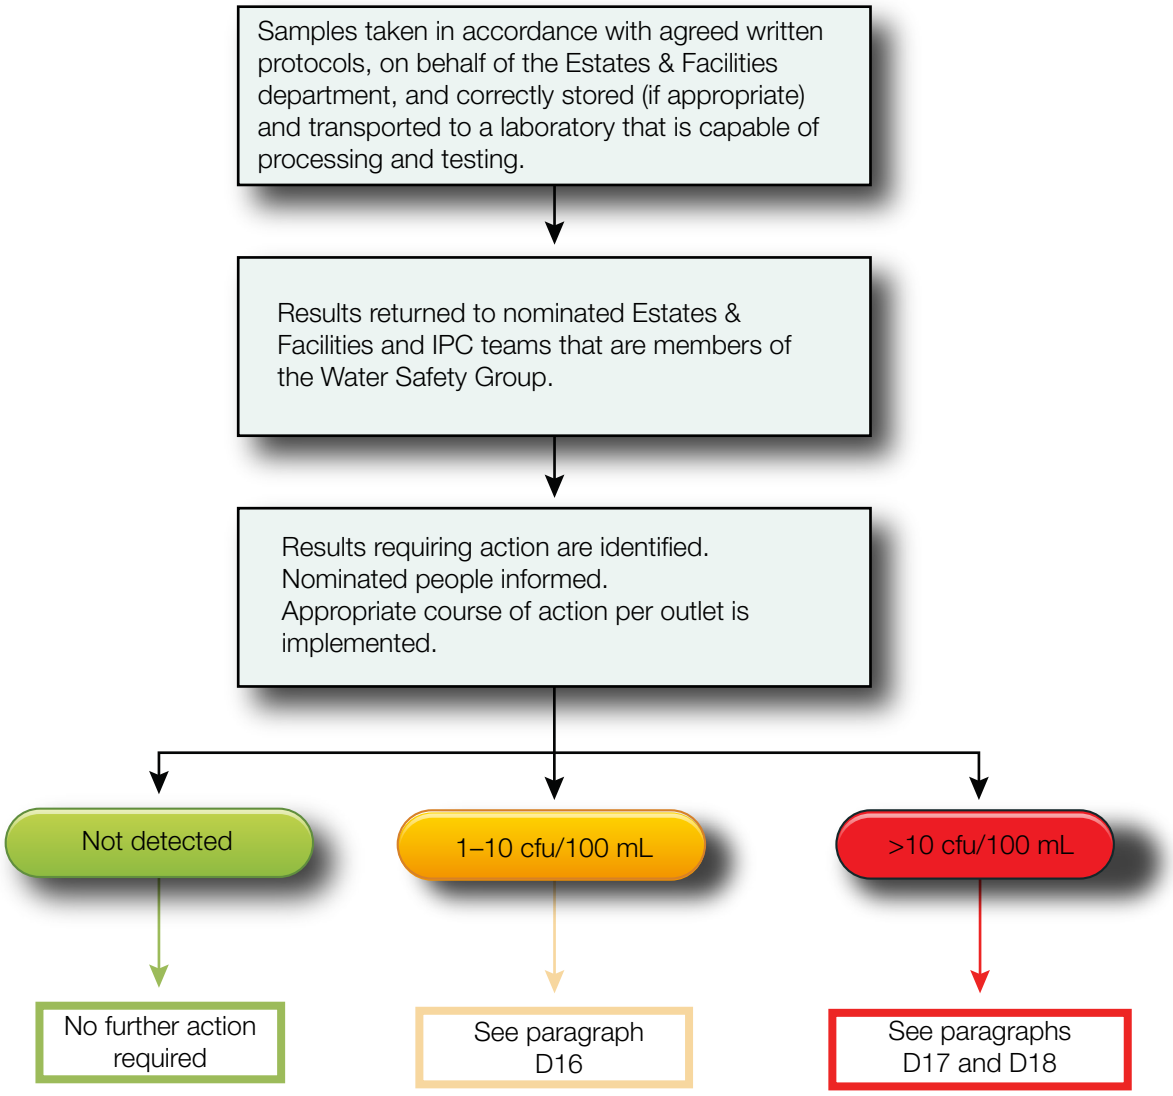

Figure D2 Summary of sampling procedure and interpretation of results for *P. aeruginosa*

What to do if a contamination problem is identified

D22. Should risk assessment or water testing identify contamination with *P. aeruginosa*, the following risk reduction and preventive measures should be considered.

a. Inform the WSG and hold a focused incident control meeting (for example, IPC team, estates and clinical staff) to ensure patient safety is prioritised and to formulate an action plan.

b. If a water outlet has been taken out of service because of contamination with *P. aeruginosa*, continue daily flushing while the outlet is out of normal use to prevent water stagnation and exacerbation of the contamination.

c. Where practical, consider removal of flow straighteners. However, the removal of flow straighteners may result in splashing and therefore additional remedial action may need to be taken. If they are seen to be needed, periodically remove them and either clean/disinfect or replace them. Replacement frequency should be verified by sampling/swabbing.

d. Splashing can promote dissemination of organisms, resulting in basin outlets becoming heavily contaminated. If splashing is found to be a problem, investigate the causes. Example causes include:

   i. the tap's designed flow profile is incompatible with the basin;

   ii. the tap discharges directly into the waste aperture;

   iii. incorrect height between tap outlet and surface of the basin;

   iv. excess water pressure;

   v. a blocked or malfunctioning flow straightener.

e. Hand-washing should be supplemented with the use of an antimicrobial hand-rub.

f. To prevent water stagnation, check for infrequently used outlets – assess frequency of usage and if necessary remove infrequently used outlet(s). For example, the provision of showers in areas where patients are predominantly confined to bed, and the resultant lack of use, could lead to stagnation.

g. Check connections to mixing taps to ensure that the supply to the hot connection is not supplied from an upstream TMV. In a hot water service, a dead-leg will exist between the circulating pipework and hot connection of a fitting such as a mixing tap. In the case of cold water services, sometimes there will be no draw-off from any part of the system and the entire service is in effect a dead-leg. To minimise the stagnation of water in a cold water system, it can be beneficial to arrange the pipework run so that it ends at a frequently used outlet. A dead-leg may also exist when a TMV is installed upstream of a mixing tap (see Figure D3). Depending on the activities of the room in which the tap is located, cold water may never be drawn through the pipe between the cold water connections of the mixing valve and mixing tap.

h. Risk-assess the water system for redundant pipework and dead-legs (for example, where water is supplied to both the cold water outlet and a TMV supplying an adjacent blended water outlet, as such cold water outlets in augmented care units may be infrequently used). When removing outlets, the branch hot and cold water pipes should also be cut back to the main distribution pipework in order to eliminate redundant pipework.

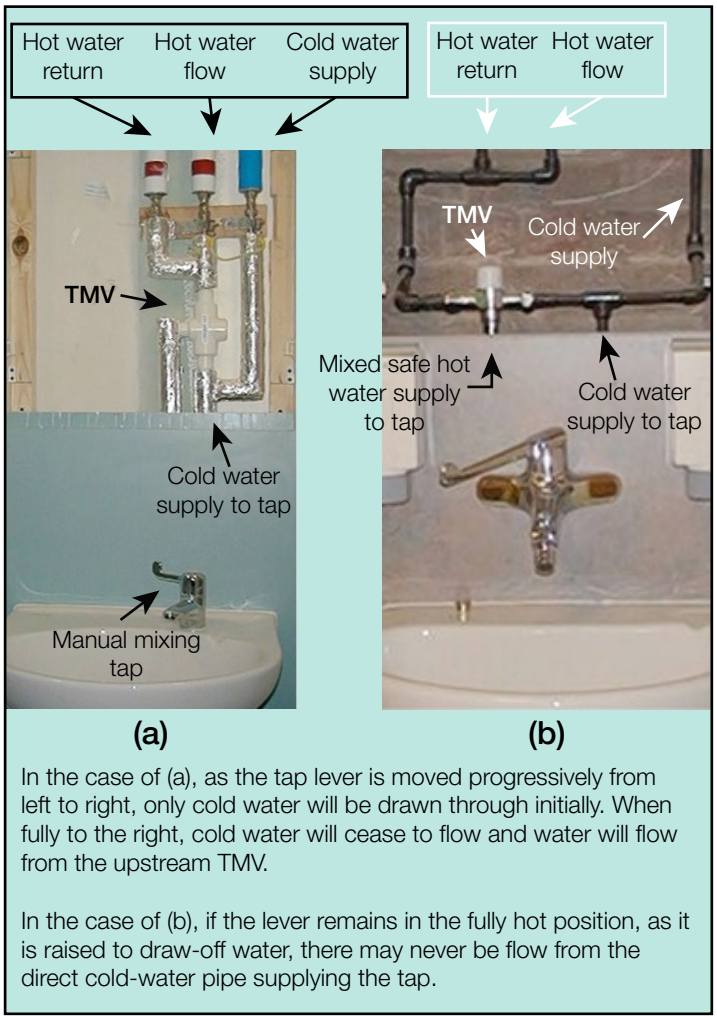

Figure D3 Dead-leg formed by the cold pipework when a TMV is installed upstream of a mixing tap

i. Assess the water distribution system for non-metallic materials that may be used in items such as inline valves, test points and flexible hoses. They should be replaced according to the guidance in safety alert DH (2010) 03 – 'Flexible water supply hoses'.

j. All materials in contact with water should have been assessed and shown they are appropriate for the intended purpose (see paragraph 1.15 in HTM 04-01 Part A) and should not leach chemicals that provide nutrients that support microbiological growth. Materials should also be compatible with the physical and chemical characteristics of water supplied to the building. Flexible pipes should only be used in exceptional circumstances (for example, where height adjustment is necessary as in installations such as rise-and-fall baths and hand-held showers).

k. POU filters, where they can be fitted, may be used to provide water free of *P. aeruginosa*. Where fitted, regard filters primarily as a temporary control measure until a permanent solution is developed, although long-term use of such filters may be required in some healthcare applications. Where POU filters are fitted to taps, follow the manufacturer's recommendations for renewal and replacement and note that the outer casing of a POU filter and the inner surface can become contaminated (see also paragraphs 7.45–7.49). There should be sufficient activity space once a POU filter has been fitted.

l. In certain circumstances, the WSG may decide it is necessary to carry out a disinfection of the hot and cold water distribution systems that supply the unit to ensure that contaminated outlets are treated. See chapter 2 of HSG274 Part 2 for guidance on how to carry out the disinfection procedure. Note that with respect to *P. aeruginosa*, hyperchlorination is not effective against established biofilms. Consider replacing contaminated taps with new taps; however, there is currently a lack of scientific evidence to suggest that this will provide a long-term solution. When replacing taps, consider fitting:

   i. removable taps;

   ii. taps that are easy to use;

   iii. taps that can be readily dismantled for cleaning and disinfection;

   iv. taps to which a filter can be attached to the spout outlet. Note: Such taps can be used for supplying water for cleaning incubators and other clinical equipment.

Note

In the event of an outbreak or incident, further advice on the management of *P. aeruginosa* contamination in water systems can be sought from PHE.

Appendix E Water sampling for *P. aeruginosa*

Note

These sampling methods will also be applicable if sampling for *Stenotrophomonas maltophilia* and *Mycobacterium* spp.

Click here for an online video showing methods for obtaining water samples.

E1. Sampling should be undertaken by staff trained in the appropriate technique for taking water samples including the use of aseptic technique to minimise extraneous contamination. The method used in this guidance may differ from the collection of water samples for other purposes (for example, for sampling *Legionella*, which should be carried out to BS 7592).

E2. Carefully label samples with the type of samples (pre- or post-flush) and outlet such that the outlet can be clearly identified; system schematics indicating each numbered outlet to be sampled can be helpful in this respect.

E3. The main strategy for sampling is to take the first sample of water (pre-flush) delivered from a tap at a time of no use (at least two hours or preferably longer) or, if that is not possible, during a time of its lowest usage. This will normally mean sampling in the early morning, although a variety of use patterns may need to be taken into account.

E4. Disinfectants in the water, such as chlorine or chlorine dioxide, will have residual activity after taking the sample and may inactivate bacteria in the sample prior to its processing and therefore the WSG should take advice from the receiving laboratory. To preserve the microbial content of the sample, neutralise oxidising biocides by dosing the sample bottle with 18 mg of sodium thiosulphate (equating to 18 mg/L in the final sample, which will neutralise up to 5 mg/L of free chlorine). It should be further noted that dosing a 1 L sample bottle with 180 mg of sodium thiosulphate (equating to 180 mg/L in the final sample) will neutralise up to 50 mg/L free chlorine or will neutralise up to at least 80 µg/L silver and 600 µg/L copper). Sterile bottles are normally purchased containing the neutraliser. However, EDTA has been found to be totally ineffective as a neutraliser for silver and therefore should not be used as such in any bacterial test including *P. aeruginosa* and *Legionella* spp. Where other disinfectants are being applied to the water system, take advice on the appropriate neutralisers to use.

E5. The tap should not be disinfected by heat or chemicals before pre-flush sampling (see paragraph E9) nor should it be deliberately cleaned or disinfected immediately before sampling.

E6. Label a sterile collection vessel (200–1000 mL volume) containing a suitable neutraliser for any biocide the water may contain. The labelling information should contain details of the tap location, sender's reference, pre- or post-flush (see paragraph E12), person sampling, date and time of sampling.

E7. If *P. aeruginosa* has been found in a preflush sample, take a second paired set of samples. The first would be a pre-flush sample as before. Run the tap for two minutes and take a second identical post-flush sample. Bacteria in this second sample (termed postflush) are more likely to originate further back in the water system. A substantially higher bacterial count in the pre-flush sample, compared with the post-flush, should direct remedial measures towards the tap and associated pipework and fittings near to that outlet. A similar bacterial count in pre-

flush and post-flush samples indicates that attention should focus on the whole water supply, storage and distribution system. A more extensive sampling regime should be considered throughout the water distribution system, particularly if that result is obtained from a number of outlets.

E8. Although water sampling is the principal means of sampling, there may be occasions when water samples cannot be obtained immediately for analysis. In the event of a suspected outbreak, swabbing water outlets (as per section 5.4 of the Standing Committee of Analysts' (SCA) 'Microbiology of drinking water – Part 2: practices and procedures for sampling') to obtain strains for typing may provide a means of assessing a water outlet, but this does not replace water sampling (see paragraph E15 on swabbing).

Procedure for obtaining the samples

E9. Pre-flush sample: Aseptically (that is, without touching the screw thread, inside of the cap or inside of the collection vessel) collect at least 200 mL water in a sterile collection vessel containing neutraliser. Replace the cap and invert or shake to mix the neutraliser with the collected water.

E10. Depending on the water distribution system design and the type of water outlet, the water feed to the outlet may be provided by:

- a separate cold water supply and hot water supply to separate outlets;
- a separate cold water supply and hot water supply, which may have its final temperature controlled by the use of an integral TMV within the outlet; or
- a separate cold water and a pre-blended hot water supply that has had its temperature reduced by a TMV prior to delivery to the outlet.

Collect at least 200 mL water in a sterile collection vessel

E11. For separate hot and cold water outlets, each outlet is individually tested with its own collection vessel and outlet identifier. For blended outlets (that is, where both hot and cold water come out of the same outlet):

- sample water with the mixing tap set to the fully cold position using an individual collection vessel and outlet identifier, and note the temperature setting;
- sample the blended outlet set to the maximum available hot water temperature using an individual collection vessel and outlet identifier, and note the temperature setting.

E12. Post-flush sample: where this is required, allow the water to flow from the tap for two minutes (see above) before collecting at least 200 mL water in a sterile collection vessel with neutraliser. Replace the cap and invert or

shake to mix the neutraliser with the collected water. This sample, when taken together with the pre-flush sample, will indicate whether the tap outlet and its associated components are contaminated or if the contamination is remote from the point of delivery (see Table D1 in Appendix D).

E13. If a sample from a shower is required, then place a sterile bag over the outlet. Using sterile scissors, cut a small section off the corner and collect the sample in a sampling container (see PHE's (2013) 'Guidelines for the collection, microbiological examination and interpretation of results from food, water and environmental samples taken from the healthcare environment'). Appropriate precautions should be taken to minimise aerosol production as described in BS 7592.

E14. The collected water should be processed within two hours. If that is not possible, then it should be refrigerated within two hours, kept at 2–8ºC and processed within 24 hours.

E15. To take a swab sample, remove a sterile swab from its container and insert the tip into the nozzle of the tap or other designated area. Care should be taken to ensure no other surfaces come into contact with the tip of the swab. Rub the swab around – that is, move it backwards and forwards and up and down, as much as possible, on the inside surface of the tap outlet or flow straightener (see photograph). Replace the swab carefully in its container, again ensuring no other surfaces come into contact with the tip of the swab. Place the swab in a transport medium or maximum recovery diluent (MRD) and send to the laboratory.

A sterile swab should be rubbed on the inside surface of the tap outlet or flow straightener

Appendix F Microbiological examination of water samples for *P. aeruginosa*

Notes

This appendix has been developed to provide technical guidance for a range of laboratories (including NHS, PHE and commercial laboratories) that have the capability and capacity to undertake water sampling and testing.

Alternative water-testing methods other than filtration methods may be used as long as they have been validated using BS EN ISO 17994 and meet the required sensitivity and specificity such as those identified in BS EN ISO 16266.

An oxidase test alone is not sufficiently specific to identify *P. aeruginosa*.

Methods approved by the Standing Committee of Analysts and listed in the 'Microbiology of drinking water – Part 8: the isolation and enumeration of *Aeromonas* and *Pseudomonas aeruginosa'* are allowed to be used.

Definition

F1. *P. aeruginosa* are Gram-negative, oxidase-positive bacteria that, in the context of this method, grow on selective media containing cetrimide (cetyl trimethylammonium bromide), usually produce pyocyanin, fluoresce under ultraviolet light 360 ± 20 nm, and hydrolyse casein. *P. aeruginosa* needs to be identified by the following methods – identification by a positive oxidase test alone is insufficient.

Testing principle

F2. A measured volume of the sample or a dilution of the sample is filtered through a membrane filter (≤0.45 µm) to retain bacteria and the filter is then placed on a solid selective and differential medium.

F3. CN agar contains cetyl trimethylammonium bromide and nalidixic acid at concentrations that will inhibit the growth of bacteria other than *P. aeruginosa*. Other selective and differential agars are available and acceptable if validated.

F4. The membrane is incubated on a selective/differential agar and characteristic colonies are counted. Confirmatory tests are carried out where necessary (see paragraph F15) and the result is calculated as the colony count per 100 mL of water.

F5. *P. aeruginosa* usually produces characteristic blue-green or brown colonies when incubated at 37°C for up to 48 hours. Confirmation of isolates is by subculture to milk agar supplemented with cetyl trimethylammonium bromide (commercially available) to demonstrate hydrolysis of casein.

Sample preparation and dilutions

F6. Water samples should be received and handled as described in the SCAs' 'The microbiology of drinking water Part 8' (currently under review). For example, samples should be examined as soon as is practicable on the day of collection. In exceptional circumstances, if there is a delay, store at 2–8°C and do not exceed 24 hours before the commencement of analysis.

Filtration and incubation

F7. Aseptically measure and dispense 100 mL of water sample into the sterile filter-holder funnel. If the funnel is graduated to indicate volume, this can also serve to measure the volume.

F8. If high bacterial numbers are present in water samples, it may be impossible to count individual colonies accurately on the filter membrane. Therefore, if high counts are expected, a range of dilutions made in sterile diluent (water, MRD or similar) can be processed in parallel with the undiluted sample. An example of this would be a 1-in-10 and a 1-in-100 dilution processed as well as an undiluted sample. Filtration of 10 mL rather than 100 mL is an alternative to filtering 100 mL of a 1-in-10 solution.

F9. Draw the water sample through the filter.

F10. Aseptically place the membrane onto the *P. aeruginosa* selective and differential agar (see paragraph F3) and incubate aerobically at 37°C.

Counting of colonies

F11. Examine plates after 22 hours ± 4 hours and 44 hours ± 4 hours of incubation.

F12. Count all colonies that produce a green-blue (demonstrating pyocyanin production) or reddish-brown pigment and those which fluoresce under ultraviolet light (optional). Exposure of colonies to daylight for two-to-four hours enhances pigment production. When there is a moderately heavy growth of *P. aeruginosa* and other organisms on the membrane, colonies adjacent to pyocyanin-producing colonies of *P. aeruginosa* can also appear green after 44 hours ± 4 hours of incubation, making the interpretation of the count difficult. Observing the plates after 22 hours ± 4 hours assists in the interpretation in these instances.

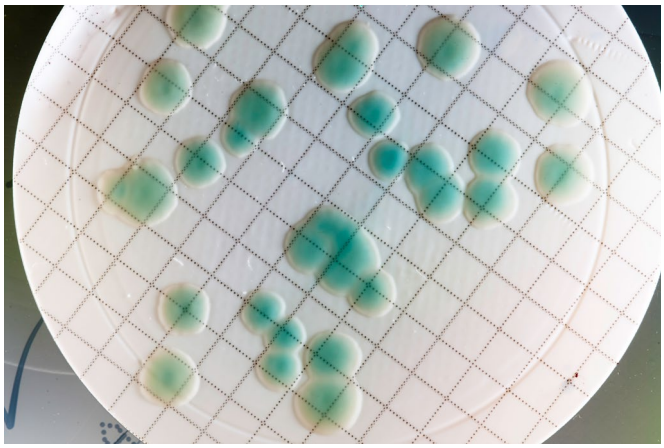

Plate showing raised counts of pyocyanin-producing colonies of *P. aeruginosa*

Processing of swabs

F13. Swabs can show presence of *P. aeruginosa* but will not provide equivalent quantitative results as water sampling. They can be used to show the presence or absence of *P. aeruginosa* at the outlet.

F14. In the laboratory, use the swab to inoculate a portion of an agar plate that is selective and differential for *P. aeruginosa* (see paragraphs F2 and F3). Streak the inoculum on the plate as for a clinical sample. Incubate as described for filter samples above. Alternatively, after sampling, place the swab in 10 mL MRD, vortex, then plate out (using serial dilution) on the appropriate media and incubate as above.

Confirmatory tests

F15. Colonies that clearly produce pyocyanin (green-blue pigmented) on the membrane are considered to be *P. aeruginosa* and require no further testing. Other colonies that fluoresce or are reddish-brown require confirmation. If more than one volume or dilution has been filtered, proceed if possible with the membrane yielding 20–80 colonies to enable optimum identification and accurate enumeration of colonies. Where there is doubt, perform additional tests to yield reliable species identification.

F16. To confirm other colonies, subculture from the membrane onto a milk cetrimide agar (MCA) plate and incubate at 37°C for 22 hours ± 4 hours. Examine the plates for growth, pigment, fluorescence and casein hydrolysis (clearing medium's opacity around the colonies). If pigment production is poor, expose the MCA to daylight at room temperature for two-to-four hours to enhance pigment production and re-examine.

F17. *P. aeruginosa* is oxidase-positive, hydrolyses casein and produces pyocyanin and/or fluorescence. Occasionally atypical non-pigmented variants of *P. aeruginosa* occur. A pyocyanin-negative, casein-hydrolysis-positive, fluorescence-positive culture should be regarded as *P. aeruginosa*. Additional tests may be necessary to differentiate non-pigmented *P. aeruginosa* from *P. fluorescens* (such as growth at 42°C or resistance to C-390, 9-chloro-9-(4-diethylaminophenyl)-10-phenylacridan or phenanthroline or more extensive biochemical tests). See Table F1.

Retention of *P. aeruginosa* isolates

F18. Where a clinical investigation is underway, inform the testing laboratory that the *P. aeruginosa* isolates and associated sampling location information should be retained for a minimum of three months as they may be required for typing at a later date.

F19. It will then be the responsibility of the testing laboratory to ensure that these isolates are supplied to the typing laboratory (for example, PHE at Colindale) when requested, and this should be written into the contract for testing.

Calculation of results

F20. Express the results as colonies of *P. aeruginosa* per 100 mL of the undiluted sample, for example:

- for 100 mL sample – the count on the membrane;
- for 10 mL of sample – the count on the membrane multiplied by 10;
- for 1 mL of sample – the count on the membrane multiplied by 100.

Reporting

F21. If *P. aeruginosa* is not detected, report as "Not detected in 100 mL".

F22. If the test organism is present, report as the number of *P. aeruginosa* per 100 mL. Reports should be specific to *P. aeruginosa*, and not generic *Pseudomonas* species.

F23. The sample reference originally submitted should be reported with each result.

Table F1

Colony on CN agar	Oxidase test	Fluorescing on MCA	Caseinolytic on MCA	Confirmed *P. aeruginosa*
Blue or green	+	NT	NT	Yes
Fluorescing and not pigmented	+	+	+	Yes
Reddish-brown non-fluorescing	+	+/–	+	Yes
NT = No testing necessary				

Microbiological typing

F24. Water and/or tap-swab isolates being sent to PHE's Antimicrobial Resistance and Healthcare Associated Infections (AMRHAI) Reference Unit for molecular analysis of *P. aeruginosa* should only be referred if the isolates have been confirmed to be *P. aeruginosa* and if there is a possible link to the outbreak strain under investigation.

F25. Referrals of *P. aeruginosa* isolates for typing should only be sent after consultation with the typing laboratory.

F26. Where many taps are positive for *P. aeruginosa*, send one colony of the *P. aeruginosa* from each water sample. Save the primary isolation plate for possible further examination once the results of typing are known and have been discussed with the typing laboratory. Analysis of results to date has consistently shown that multiple picks have been representatives of the same strain; since multiple taps are being sampled, an idea of the extent of homogeneity or otherwise will still be gained where only one colony is sent from each water sample.

F27. If only two or three taps are positive for *P. aeruginosa*, then send two separate colony picks of confirmed *P. aeruginosa* from the primary plate per water sample to AMRHAI (taking the stipulations in paragraph F25 into account). Label these clearly as being from the same water sample (so that AMRHAI can accumulate data on how common mixed strains are seen in the same tap water).

F28. It is important that the request forms have information about the links between tap water and cases as illustrated in the following examples:

a. water from tap in room "A" ref patient "X";

b. water from taps in dirty utilities;

c. tap water from room "C" with no cases.

F29. It is important to recognise that there are some types of *P. aeruginosa* that are relatively commonly found in the environment and among patient samples globally. These include the PA14 clone and clone C; a match between patient and water samples with these strains is not necessarily evidence of transmission between the two.

F30. If a contamination problem has been identified, the remediation measures in paragraph D22 of Appendix D should be followed.

Flowchart showing the processing and enumeration of *P. aeruginosa* by membrane filtration

1. Executive summary

Multi-drug-resistant (MDR) Gram-negative bacterial infections have become prevalent in some European countries. Moreover, increased use of broad-spectrum antimicrobial agents selects organisms with resistance and, by increasing their numbers, increases their chance of spread. This report describes measures that are clinically effective for preventing transmission when used by healthcare workers in acute and primary healthcare premises. Methods for systematic review 1946—2014 were in accordance with SIGN 50[1] and the Cochrane Collaboration;[2] critical appraisal was applied using AGREEII.[3] Accepted guidelines were used as part of the evidence base and to support expert consensus. Questions for review were derived from the Working Party Group, which included patient representatives in accordance with the Patient Intervention Comparison Outcome (PICO) process. Recommendations are made in the following areas: screening, diagnosis and infection control precautions including hand hygiene, single-room accommodation, and environmental screening and cleaning. Recommendations for specific organisms are given where there are species differences. Antibiotic stewardship is covered in a separate publication.

2. Lay summary

MDR Gram-negative bacteria are bacteria (or germs) that are resistant to at least three different antibiotics. These bacteria are commonly found in the gut, where they do no harm; however, they can cause infection at other body sites, mainly in patients who are vulnerable due to other underlying diseases, injury or hospitalization. Infection often happens when the bacteria enter the body through an open wound or via a medical device such as a catheter. Infections caused by MDR Gram-negative bacteria are difficult to treat, and can cause additional pain to patients with slow wound healing and other complications such as pneumonia or infection in the blood. This can prolong the length of stay in hospital and, in some cases, can cause death.

Some types of resistant Gram-negative bacteria can be carried on the skin rather than the gut, again with no obvious signs or symptoms. 'Colonization' describes this carriage of bacteria in the gut, on the skin or in the nose, throat or elsewhere on the body. Although the patients lack symptoms of infection, they may still need to be isolated/segregated and/or other contact precautions may be necessary in order to stop their resistant bacteria spreading to others.

3. Introduction

This guidance has been prepared by the Working Party to provide advice on screening (testing), treatment and precautions needed to prevent the spread of MDR Gram-negative bacteria. The guidance describes appropriate infection prevention and control precautions to include hand hygiene, equipment and environmental cleaning and guidance on screening for MDR Gram-negative bacteria. There is an accompanying guideline describing best practice in antimicrobial prescribing and stewardship which should be used in conjunction with this report.

The Working Party comprises a group of medical microbiologists and scientists, infectious disease physicians, infection control practitioners, epidemiologists and patient representatives. The patient representatives are lay members and have direct experience of the treatment of healthcare-associated infections through personal experience and/or through membership of the Healthcare-acquired Infection Service Users Research Forum, patient charities and/or through involvement in the development of National Institute for Health and Care Excellence (NICE) guidelines.

4. Guideline Development Team

4.1. Guideline Advisory Group

- Martin Kiernan, Nurse Consultant, Prevention and Control of Infection, Southport and Ormskirk NHS Trust, Southport, UK
- Phil Wiffen, Cochrane Pain, Palliative and Supportive Care Group Pain Research, Churchill Hospital Oxford, Nuffield Department of Clinical Neurosciences, Oxford, UK
- Karla Soares-Wieser, Enhance Reviews Ltd, Wantage, UK

4.2. Acknowledgements

The authors would like to acknowledge the support of the Infection Prevention Society (IPS) for their input into the development of these guidelines, as well as the associations, societies, Royal Colleges and patient groups who helped with the external review. APRW was supported, in part, by the National Institute for Health Research University College London Hospitals Biomedical Research Centre. The authors wish to thank Claire Brown, Senior Nurse Infection Control Health Protection Scotland for help in writing the staff and patient information leaflets.

4.3. Source of funding

A grant from the British Infection Association (BIA), the Healthcare Infection Society (HIS) and the British Society for Antimicrobial Chemotherapy (BSAC) funded Karla Soares-Wieser and others at Enhance Reviews Ltd, Lyford, Wantage and Paul Wiffen to perform the systematic review.

4.4. Disclosure of potential conflict of interest

- APRW: Consultant on Drug Safety Monitoring Boards for Roche and Genentech. Advisory panel for 3M.
- DML: Advisory boards or consultancy for Achaogen, Adenium, Alere, Allecra, AstraZeneca, Basilea, Bayer, BioVersys, Cubist, Curetis, Cycle, Discuva, Forest, GSK, Longitude, Meiji, Pfizer, Roche, Shionogi, Tetraphase, VenatoRx and Wockhardt. Paid lectures for AOP Orphan, AstraZeneca, Bruker, Curetis, Merck, Pfizer and Leo. Relevant shareholdings in Dechra, GSK, Merck, Perkin Elmer and Pfizer (collectively amounting to $<$10% of portfolio value).
- JAO: Part-time employment at Bioquell during the production of these guidelines. Paid lectures for 3M. Research funding from Pfizer and the Guy's and St Thomas' Charity.
- PJ: Advisory board for Baxter.
- DAE: ECCMID conference attendance funded by Astellas and Eumedica.
- BO: Advisory board for Astellas and Forest. Lecture for Alere.
- CM: Travel expenses funded by Mérieux Diagnostics.
- MC: IPS conference attendance funded by corporate sponsorship from Mölnlycke Healthcare.
- PH: Consultancy for bioMérieux, Becton-Dickinson, Eumedica, Merck, Novartis, MagusCommunications, Pfizer and Wyeth. Director of ModusMedica (medical education company). Research funded by Merck, Novartis and Pfizer.
- All other authors declared no conflict of interest.

4.5. Relationship of authors with sponsors

BSAC, BIA and HIS commissioned the authors to undertake the Working Party Report. IPS provided additional panel members and financial support for them to attend meetings. The authors are members of these societies.

4.6. Responsibility for guidelines

The views expressed in this publication are those of the authors, and have been endorsed by the sponsoring societies following consultation.

5. Working Party Report

Date of publication: January 2016 (published online 16th November 2015)

5.1. What is the Working Party Report?

This report is a set of recommendations covering prevention of transmission of MDR Gram-negative bacteria (i.e. resistant to at least three different antibiotics).

Antimicrobial chemotherapy and stewardship are covered in a separate publication.

The Working Party recommendations have been developed systematically through a multi-professional group based on published evidence. They should be used in the development of local protocols for all acute and long-term healthcare settings.

5.2. Why do we need a Working Party Report for these infections?

Colonization and infection by MDR Gram-negative bacteria have become prevalent in some European countries. Heavy use of broad-spectrum agents selects for organisms with resistance, and increases their chance of spread. National antibiotic consumption is increasing in the UK (6% increase in 2013 compared with 2010).[4] The spread of these infections risks increasing the length of hospital stay, and has an adverse effect on the quality of care of patients. Public awareness of resistance and healthcare-associated infections is increasing, and the paucity of new antimicrobial agents to treat these infections has resulted in the formulation of the five-year Antimicrobial Resistance Strategy by the Department of Health for England to address the problem. When outbreaks of infection involving MDR strains occur, there is a considerable financial, physical and psychological cost. Unless controlled, outbreaks are likely to become more common and MDR strains will become endemic. Evidence-based infection prevention and associated quality improvement methods are effective in reducing the number of infections with these organisms.

5.3. What is the purpose of the Working Party Report's recommendations?

This report describes measures that are clinically effective for preventing infections when used by healthcare workers in acute and long-term health care.

5.4. What is the scope of the guidelines?

Two sets of guidelines have been developed. This report includes appropriate infection prevention and control precautions. The other report describes best-practice antimicrobial prescribing and stewardship.[5]

5.5. What is the evidence for these guidelines?

In the preparation of these recommendations, systematic reviews of peer-reviewed research were undertaken. Expert opinion was also derived from published guidelines subjected to validated appraisal.[3] Evidence was assessed for methodological quality and clinical applicability according to the protocols of the Scottish Intercollegiate Guidelines Network (SIGN).

5.6. Who developed these guidelines?

A group of medical microbiologists, scientists, infectious disease physicians, infection control practitioners, epidemiologists and patient representatives.

5.7. Who are these guidelines for?

Any healthcare practitioner can use these guidelines and adapt them for local use. Users are anticipated to include clinical staff (i.e. medical, nursing and paramedical staff) as well as healthcare infection prevention and control teams. The guidelines should be used to improve practice of infection prevention, and to help patients and their carers to understand the methods available to prevent acquisition of antibiotic-resistant bacteria.

5.8. How are the guidelines structured?

Each section comprises an introduction, a summary of the evidence base with levels, and a recommendation graded according to the available evidence.

5.9. How frequently are the guidelines reviewed and updated?

The guidelines will be reviewed at least every four years and updated if change(s) in the evidence are sufficient to require a change in practice.

5.10. Aim

The primary aim of this report was to assess the current evidence for prevention and control of MDR Gram-negative infections.

6. Summary of guidelines

The guidelines relate to MDR Gram-negative bacteria and have been derived from current best peer-reviewed publications and expert opinion. Table IV contains expert opinion. Each recommendation is associated with a class of supporting evidence, as follows.

6.1. Surveillance

1,2. The minimum susceptibility tests performed on all significant Gram-negative isolates should include meropenem; in addition, cefpodoxime should be tested for Enterobacteriaceae, and ceftazidime should be tested for *Pseudomonas* spp. Strong

3. Travel history (i.e. countries or known endemic areas visited within previous year) should be collected for all patients with carbapenemase-producing Gram-negative bacteria. Strong

4. Each healthcare organization should have access to robust microbiological arrangements for detecting and reporting all MDR Gram-negative organisms in routine clinical samples and for screening using highly-sensitive tests with a diagnostic turnaround time of $<$48 h. Conditional

6.2. Screening

5. Active screening rather than passive surveillance is recommended for high-risk specialties. Conditional
6. Patients at high risk of colonization or infection with carbapenem-resistant organisms include those admitted to intensive care units (ICUs) and from long-term care facilities (e.g. care homes). Conditional
7. Screening for rectal and wound carriage of carbapenemase-producing Enterobacteriaceae should be undertaken in patients at risk. Strong
8. All patients transferred from, or with a history of admission to, healthcare facilities with known endemic carbapenemase-producing Enterobacteriaceae in the preceding year should be screened. Strong
9. Screening for carbapenem-resistant *Acinetobacter baumannii* and MDR *Pseudomonas aeruginosa* is required in the management of outbreaks. Strong
10. A rectal swab (with visible material) or stool sample (and urine sample if catheter present) should be used for screening for MDR Enterobacteriaceae and *P. aeruginosa*. For *Acinetobacter* spp., skin sites should be sampled, or, if a catheter or endotracheal tube is present, urine or respiratory secretions should be sampled. Conditional
11. In the event of secondary cases of carbapenem-resistant Enterobacteriaceae, standard infection control precautions (SICPs) and contact precautions should be monitored and re-inforced among clinical staff. Screening of patients not identified as carriers should be repeated weekly and on discharge from affected units until no new cases are identified for more than seven days. Strong
12. Patients with previous samples with carbapenem-resistant or other MDR Gram-negative bacteria should be screened at the time of admission. Conditional

6.3. Prevention of transmission

13. In addition to SICPs, apply contact precautions for those patients who present an infection risk. Strong
14. Where possible, single-room isolation should be provided for patients with MDR Gram-negative bacterial infection/colonization, and contact precautions should be continued for the duration of their stay. Conditional
15. Use disposable gloves and gowns or aprons to care for patients with MDR Gram-negative bacteria: *A. baumannii*, carbapenem-resistant and extended-spectrum β-lactamase (ESBL)-producing Enterobacteriaceae, *P. aeruginosa*. Strong
16. Identify and place infected and colonized patients in single rooms where available in this order of priority: carbapenem-resistant Enterobacteriaceae, carbapenem-resistant *A. baumannii*, ESBL-producing *Klebsiella* spp., carbapenemase-producing *P. aeruginosa*, ESBL-producing *Escherichia coli* and other Enterobacteriaceae, AmpC Enterobacteriaceae. Strong
17. If insufficient rooms are available, cohort patients following local risk assessment. Conditional
18. Hand hygiene is required before and after direct patient contact; after contact with body fluids, mucous membranes and non-intact skin; after contact with the immediate patient environment; and immediately after the removal of gloves. Strong

6.4. Cleaning and environment

19. Environmental screening should be considered where there is unexplained transmission of MDR Gram-negative organisms or a possible common source for an outbreak. Strong
20. Respiratory and other contaminated equipment should be decontaminated (or respiratory secretions discarded) away from the immediate bed area in designated cleaning sinks and not in handwash sinks. Strong
21. For *P. aeruginosa*, including MDR strains, at a minimum, in accordance with the organization's water safety plan, a risk assessment should be made when levels of patient colonization or infection rise in order to determine if point-of-use filters should be installed or if taps need to be changed. Strong
22. Terminal disinfection of vacated areas with hypochlorite should be used in the control of outbreaks of infection due to MDR Gram-negative bacteria. Conditional
23. Hydrogen peroxide vapour should be considered as an adjunctive measure following cleaning of vacated isolation rooms/areas. Conditional
24. The routine use of selective decontamination of the mouth or digestive tract is not recommended for control of MDR Gram-negative bacteria. Conditional

6.5. Miscellaneous

25. Monitor hand hygiene of all staff when patient cohorting is being applied. Strong

7. Implementation of these guidelines

7.1. How can the guidelines be used to improve clinical effectiveness?

The guidelines can be used to inform local infection prevention and control guidance, and to direct clinical decision-making. They provide a framework for clinical audit tools aiming to achieve quality improvement.

7.2. How much will implementation of the guidelines cost?

In most areas, there are no anticipated additional costs unless existing practice falls well below currently-accepted best practice. Failure to implement the recommendations would result in greater costs in terms of economics and quality of life. Screening and isolation will result in significant cost pressures where they are not currently practised, but these costs are set against reduced transmission and fewer cases needing antibiotic treatment. Prolonged isolation can have adverse effects on a patient's psychological health, so may have additional unexpected costs.

7.3. Summary of audit measures

The following are expressed as percentage compliance:

- All Gram-negative isolates requiring antibiotic treatment are to be tested for susceptibility to meropenem (or all blood isolates should be tested).
- The microbiology laboratory reports all patients infected or colonized with carbapenemase-producing Gram-negative bacteria to Public Health England (PHE) or an equivalent body.
- All patients colonized or infected with carbapenem-resistant Enterobacteriaceae and *A. baumannii* are placed under contact precautions within 6 h of identification.
- All patients colonized or infected with carbapenem-resistant Enterobacteriaceae and *A. baumannii* are placed under contact precautions in a single room or cohort for the duration of their stay.
- Travel history is obtained at the time of admission for all acute hospital patients, and patients from endemic areas are screened.

7.4. E-learning tools

Continuing Professional Development questions and model answers are listed for self-assessment in Appendix 4.

8. Methodology

8.1. Evidence appraisal

Methods were in accordance with SIGN 50[1] and the Cochrane Collaboration,[2] and critical appraisal was applied using AGREEII.[3] Accepted guidelines were used as part of the evidence base and to support expert consensus. Questions for review were derived from the Working Party Group, which included patient representatives in accordance with the PICO process.[1]

K. Soares-Wiesner of Enhance Reviews Ltd and Dr P. Wiffen of Pain Research and Nuffield Department of Clinical Neurosciences, Oxford University used a systematic review process. Guidelines and research studies were identified for each search question. Systematic reviews, randomized controlled trials and observational studies were included and assessed by two reviewers. In context, observational studies included non-randomized controlled studies, controlled before–after studies and interrupted time series.

All languages were searched. Search strategies for each area are given in the sections below. MeSH headings and free-text terms were used in the Cochrane Library (Issue 11 2012), Medline (1946–2012), Embase (1980–2012) and Cumulated Index of Nursing and Allied Health Literature (CINAHL) (1984–2012). On 23rd May 2014, an update search was conducted on Medline alone using the same strategy for references after 1st January 2013. Reference lists of included studies were searched. Two review authors independently screened all citations and abstracts identified, and screened full reports of potentially eligible studies (those that addressed review questions in primary or systematic secondary research or a clinical or in-use study). Disagreements were resolved by discussion, and rationales for exclusion of studies were documented. Pretested data extraction forms were used, and study characteristics and results were collected. Data were extracted from observational studies for multiple-effect estimates: number of patients, adjusted and unadjusted effect estimates with standard error or 95% confidence interval (CI), confounding variables and methods used to adjust the analysis. If available, data were extracted from contingency tables. Risk of bias was assessed using SIGN critical appraisal checklists. Interrupted time series were assessed using the Cochrane Effective Practice and Organisation of Care (EPOC) Group.[1,6] Quality was judged by reported details of protection against secular changes (intervention independent of other changes) and detection bias (blinded assessment of primary outcomes and completeness of data). For outbreak patterns associated with particular pathogens, the Working Party made additional searches of descriptive studies to extract effective interventions.

Clinical outcomes were mortality, effectiveness of treatment and length of hospital stay. Microbial outcome measures were decreases in the prevalence of multi-drug resistance among Gram-negative bacteria, or decreases in colonization or infection by specific Gram-negative pathogens. Risk ratios (RR) were used for dichotomous variables, and mean differences with 95% CI were used for continuous outcomes.[7] Analyses were performed using Revman 5.2.[8] SIGN summary tables were used.

Evidence tables and judgement reports were presented and discussed by the Working Party, and guidelines were prepared according to the nature and applicability of the evidence, patient preference and acceptability, and likely costs. The strength of evidence was defined by SIGN (Table I), and the strength of recommendation was adopted from GRADE (Grading of Recommendations Assessment, Development and Evaluation) (Table II). The grading relates to the strength of the supporting evidence and predictive power of the study designs, rather than the importance of the recommendation. Any disagreements between members were resolved by discussion. For some areas, only expert opinion is available; in such cases, a good practice recommendation has been made.

8.2. Consultation process

On completion, these guidelines were opened to consultation with the stakeholders listed in Appendix 1. The draft report was placed on the HIS website for one month. Views were invited on format, content, local applicability, patient acceptability and recommendations. The Working Party considered and collated comments, and agreed revisions.

9. Rationale for recommendations

9.1. Epidemiology

9.1.1. What is the definition of multi-drug-resistant Gram-negative bacteria?

For the purposes of this guideline, MDR Gram-negative bacteria were defined as having three or more antimicrobial

Table I
Levels of evidence for intervention studies[1,6]

1++	High-quality meta-analyses, systematic reviews of RCTs or RCTs with a very low risk of bias.
1 +	Well-conducted meta-analyses, systematic reviews or RCTs with a low risk of bias.
1 −	Meta-analyses, systematic reviews or RCTs with a high risk of bias.[a]
2++	High-quality systematic reviews of case–control or cohort studies. High-quality case–control or cohort studies with a very low risk of confounding or bias and a high probability that the relationship is causal. Interrupted time series with a control group: (i) there is a clearly defined point in time when the intervention occurred; and (ii) at least three data points before and three data points after the intervention.
2+	Well-conducted case–control or cohort studies with a low risk of confounding or bias, and a moderate probability that the relationship is causal. Controlled before–after studies with two or more intervention and control sites.
2−	Case–control or cohort studies with a high risk of confounding or bias and a significant risk that the relationship is not causal. Interrupted time series without a parallel control group: (i) there is a clearly defined point in time when the intervention occurred; and (ii) at least three data points before and three data points after the intervention. Controlled before–after studies with one intervention and one control site.
3	Non-analytic studies (e.g. uncontrolled before–after studies, case reports, case series).
4	Expert opinion. Legislation.

RCT, randomized controlled trial.
[a] Studies with an evidence level of '1−' and '2−' should not be used as a basis for making a recommendation.

Table II
Recommendation grading[1]

	Recommendation
Undesirable consequences clearly outweigh desirable consequences	Strong recommendation against
Undesirable consequences probably outweigh desirable consequences	Conditional recommendation against
Balance between desirable and undesirable consequences is closely balanced or uncertain	Recommendation for research and possibly conditional recommendation for use restricted to trials
Desirable consequences probably outweigh undesirable consequences	Conditional recommendation for
Desirable consequences clearly outweigh undesirable consequences	Strong recommendation for

resistance mechanisms affecting different antibiotic classes. For a full discussion of the definitions in use, please refer to the companion paper.[5]

9.1.2. Which Gram-negative bacteria cause infection control problems?

Opportunistic Gram-negative bacteria that present increasing resistance issues include Enterobacteriaceae (*E. coli*, *Klebsiella* spp., *Enterobacter* spp., *Serratia* spp., *Citrobacter* spp., Proteeae) and the non-fermenters, *P. aeruginosa* and *A. baumannii*. *Stenotrophomonas maltophilia* is inherently MDR in most cases, but a less common cause of cross-infection. Gonococci are Gram-negative bacteria and are increasingly resistant, but were excluded because relevant public health control actions are substantially different.

In this report, emphasis is placed on strains resistant to β-lactams, including carbapenems, cephalosporins and β-lactamase inhibitor combinations, and strains resistant to fluoroquinolones insofar as these are the core components of most therapies for severe infections. Aminoglycosides are most often used as adjuncts to β-lactam therapy in severe infection, whereas polymyxins are mainly used in cases where β-lactams cannot be used due to resistance. Resistance to these latter groups of agents should nevertheless prompt concern, especially where it is coupled with resistance to multiple β-lactams, as is often the case. Means of infection control remain the same irrespective of the specific resistance.

9.1.3. What are the relative contributions of community and hospital acquisition?

The mechanisms and time course of resistance accumulation by Gram-negative opportunists, both internationally and in the UK, are reviewed in a companion paper.[5] This introduction, rather, is concerned with the distribution of these resistance types in hospitals, long-term care facilities and the community. The distinction between these sectors is increasingly blurred, with many elderly patients moving back and forth between hospital and care homes,[9] and with hospital stays becoming shorter, so that healthcare-associated infections often become apparent after hospital discharge[10] or on re-admission. Consequently, MDR Gram-negative bacteria — including those producing carbapenemases — are

increasingly seen in general practice specimens, principally urine samples. Careful enquiry often reveals that the patient recently received secondary care. The period of time that may elapse from acquisition in hospital, often in colonization sites, to the development of an obvious infection in the community is variable, and different papers use different intervals when classifying infection diagnosed in the community as 'healthcare-associated'. Intervals of one to three months are commonly used to distinguish community acquisition from that acquired during hospital admission, but the literature shows that carriage, and the potential for infection, can persist for much longer periods (commonly one year); it is recommended that this longer period should be used.[11]

9.1.4. What is the evidence for reservoirs and spread of multi-drug-resistant Gram-negative bacteria in care homes and secondary care?

Enterobacteriaceae, *P. aeruginosa* and *Acinetobacter* spp., whether resistant or not, can all be transferred among vulnerable patients by staff vectors and contaminated equipment, leading to well-defined local clonal outbreaks.[12] Both *A. baumannii* and *Klebsiella pneumoniae* (by virtue of their capsules) can survive on dry surfaces, including hands.[13,14] MDR Enterobacteriaceae can colonize the gut, providing — without any symptoms — a reservoir for transfer to other body sites where infection may ensue, or transfer to other patients. The risk of transmission is increased if the carrier experiences diarrhoea or incontinence.

In general, and excluding particular high-risk clones discussed below, there is no evidence that MDR strains are more likely to be associated with cross-infection than other strains. Enterobacteriaceae that owe carbapenem resistance to combinations of ESBLs or AmpC β-lactamase activity together with porin loss are often thought to have impaired fitness, and to be less likely to spread among patients than those with carbapenemases, but cross-infection by porin-deficient Enterobacteriaceae has been reported from Italy, Korea and Portugal.[15—17] In a nested case—control study in the USA, mechanical ventilation, pulmonary disease, days of antibiotic treatment and colonization pressure were associated with acquisition of carbapenem-resistant Enterobacteriaceae.[18] Typing of *K. pneumoniae* in this study suggested clonal transmission within and between hospitals.

9.1.4.1. High-risk clones. Bacterial typing has revealed the role of 'high-risk clones' in the international spread of resistance.[19] For example:

- The majority of fluoroquinolone-resistant ESBL-producing *E. coli* causing infection in hospitals and the community belong to sequence type (ST) 131-B2-O25b.[20,21]
- The growing prevalence of *K. pneumoniae* carbapenemase (KPC)-producing *K. pneumoniae* in hospitals (e.g. in Israel, Italy and the USA) substantially reflects the clonal expansion of ST258 variants with KPC-2 or -3 enzymes.[22]
- In Russia, Belarus and Kazakhstan, there is extensive nosocomial spread of ST235 *P. aeruginosa*, with VIM-2 carbapenemase only susceptible to colistin.[23]

Except in the case of ST131 *E. coli* (where infection may be preceded by a long period of innocuous gut carriage), UK hospitals are minimally affected by these lineages, although both ST258 *K. pneumoniae* and ST235 *P. aeruginosa* have been recorded.[22,24] National clones that have achieved considerable traction in the UK include *A. baumannii* OXA-23 clone 1, recorded at >60 hospitals.[19,25] It remains uncertain whether this prevalence reflects site-to-site transfer via colonized patients, or the selection, at multiple sites, of a pre-existing but previously rare subtype of this very clonal species. Focusing infection control on specific types rather than resistances has not been explored for ESBL-producing *E. coli*.

E. coli ST131 has spread globally, and is transmitted within hospitals, families, through pets and long-term care facilities whilst being very rare in food animals. It is often resistant to fluoroquinolones and multiple other antimicrobials, as well as producing CTX-M ESBLs.[26] The lineage can be distinguished by serotyping and polymerase chain reaction (PCR).[27] Among faeces sent for culture from international travellers returning to the UK, many of which were from the Indian subcontinent, 18% contained ESBL *E. coli*, mainly with CTX-M-15 enzymes, and 2.1% had ST131 strains with ESBL.[28]

9.1.4.2. Plasmid outbreaks. In this situation, a plasmid or family of related plasmids disseminate(s) among strains of one or more species in a locale.[29,30] This is the case, for example, in the current spread of pKpQIL plasmids encoding KPC carbapenemases in and around Manchester.[31] Unlike in a clonal outbreak, the isolates are diverse in terms of species, strain and in their antibiograms, which also reflect the host strain and any other plasmid(s) carried. Single-strain clusters occur within this overall diversity, but do not come to dominate the picture as in a classical single-strain outbreak. It is inferred (although rarely proven) that frequent plasmid transfer among gut bacteria leads to the diversity of strains involved.[32] As there is no single 'outbreak' organism to target this scenario, it is more challenging for infection control teams than a classical outbreak. Moreover, it presents a greater recognition challenge to the microbiology laboratory; consequently, reliable and consistent application of SICPs is extremely important.

9.1.4.3. Outbreaks due to Pseudomonas aeruginosa contamination of water systems. Classical clonal outbreaks of hospital infection have a clear train of transmission if carriage is taken into account, and, assuming consistent application of contact precautions, can be controlled in a relatively short time if the strain(s) are not re-introduced.[12] However, a different epidemiology is seen occasionally, particularly with *P. aeruginosa* (MDR or not), when a single clone or small number of clones causes infections in multiple patients in a unit or hospital, often without obvious links, over a prolonged period, sometimes extending over several years and with gaps of months between cases.[33,34] Such instances often reflect contamination of the hospital plumbing system by the pseudomonas clone(s), and control may require modification/assessment, including, for example, replacing sinks and toilets with easier-to-clean models less prone to splashback, educating staff to reduce blockages and inappropriate storage, reviewing cleaning protocols, and reducing shower flow rates to minimize flooding.[35,36]

9.1.4.4. Long-term care facilities and the spread of multi-drug-resistant Enterobacteriaceae. Long-term care facilities are increasingly identified as reservoirs of antibiotic resistance, particularly for colonization. The data to support this

view are considerable but are not based on systematic surveillance, except in France, where the incidence of ESBL-producing Enterobacteriaceae infection per 1000 days in long-term care facilities increased from 0.07 in 1996 to 0.28 in 2005. This largely reflected the proliferation of *E. coli* with CTX-M enzymes, which were later recognized as representatives of the international ST131 clone.[37,38]

Long-term care facilities range from establishments offering assisted living to largely independent residents through to those providing complex medical support.[39,40] This spectrum of care varies between countries, reflecting healthcare organization and cultural factors.[41–43]

The distribution of incontinent and catheterized residents is likely to influence the transmission of Gram-negative bacteria, including those with multi-drug resistance. Variation may be very local; March *et al.* found that gut carriage of resistant bacteria varied across five subunits in one long-term care facility in Bolzano, Italy.[44] Overall, carriage was higher than in the hospital's geriatric unit, which perhaps had more knowledge and reliable application of infection prevention and control precautions (75% of 111 in long-term care facility vs 22% of 45 in geriatric unit). In contrast, Gruber *et al.* in Germany found higher carriage rates of MDR bacteria in geriatric units (32.6%) than in nursing homes (18.5%) or ambulatory care (15.6%).[45]

While most resistance studies on long-term care facilities relate to those caring for the elderly, spread of carbapenemase producers as gut colonizers has also been recorded in a care home for children and young adults with neurodevelopmental problems.[46]

The literature supporting the view that long-term care facilities constitute a reservoir of multi-drug resistance comprises, firstly, numerous analyses showing that previous stay in a long-term care facility is a risk factor for later infections with MDR Gram-negative bacteria, including those with ESBLs and carbapenemases; and, secondly, multiple snapshot surveys showing frequent (although very variable) gut carriage of ESBL-producing *E. coli* and *Klebsiella* spp. among residents in long-term care facilities, including in Australia, Belgium, France, Germany, Israel, Japan, Malaysia, the UK, Italy and the USA where these enzymes have already proliferated in hospitals.[44,47–51] Accumulation of MDR Gram-negative bacteria in long-term care facilities probably reflects a combination of:

- the frequent transfer into long-term care facilities of patients/residents who were initially colonized or infected in hospitals;
- oro-faecal transfer within long-term care facilities, reflecting breakdowns of personal hygiene in populations with high rates of dementia and incontinence;
- frequent antibiotic use and its contingent selection pressure on the gut flora; and
- high rates of urinary tract catheterization.

Only one sizeable UK study of the carriage of MDR Gram-negative bacteria by nursing home residents has been published.[9] This was conducted in Belfast from 2004 to 2006, early in the national dissemination of *E. coli* with CTX-M ESBLs. This study included 16 long-term care facilities, and found *E. coli* that were both ciprofloxacin-resistant and produced ESBLs in faeces from 119 of 294 residents (40.5%). This was a 40-fold higher carriage rate than for diarrhoeal samples from community patients. Virtually all (99%) of these MDR isolates were ST131 variants; half belonged to the CTX-M-15-positive 'strain A' variant that is common elsewhere in the UK.[52,53] Two small (six- and 12-bed) long-term care facilities had no colonized residents, and others had up to 75% (18/24) colonized residents, with considerable diversity among the ST131 variants at many sites. Fluoroquinolone use and a history of urinary tract infection were independently associated with carriage in a multi-variate model.[9] Duration of nursing home residency did not correlate with increased likelihood of carriage, although it seems likely that carriers commonly acquire their organism within their long-term care facilities.

9.1.5. Multi-drug resistance in the community

Multi-drug resistance remains uncommon among true community-acquired infections in the UK, and few studies have correlated resistance in clinical infections and faecal carriage in these cases. Nevertheless, stool carriage of ESBL-producing faecal *E. coli* was found in 11.3% of patients in Birmingham, rising to 22.8% in those with surnames suggesting a Middle Eastern or South Asian patrimony compared with 8.1% among names suggesting European patrimony. This differential perhaps reflects frequent travel to parts of the world where ESBLs are common outside the hospital setting.[54] A few references specifically indicated travel to South or East Asia as a risk factor for acquisition of ESBL-producing *E. coli* in faeces. Carriage is often persistent and, in Canada, prior travel to a country with a high prevalence of ESBL-producing *E. coli* was identified as a risk factor for subsequent urinary infection with these organisms, typically with the particular ESBL type prevalent in the country visited.[55]

Most cases of infection or colonization by carbapenemase-producing Enterobacteriaceae and non-fermenters occur in hospital and healthcare settings, at least in Europe and North America.[22,56–58] However, in areas of high prevalence, particularly parts of the Indian subcontinent, it seems that a large reservoir of community carriers of carbapenemase-producing Enterobacteriaceae has been established, which likely eclipses the hospital-based reservoir in terms of numbers, but not risk.[59,60]

MDR *P. aeruginosa* and other non-fermenters are an important problem in patients with cystic fibrosis, who also span the hospital/community divide. There is a growing prevalence of high-risk clones, such as the Liverpool epidemic *P. aeruginosa* strain.[61] Cross-infection occurs[62] and can be interrupted by segregation of colonized and non-colonized patients with cystic fibrosis.[63] Resistance is often extensive but evolves very variably in the individual patient, and there is no specific resistance pattern associated with any of the successful cystic fibrosis lineages.[64]

9.1.6. What is the role of agricultural use of sewage and antibiotic treatment in veterinary practice in spreading extended-spectrum β-lactamases?

Gut *E. coli* are ubiquitous in mammals, and MDR strains are reported repeatedly in both food and companion animals.[65] Johnson *et al.* demonstrated that the same ESBL-producing *E. coli* strains can be shared among household members and their pet dog, although the direction of transmission is uncertain.[66] Transmission of resistant *E. coli* down the food chain can occur. At a population level, fluoroquinolone-resistant *E. coli* from chickens and humans were reportedly more similar than fluoroquinolone-resistant and -susceptible *E. coli* from

humans.[67] However, sequence typing needs to be examined. In the Netherlands, the same *E. coli* strains, plasmids and ESBL genes ($bla_{CTX-M-1}$ and bla_{TEM-52}) were found in humans, broilers and retail chicken meat.[68] However, the ESBLs in retail chicken meat in the UK are predominantly CTX-2 or -14-like,[69,70] and their host strains are non-clonal, whereas clonal ST131 *E. coli* with CTX-M-15 enzyme predominates among human ESBL isolates and is very rare in chicken meat.

Recently, a large UK, German and Dutch study found that only 1.2% of ESBL-producing *E. coli* from food animals resembled human ESBL-producing isolates. The authors concluded that human-to-human faecal-oral or plasmid transmission was considerably more important than food chain transmission, but noted that food animals represent a reservoir (and evolution site) for resistant strains that may pose future challenges in humans.[71]

9.1.7. What insights have national Escherichia coli bacteraemia surveillance provided?

Bacteraemias caused by *E. coli* result from a variety of aetiologies including pre-existing urinary tract infection, indwelling urinary catheters and biliary-related infection. In sentinel surveillance undertaken by PHE, most cases arose in elderly patients in the community who had visited their general practitioner at least once in the preceding weeks with urinary tract infection, suggesting that co-morbidity or treatment failure may be a significant factor.[72] One-third of patients with bacteraemia had received antibiotics for genitourinary infection in the preceding four weeks, but the adequacy of treatment was not known. There is a notable rise in incidence in the summer for all Gram-negative bacteraemias,[73–76] and a number of hypotheses are possible, including the role that hydration status in the elderly has to play in predisposition to infection. Reporting resistance data in *E. coli* bacteraemia helps in making local risk assessments on patients transferred from other hospitals.[77]

9.1.8. Is there evidence for high-/low-risk areas within a healthcare facility?

Sharing a room with a colonized patient and ICU admission are risk factors for acquisition of carbapenem-resistant organisms.[78–80] A German point prevalence study of 56 hospitals in 2011 showed that, overall, prevalence of resistance was highest in ICUs (ESBL-producing *E. coli* 2.5% on ICU) and higher on medical wards compared with surgical wards,[81] as also seen in a UK study.[82] A European survey of 19,888 patients, mainly in Belgium and France, showed the highest prevalence of healthcare-acquired infection in ICUs (28.1%).[83]

Long-term care facilities report high prevalence of colonization with MDR Gram-negative bacteria in residents compared with acute hospitals, associated with prolonged stay, antimicrobial treatment and faecal incontinence.[84,85] In one series of carbapenem-resistant *Acinetobacter* and *Klebsiella* isolates, over half were obtained from patients admitted from long-term acute care facilities.[86]

Evidence

ICUs in acute hospitals and any long-term care facilities have higher prevalence of MDR Gram-negative bacteria than general wards. 2+

Recommendation

Patients at high risk for colonization or infection with carbapenem-resistant organisms include those admitted to ICUs and from long-term care facilities (e.g. care homes). Conditional

9.2. Is there evidence of differences between organisms in respect of transmission, morbidity and mortality?

9.2.1. Resistant Enterobacteriaceae

Enterobacteriaceae are part of the gastrointestinal flora of humans and animals, and some are readily transmitted, particularly in the healthcare setting (Table III). It remains unclear why the *E. coli* ST131 lineage has been so successful compared with many other ESBL-producing strains.[87] Transmission from patient to patient is believed to be mainly via hands of staff, although common environmental sources have occasionally been described and should be sought where no other plausible vectors can be found (e.g. ventilator equipment or water supply).[12,35,88,89] Infection prevention and control relies on the consistent application of SICPs (e.g. hand hygiene, appropriate use of personal protective equipment, and ensuring a clean and well-maintained care environment). Patient screening, used as part of a bundle of infection prevention and control measures, is effective for identifying carriage of ESBLs by *E. coli*, *K. pneumoniae* and *Enterobacter* spp.[90–92]

For colonization or infection with ESBL-producing bacteria, the presence of a gastrostomy, urinary catheter or nasogastric tube were risk factors.[93–95] Antibiotic treatment has been shown to select for ESBL-producing *E. coli* in a variety of healthcare settings.[96] For some strains, piperacillin-tazobactam can select for quinolone-resistant bacteria that produce CTX-M,[97] and carbapenem use is associated with acquisition of carbapenem-resistant *E. coli*.[98]

Screening for carriers with subsequent isolation of those identified is effective in preventing transmission, and is important for early recognition.[99] Awareness of carriage is important and, therefore, communications regarding those identified to be infected or colonized with MDR strains is essential when transferring patients within and between institutions.

9.2.2. Acinetobacter baumannii

Infection control precautions against *A. baumannii* have been adapted following experience with outbreaks, and generally address the organism's major epidemic modes of transmission and the excessive use of broad-spectrum antibiotics (Table III). Control can sometimes be achieved when a common source is identified and eliminated.[12,100] A review of 51 hospital outbreaks showed that 25 had common sources. Of these, 13 outbreaks were predominantly respiratory tract infections, and 12 were predominantly bloodstream or other infections. They were controlled by removal or disinfection and sterilization of contaminated ventilator (or related) equipment or contaminated moist fomites.[12]

When neither common sources nor environmental reservoirs are identified, control has depended on surveillance and isolation of colonized and infected patients, along with promoting improvements in the hand hygiene practices of healthcare workers,[101] and ensuring the aseptic care of vascular catheters and endotracheal tubes.[12] Increased cleaning of the general care environment has been the next most common outbreak

intervention,[12] reflecting the concern that *Acinetobacter* spp. can survive for months on wet or dry surfaces, thereby facilitating nosocomial transmission.[102] Disinfection regimens used on surfaces include 0.1% hypochlorite[103,104] and, increasingly, hydrogen peroxide vapour.[105–109]

Patient screening has been suggested in a number of studies.[104,110,111] Several studies also advocate reduced prescribing of broad-spectrum antibiotics, such as fluoroquinolones or carbapenems.[12,112] Antibiotic exposure is often a risk factor for an outbreak; however, the use of multiple interventions and historical controls complicates interpretation of these studies. Patient decolonization by skin cleansing with chlorhexidine or the use of polymyxin on wounds, orally or by inhaled aerosol, has been an occasional adjunctive control measure but may be a risk for development of resistance.[113–115] Often, the use of a multi-factorial or 'bundle' approach is the most effective way of controlling this organism.[116]

9.2.3. *Pseudomonas aeruginosa*

Sources and mechanisms of transmission vary, and surveillance is complicated by the close association between patient and environmental isolates. Association with moist environmental sources is well documented, although significant persistence on dry surfaces, including hospital linen and floors, with a range of 6 h to 16 months is reported.[117] Water systems act as a source of infection, or indicate environmental contamination from other sources (e.g. staff hands or re-usable care equipment being cleaned in handwash sinks).[34] Levels of sink colonization are higher in critical care areas than general wards.[118]

Transmission occurs via the hands of healthcare workers, contaminated either from patients or from the environment, and has been reviewed systematically by Loveday.[34,119–124] Pseudomonal carriage on hands may be less persistent than for other Gram-negative bacteria, but other factors such as glove usage and artificial nails contribute.[13,125–127] Patient-to-patient transmission can occur via the air among patients with cystic fibrosis, with evidence of infectious droplet nuclei,[128] or via patient hand and environmental contamination.[129,130]

Sporadic and epidemic strains tend to co-exist and may be difficult to track without molecular typing.[124,131] There is no evidence for the effect of routine surveillance on the control of MDR *Pseudomonas* spp., but reports of outbreak interventions support the utility of screening.[132,133]

There is little evidence that isolating patients in single rooms reduces endemic MDR *Pseudomonas* spp. levels. In outbreak settings, use of isolation measures as part of a multi-faceted infection control regime is usual, but direct evidence for the impact of isolation alone is lacking.[132,134–138] There is a risk of bias in outbreak reports, and balance between desirable and undesirable effects of physical isolation should be considered. There is a poor level of specific evidence as to the effect of hand hygiene, but expert opinion extrapolated from other situations supports the use of this measure as part of a wider infection prevention strategy.[33,132,133,138,139] Care should be exercised with production, storage and turnover of cleaning products as the organism has a degree of tolerance to disinfectants, and there is evidence for pseudomonal contamination of detergent-type cleaning products.[140,141]

9.3. Surveillance

9.3.1. Selection of samples and antimicrobials to test

In order to support surveillance and infection control, national uniformity is needed in the testing of clinically significant isolates and in the detection of MDR strains. This may involve widespread testing of organisms with antibiotics that would not ordinarily be used in the individual patient.

In particular, testing of parenteral agents against urinary Gram-negative isolates from community patients is necessary. This may impose costs on diagnostic laboratories without matching benefits beyond earlier detection of spread of such infections. At present, the major requirement is detection of carbapenem-resistant organisms, although detection of quinolone-resistant and ESBL-producing organisms is important. Plasmid transmission of carbapenemases to a wide variety of Gram-negative species makes it difficult to be proscriptive. Validated, sensitive algorithms for testing need to be developed if universal testing is not applied. Testing cephalosporin-resistant isolates solely for carbapenem resistance may miss strains with OXA-48 carbepenemases, but this is a useful minimum standard for detection of other carbapenemases. Wider testing of temocillin may detect more OXA-48-producing strains.[142]

The basic phenotypic strategy to detect carbapenemase producers is to use a carbapenem as an indicator, and then to undertake supplementary tests to distinguish carbapenemase producers from those that have other carbapenem resistance mechanisms.[143] Some carbapenemases may not be associated with clinical resistance to carbapenems, and tests that detect hydrolytic capacity [e.g. the modified Hodge/clover leaf test, or synergy tests between carbapenems and boronates (to inhibit KPC enzymes) or EDTA (to inhibit metallo-carbapenemases)] are more useful in identifying these strains. European Committee on Antimicrobial Susceptibility Testing (EUCAST) advice is that Enterobacteriaceae with a minimum inhibitory concentration (MIC) for meropenem >0.12 mg/L should be treated with suspicion, not just those with MICs above the clinical breakpoint of 2 mg/L; the screening MIC of >0.12 mg/L equates to a zone with a diameter of <25 mm on Mueller-Hinton agar.[144] Ertapenem is a more sensitive indicator of carbapenemase production than meropenem or imipenem, but is less specific as it is affected more than other carbapenems by porin-mediated mechanisms. It is also less used and tested. Meropenem or imipenem have better specificity and are to be recommended for screening for national surveillance. EUCAST screening breakpoints should be used.[143]

Many laboratories do not test meropenem susceptibility routinely for all Gram-negative blood isolates. For national surveillance of carbapenem resistance to be effective, phenotypic meropenem resistance must be tested for all blood isolates, and resistance must be reported to central authorities. However, provision for reporting meropenem-resistant Gram-negative isolates from all body sites is important, and should not burden laboratories excessively; electronic and paper reporting systems should be made available. All secondary and tertiary care hospitals, as well as private hospitals, should be included. Monitoring by identifying specific carbapenemases would require reference laboratory reports; therefore, local confirmatory tests are encouraged. Automated PCR methods are being developed or available for specific carbapenemase gene detection, but are not yet widely used. Most meropenem resistance in *P. aeruginosa* is due to loss of

Table III
Dissecting the epidemiology of multi-drug-resistant (MDR) Gram-negative rods

	Resistant Enterobacteriaceae		MDR non-fermenters		
	AmpC, ESBL	CPE	*Acinetobacter baumannii*[a]	*Pseudomonas aeruginosa*	*Stenotrophomonas maltophilia*
Microbiology	Fermentative, oxidase-negative, motile or non-motile, facultatively anaerobic, rods		Non-fermentative, oxidase-negative, non-motile, obligate aerobic, coccobacilli[330]	Non-fermentative, oxidase-positive, motile, aerobic, rods[331]	Non-fermentative,[b,332] motile, oxidase +/−, obligate aerobic, rods[333]
Reservoirs	Human and animal gastrointestinal tract, water		Respiratory and gastrointestinal tract, dry surfaces[330,334]	Ubiquitous: plants, animals, moist environments[331]	Ubiquitous: plants, animals, humans, moist environments[333,335]
Sites of colonization	Gastrointestinal tract[22]		Skin, respiratory and gastrointestinal tract[187,334,336]	Gastrointestinal tract, moist body sites (throat, nasal mucosa, axillary skin, perineum)[337]	Respiratory and gastrointestinal tract[333,335,338]
Duration of colonization	Months to more than one year[339–341]		Days to weeks[334]	—	—
Clinical manifestation	Urinary tract (e.g. *E. coli*), pneumonia (e.g. *K. pneumoniae* and *Enterobacter* spp.), intra-abdominal infection[337,342]		Ventilator-associated pneumonia, catheter-related bloodstream and urinary tract infections, wound infections[330,334]	Pneumonia, urinary tract, surgical site, bloodstream infections, cystic fibrosis lung, burns[331]	Pneumonia, bloodstream infections; less commonly, urinary tract and wound infections[333,335]
Environmental survival	Hours to weeks on dry surfaces;[117] contaminated environment likely to play a minor role in transmission[252,263]		Weeks to months on dry surfaces;[117,251] difficult to remove from surfaces by cleaning and disinfection[103,106]	Contaminates moist hospital environments: tap aerators, respiratory therapy equipment[337]	Contaminates moist hospital environments; can form biofilms on surfaces; low biocide susceptibility[333,335]
Transmission routes	Hands (++), contaminated surfaces (+/−)[319]		Contaminated surfaces (++), hands (+), air (+/−)[31,252,334]	Hands (+), contaminated moist surfaces (+), air (+/−), water systems[337,343]	Hands (+), contaminated moist surfaces (+), air (+/−)[333,343]
Antimicrobial resistance — intrinsic	Ampicillin, first- and second-generation cephalosporins.[344] *Serratia* and *Proteeae* spp. are intrinsically resistant to polymyxins		Ampicillin, amoxicillin-clavulanate, cefazolin, cefotaxime, ceftriaxone, ertapenem, trimethoprim, fosfomycin[330]	Some β-lactams and fluoroquinolones, macrolides, tetracyclines, cotrimoxazole[345]	Most agents except cotrimoxazole[333,335]
Antimicrobial resistance — acquired	Penicillins (except temocillin), ESBLs, carbapenems (through mechanisms other than more common acquired carbapenemases), aminoglycosides, sulphonamides, quinolones[344,346]	Most or all β-lactams, carbapenems, polymyxins (rarely) (exact profile depends on particular carbapenemase and any co-produced ESBL)[31,347]	Quinolones, aminoglycosides, β-lactams (including carbapenems), polymyxins, tigecycline[330,348]	Aminoglycosides, β-lactams (including carbapenems), monobactams, fluoroquinolones, polymyxins[345]	Trimethoprim/sulfamethoxazole

Common acquired resistance enzymes	AmpC (intrinsic in Enterobacter), ESBLs (TEM, SHV, CTX-M), various aminoglycoside-modifying enzymes	Carbapenemases (KPC, VIM, IMP, NDM)[22]	Various aminoglycoside-modifying enzymes or ribosomal methyltransferase, class-D OXA type carbapenemases[330,349]	Metallo-β-lactamases (VIM and IMP)[345]	*sul* genes (resistance to sulphonamide)
Mortality (bacteraemia)	Moderate/substantial increase in attributable mortality[342,350]	Stark increase in attributable mortality[22,262,351]	Minimal increase in attributable mortality[350]	Moderate/substantial increase in attributable mortality depending on type of infection[350,352]	Minimal increase in attributable mortality[353]
Risk factors	Hospital: prolonged hospital stay, prior hospitalization, previous use of antibiotics, presence of indwelling catheters, mechanical ventilation Community: older age, recurrent urinary tract infections/prior invasive procedures (e.g. catheterization), known faecal carriage, contact with healthcare facilities, antimicrobial treatment[143]	Prior antimicrobial use, length of stay, severity of illness, mechanical ventilation, admission to ICU, high procedure score, presence of wounds, positive culture from a blood isolate, transfer between hospital units within the same hospital, prior surgery, prior hospital stay, proximity to other colonized/infected patients, presence of a biliary catheter and recent transplantation.[168] For NDM, prior hospitalization on Indian subcontinent; for OXA-48, prior hospitalization in Middle East	(i) Major trauma, particularly burns, surgery and battlefield injury; (ii) previous antimicrobial therapy; (iii) prolonged hospital and ICU stay; (iv) mechanical ventilation, drainage tubes and indwelling catheters; (v) high prevalence of MDR *Acinetobacter* spp. on the unit; (vi) proximity to other colonized/infected patients[330,349]	(i) Prior use of antibiotics; (ii) mechanical ventilation; (iii) prolonged hospital and ICU stay; (iv) co-morbidities (e.g. cystic fibrosis, burns units)[352,354]	Severely compromised health status, malignancy, indwelling devices (such as intravascular catheters and ventilation tubes), exposure to broad-spectrum antimicrobials, long hospital stay, ICU stay[333,335]
At-risk population	Patients in acute, long-term and community settings; patients travelling to areas of high prevalence[56]	Patients in acute settings, particularly those with recent travel to areas of high prevalence[22,355]	Immunocompromised patients in the ICU and burns units;[330] rare cause of community-acquired infection[334,356]	Immunocompromised patients in the ICU and burns units; patients with cystic fibrosis;[345] rare cause of community-acquired infection[337]	Immunocompromised patients in the ICU; patients with cancer and cystic fibrosis; rare cause of community-acquired infection[333,357]
Common international clones	*E. coli* ST131 with CTX-M ESBLs[19]	*K. pneumoniae* ST258 with KPC enzymes[19,22]	International clones I–III[19,330]	Clonal diversity.[19] A few international high-risk clones [e.g. ST111 (serotype O12)] acquire multi-drug resistance; spread of ST235 with VIM carbapenemase in Russia, Belarus and Kazakhstan	Clonal diversity[333,335]

KPC, *Klebsiella pneumoniae* carbapenemase; *E. coli*, *Escherichia coli*; *K. pneumoniae*, *Klebsiella pneumoniae*; ESBL, extended-spectrum β-lactamase; CPE, carbapenem-producing Enterobacteriaceae; ICU, intensive care unit.

[a] From a taxonomic viewpoint, four species are virtually indistinguishable (*A. baumannii*, *Acinetobacter calcoaceticus*, genomic species 3 and genomic species 13TU) so are grouped together as '*A. calcoaceticus–A. baumannii* complex'; however, *A. baumannii* is by far the most important human pathogen in this group. However, as methods commonly used to speciate *Acinetobacter* spp. in the clinical laboratory are unable to distinguish these species, the relative contribution of each to the burden of human disease is difficult to establish.

[b] Recent data indicate that the 'non-fermentative' status of *S. maltophilia* should be re-assessed.

OprD porin and not a carbapenemase. Sensitivity to ceftazidime, piperacillin-tazobactam and carbenicillin despite meropenem resistance suggests this mechanism, and also suggests that neither high-level infection control action nor submission to a reference laboratory is needed.

To detect ESBLs, *E. coli*, *Klebsiella* spp. and *Proteus mirabilis* should be screened for clavulanate-reversed resistance to ceftazidime and cefotaxime[143] or cefpodoxime. AmpC producers are resistant to cefotaxime (reversed by cloxacillin), but susceptible (or intermediate) to cefepime. For AmpC-inducible genera, such as *Enterobacter* spp. and *Citrobacter freundii*, comparison of cefepime and cefepime plus clavulanate discs can be used to detect additional presence of ESBLs. Confirmation of ESBL production is most easily accomplished by comparing inhibition zones for discs with cephalosporin alone with discs containing clavulanic acid. A zone expansion of >5 mm indicates ESBL production. Alternatively, an Etest strip is used to demonstrate at least eight-fold reduction in MIC.

Faster diagnostic methods may be considered, particularly during outbreaks, to allow more rapid isolation. Selective media or combinations of non-selective media and a chromogenic or genetic test achieve a result within 24 h. Detection within a few hours is possible if molecular tests are applied directly to the clinical specimen, although this approach is still new.

Various selective commercial media are available to seek ESBL, CTX-M ESBL or carbapenemase producers directly from clinical specimens or early growth in blood culture bottles. Media-seeking ESBL producers often have good sensitivity but poor specificity in distinguishing these organisms from strains that hyperproduce AmpC enzymes.[145–147] The sensitivity of media-seeking carbapenemases varies with the particular enzyme,[148] with OXA-48 being the most difficult to detect due to the low levels of resistance often conferred. The alternative approach is to seek ESBL or carbapenemase activity in colonies growing on non-selective agars. Colorimetric and biochemical approaches include the following:

- The chromogenic oxyimino-cephalosporin HMRZ-86 turns from yellow to red on hydrolysis.[149] If used in combination with inhibitors, it can be used to distinguish strains with AmpC, ESBLs or metallo-carbapenemases, although KPC enzymes may be confused with AmpC and it is unclear whether OXA-48 is detected.
- Acidimetric β-lactamase tests can be adapted to detect carbapenemase producers, as in the 'Carba-NP' test where, again, some authors report problems in detecting OXA-48.[150–152]
- MALDI-ToF assays for carbapenemase activity, exploiting the molecular mass change that occurs when the β-lactam molecules are hydrolysed.[153]

Molecular tests can be used to seek β-lactamase genes in overnight cultures. One PCR/array system (Check-MDR CT03) can rapidly detect a wide range of relevant acquired AmpC, ESBL and carbapenemase genes, distinguishing between those encoding classical and extended-spectrum TEM and SHV types.[154]

PCR may be used directly on rectal swabs, without culture, and can give results within 1h of the specimen being taken.[155] Sensitivity and specificity are good, although positive results are often obtained for patients from whom the laboratory fails to grow a carbapenemase-producing pathogen.[156] This is a wider issue with molecular diagnostics when used directly on specimens, and may either indicate a poor positive predictive value or that the culture is not the 'gold standard'.[157]

Recommendation

The minimum susceptibility tests performed on all significant Gram-negative isolates should include meropenem; in addition, cefpodoxime should be tested for Enterobacteriaceae, and ceftazidime should be tested for *Pseudomonas* spp. Strong

9.3.1.1. When to seek reference laboratory typing of isolates

- To inform cross-infection and outbreak investigations.
- To seek a particular type associated with specific clinical characteristic(s) (e.g. K1 capsular type of CC 23 of *K. pneumoniae* associated with hypermucoviscosity and liver abscesses).
- To provide national/international context (e.g. in tracking the spread of 'high-risk clones', such as ST258 *K. pneumonia*, with KPC carbapenemases).

Typing results can never stand alone, and need to be interpreted in the context of all available epidemiological, clinical and demographical data.[158] Typing of isolates is helpful to inform cross-infection and outbreak investigations among groups of patients with potential links. Comparison of isolates without epidemiological linkage information may result in patients being linked in error, simply because they share the same international high-risk clone, or both have representatives of a widespread cluster. Typing of environmental isolates may be helpful, especially where a piece of equipment common to all the affected patients is implicated. However, it may also be confusing and needs to be focused. All environmental samples should have a clear link to an affected patient; there is no point in typing environmental isolates on their own. Isolates from sink plug holes/drains may well match patient isolates, but this provides little information regarding the source as the isolate is likely to have come from the patient rather than the patient having acquired it from a drain. Large-scale environmental sampling is rarely helpful, and there should be a clear hypothesis as to a likely source and the link between that source and the patient(s).

9.3.2. What national surveillance is performed and how should it be developed?

National surveillance of antimicrobial resistance is essential in detecting the emergence of new strains and resistance mechanisms, providing information for formularies and assessing the effect of control strategies. Outputs must be timely and tailored to the needs of medical and nursing staff, healthcare organizations and commissioners of health care. The World Health Organization (WHO) provides WHONET database software, which is used for collecting data in some areas, while the European Antimicrobial Resistance Surveillance Network (EARS-NET) provides resistance information on blood and cerebrospinal fluid isolates across Europe.[159] EARS-NET identified the early accumulation of carbapenemases in *K. pneumoniae* in Greece,[160] although they are now also

proliferating in other countries such as Italy. As such, travel history on admission can be a useful indicator of risk of carriage of MDR organisms.

In the UK (except Scotland), PHE collects susceptibility data in a voluntary scheme for bloodstream isolates of all species. The Second Generation Surveillance System is a web-enabled database application that collects both communicable disease reports (which were previously collected by the UK CoSurv system and include bloodstream isolates) and antimicrobial resistance reports (which were previously collected by the UK AmSurv system).[159] Antimicrobial resistance reporting is voluntary and only applies to England, but now covers over 80% of laboratories. In May 2015, an enhanced surveillance system for the surveillance of carbapenemase-producing Gram-negative bacteria was launched. In addition, the BSAC Resistance Surveillance Project (http://www.bsacsurv.org) tracks the prevalence of antibiotic resistance for a range of species and antibiotics in bacteraemia and lower respiratory tract infection, based on collection and central testing of isolates from a panel of 40 laboratories across the UK and Ireland.

Evidence

There is a significant increasing trend of carbapenem-resistant *K. pneumoniae* and other Gram-negative bacteria in most European countries, with major proliferation in Greece and Italy, suggesting a risk of occurrence in the UK. 2+

Recommendations

Laboratories should test meropenem susceptibility in all clinically significant Gram-negative isolates. Strong

Travel history (i.e. countries or known endemic areas visited within previous year) should be collected for all patients with carbapenemase-producing Gram-negative bacteria. Strong

9.3.3. How should we undertake local screening, why is it important and how should it be interpreted?

Screening at hospital level is useful for infection control, and to track resistance types (e.g. carbapenemase producers) by rectal swab or stool on admission, weekly during hospital stay and at discharge (Table III). Rectal swabs have maximum sensitivity for MDR pathogens (other than *Acinetobacter* spp.), but it is critical to ensure the compliance of staff with guidance on how and when to take samples by means of audit and feedback, as well as the specific actions arising from a positive result.[161] When a carbapenem-resistant organism is identified (or an isolate with any other index resistance is sought), any epidemiologically-linked patients should be screened. Screening of other patients depends on an assessment of risk of shedding of the organism and duration of exposure, and is less likely to be required if the patient has been isolated from admission.[162]

The primary purpose of local screening is the detection of outbreaks of resistant colonizing or infecting organisms with minimum delay. Few hospitals have sufficient single rooms to allow segregation of all patients at risk when they are admitted. Therefore, local identification of carriers allows prioritization of single rooms, potentially limiting spread. Hospital-level surveillance provides faster notification of an emergent problem than awaiting results from the reference laboratory, particularly if a single clone and species is responsible. Passive surveillance of clinical infections alone will be too delayed to help to limit spread. In an outbreak, isolation and infection control precautions are only effective if combined with active surveillance.[161] A plasmid-based outbreak (e.g. carbapenemase producers) can be more difficult to recognize because multiple bacterial species may be involved.

9.3.4. At what point should passive surveillance switch to active surveillance (screening)?

Examination of routine diagnostic tests or discharge summaries requires few resources compared with screening an entire 'at-risk' group. However, screening quickly identifies patients colonized with MDR Gram-negative pathogens who require source isolation but who might otherwise be placed in a shared bay. Choosing to screen depends on available resources, outbreak progression and clinical characteristics. Current national advice to screen patients at risk for carbapenemase-producing Enterobacteriaceae is made despite a low prevalence of these organisms in most UK centres because the clinical risk of spread is thought to be high.[162]

Passive surveillance of routine cultures did not distinguish 12 (86%) of 14 patients later found to have faecal carriage of carbapenemase-producing *K. pneumoniae*.[163] MIC was highly dependent on the inoculum. On average, routine cultures identify patient carriage of ESBL Enterobacteriaceae three days later than active screening.[164] The virulence of the strain, host susceptibility and the sensitivity of the diagnostic method will affect the efficiency of passive identification of patients.[161] As such, no single recommendation can be made.

Evidence

Passive surveillance is less sensitive and slower in identifying outbreaks of MDR Gram-negative infections than active screening. 3

Recommendation

Active screening rather than passive surveillance is recommended for high-risk specialties. Conditional

9.4. What is the evidence that infection prevention and control precautions prevent transmission?

Trials of infection control strategies are difficult to mount with sufficient power to determine efficacy, and most trials use a package of measures so the effect of single interventions cannot be extracted. A systematic review of infection control precautions in care settings for patients receiving stem cells or treatment for cancer showed a combination of prophylactic antibiotics, control of air quality and isolation in a room was associated with a lower rate of mortality [odds ratio (OR) 0.60, 95% CI 0.50–0.72] at 30 days.[165] Gram-negative bacteraemia was reduced by the package of measures. Gram-negative infections were significantly less common in patients who were isolated, but there were insufficient data to assess the specific effect on MDR strains. Environmental cleaning and screening are discussed in other sections.

9.4.1. Are standard infection control precautions sufficient to stop transmission?

Existing national guidelines are unequivocal that SICPs should be used by all staff, in all care settings, at all times, for all patients (adults, children and infants), whether infection is known to be present or not, in order to ensure the safety of

those being cared for, staff and visitors in any environment where care is given. SICPs are the basic infection prevention and control measures necessary to reduce the risk of transmission of infectious agents from both recognized and unrecognized sources of infection.

Sources of (potential) infection include blood and other body fluid secretions or excretions (excluding sweat), non-intact skin, mucous membranes, and any equipment or items in the care environment that could have become contaminated.

To be effective in protecting against infection risks, SICPs must be used continuously by all staff. Patients who move frequently between the hospital, the community and long-term care facilities may render location-based screening inadequate as a means to identify outbreaks.

However, as underscored by recent systematic reviews,[166,167] there is a paucity of evidence directly testing infection prevention and control advice as related to Gram-negative organisms, particularly MDR strains. A similar lack of evidence was noted in the ESCMID guidelines on preventing transmission of MDR Gram-negative bacteria.[161] Nevertheless, the European Centre for Disease Prevention and Control (ECDC) risk assessment on carbapenemase-producing Enterobacteriaceae showed that there was agreement across Europe that SICPs are an essential integral part of any strategy to control MDR Gram-negative organisms.[168] The supporting European survey of carbapenemase-producing Enterobacteriaceae emphasized the importance of diagnosis, early containment through patient screening and SICPs.[169]

A number of authoritative bodies have produced detailed guidance on carbapenemase-producing Enterobacteriaceae in particular based on expert consensus; these emphasize the importance of continuous implementation of SICPs, with particular emphasis on hand hygiene.[143,162,170,171] PHE, the Centers for Disease Control and Prevention, and ESCMID all recommend contact precautions (patient isolation) in addition to SICPs for all colonized or infected patients with MDR Gram-negative bacteria, as well as those previously colonized and not known to be free of these bacteria.[161,162,170] All patients should be assessed for transmission risk on or before arrival at the care area, and reviewed for any changes in risk during their stay.

In an endemic setting (with constant challenge from admissions of colonized or infected patients), ESCMID does not recommend isolation for ESBL *E. coli*. Other guidance emphasizes basing isolation on a risk assessment while maintaining high levels of hand-hygiene compliance and environmental cleaning.[143] The ST131 clone of *E. coli* appears to be more readily transmissible, and further study is needed.

Other guidelines use general principles based on a range of pathogens. Both National Evidence-Based Guidelines (EPIC 3) and Health Protection Scotland's National Infection Prevention and Control Manual specify good-practice standards based predominantly on expert consensus or Health and Safety legislation, rather than evidence from controlled trials.[166,172]

SICPs include[166,173] the following elements:

- hand hygiene;
- environmental cleanliness, including the decontamination of patient care equipment, the safe management of linen and disposal of healthcare (clinical) waste;
- safe use and disposal of sharps;
- aseptic practice;
- respiratory hygiene; and
- assessment of infection risk, use of personal protective equipment and patient placement.

Contact precautions entail donning personal protective equipment on room entry, and discarding before exiting the patient room. A single room is preferred.[173] Hand hygiene is performed before touching the patient, and prior to wearing gloves for touching the patient and the patient's environment.

Strategies to minimize the transmission of pathogens, including MDR Gram-negative bacteria, will only be successful if there is a reliable high level of compliance with SICPs and contact precautions by all healthcare workers.[174,175] Training, education, audit and feedback are therefore important. Low levels of compliance with hand hygiene and inappropriate glove usage are commonly described.[174,176] Invasive medical devices breach the body's natural defence mechanisms and increase the likelihood of infection and colonization; therefore, device avoidance and minimization are important.

Evidence

Consistent application of SICPs with contact precautions for patients colonized or infected with MDR Gram-negative pathogens reduces transmission. 3

Recommendation

In addition to SICPs, apply contact precautions for those patients who present an infection risk. Strong

Good Practice Recommendation[166]

Apply and maintain SICPs in all care settings, at all times, for all patients.

9.4.2. Screening

9.4.2.1. What is the role of screening in patients and staff?

Early detection of patients colonized or infected with MDR Gram-negative organisms is important for managing their status effectively, and for implementing timely interventions to prevent subsequent spread. Screening of potential colonization sites of patients (e.g. faeces) is essential in limiting the spread of carbapenemase producers in hospitals. Identification of other MDR Enterobacteriaceae is useful to identify those patients who may need carbapenems if treated empirically. Although ESBL *E. coli* are often resistant to ciprofloxacin, the proportion varies widely by country.[26,177,178]

In a multi-centre German study of screening of patients with haematological malignancies, colonization rates with ESBL Enterobacteriaceae varied between 5.3% and 21.8% of patients.[179] In a Korean study of ICU patients, 28% of 347 were found to have ESBL Enterobacteriaceae faecal carriage on admission, and another 12% acquired these organisms during follow-up in ICU. As assessed by pulsed-field gel electrophoresis, none of the acquisitions were nosocomial transmissions, but the methods used would not have readily identified plasmid outbreaks.[180] Routine screening of urine for ESBL *E. coli* and *Klebsiella* spp. followed by single-room isolation of carriers did not result in any significant reduction in the number of ESBL producers isolated from non-urinary sites in hospital.[181] Against the background of a high prevalence of ESBL

Enterobacteriaceae in Korea, routine screening of carriage sites was not cost-effective in ICUs.[180] The risk of dissemination in the local community was high. In Europe, ST131 CTX-M-15 strains are common, but specific screening for that strain has not been studied.

A nationwide intervention in Israel against a clonal outbreak of ST258 *K. pneumoniae* (with a KPC carbapenemase) was successful because it depended on mandatory patient screening and isolation, and patient and staff cohorting.[77] Short- and long-term care facilities were involved, as the latter were a reservoir for re-introduction to acute units. Compliance with national guidelines was reinforced by visits to facilities, reporting of carrier and isolation status, and contact tracing. In high-intensity units such as ICUs, rectal swabs from all the patients on the ward were assessed. Two rectal swabs negative by culture and one rectal swab negative by PCR were required before screening was discontinued for an individual patient in any ward. The programme successfully reduced acquisition of carbapenem-resistant organisms from 55.5 to 4.8 instances per 100,000 patient-days. Screening for non-fermenters such as *Pseudomonas* spp. or *Acinetobacter* spp. is not supported by high-quality evidence, but may be performed in outbreaks (Tables III and IV).

There is usually no indication for screening faecal cultures from healthcare workers or family members, although good personal hygiene should be emphasized. Outbreak investigations that do not identify a single environmental source suggest that transmission is occurring via the hands of hospital staff, but hand cultures are usually negative, presumably because contamination is transient.[182] Gram-negative organisms isolated from nurses' hands are, in most cases, different from those causing significant infections in patients.[13,183] However, outbreak reports are selective and open to bias.

Evidence

Mandatory screening and full implementation of SICPs combined with contact precautions throughout the area of care is effective in controlling clonal outbreaks of carbapenemase-producing pathogens. 2++

Routine screening of carriage sites for ESBL-producing Enterobacteriaceae for infection control purposes may not be cost-effective if community transmission and carriage is frequent. Screening and isolation of carriers of ESBL *Klebsiella* spp. is more likely to be useful than that for ESBL *Enterobacter* spp., *Serratia* spp. or *E. coli*. However, specific screening for specific clones has not been studied. 3

Recommendation

Screening for rectal and wound carriage of carbapenemase-producing Enterobacteriaceae should be undertaken in patients at risk. Strong

Good Practice Recommendation

Routine screening of family contacts and staff is not recommended.

9.4.2.2. What organisms should screening include? Enterobacteriaceae and non-fermenters (i.e. *A. baumannii* and *P. aeruginosa*) constitute the majority of MDR Gram-negative pathogens causing healthcare-acquired infections. Carbapenem-resistant organisms should have priority, as meropenem is currently the most widely used broad-spectrum antibiotic of last resort. Some MDR strains are readily transmissible and require patient isolation. Most carbapenem resistance seen in Enterobacteriaceae, at least among reference laboratory submissions, is now associated with production of KPC, OXA-48, NDM and VIM carbapenemases; almost all carbapenem resistance in *A. baumannii* is associated with OXA-23-, OXA-40-, OXA-51- and OXA-58-related carbapenemases. Carbapenem resistance in *P. aeruginosa* may involve carbapenemase production, but is more commonly related to porin loss, which confers a narrow-spectrum carbapenem-specific resistance profile.

ESBL producers and plasmid or chromosomal AmpC Enterobacteriaceae are resistant to a number of antibiotics, and infection control precautions are used to prevent transmission. A major driver for the use of carbapenems is the suspicion of the presence of ESBL. Screening for ESBL producers may therefore be useful in guiding and thereby limiting empirical use of carbapenem, although no confirmatory reports are available. Where isolation facilities are limited, cephalosporin-resistant Enterobacteriaceae cases and carriers should have a lower priority than patients carrying carbapenem-resistant Enterobacteriaceae. Subject to local risk assessment, colonized patients with diarrhoea or discharging wounds would usually take precedence for single rooms over patients without those characteristics but the same MDR organism.

Recommendation

Screening for carbapenem-resistant *A. baumannii* and MDR *P. aeruginosa* is required in management of outbreaks. Strong

9.4.2.3. Who, how and when to screen patients for multidrug-resistant Gram-negative bacilli?

9.4.2.3.1. Who to screen. The potential risk factors identified for colonization or infection with MDR Gram-negative organisms are similar and wide ranging, and include recent antimicrobial treatment, presence of indwelling devices, severity of illness, admission to an ICU, transfer between hospital units, residence in long-term care facilities, previous surgery, hospital inpatient stay within the preceding year (particularly overseas in an endemic area), recent solid organ or stem cell transplantation, presence of wounds, presence of biliary catheter and mechanical ventilation.[38,161]

Although only limited data are available from studies on interhealthcare transmission of carbapenem-resistant Gram-negative bacteria within countries, a number of descriptive studies indicate that cross-border transfer of patients is associated with a risk of transmission of carbapenem-resistant organisms, particularly in respect of patients coming from the Middle East, India, Pakistan, Italy and Greece.[168] This applies to patients transferred from endemic areas to healthcare facilities in another country, and where patients have received medical care abroad in areas with high rates of carbapenem-resistant organisms. Based on this, a recent ECDC report recommended that all countries should develop guidance for active screening of faeces of all patients transferred from any healthcare facility in an endemic area.[161] Among the first 250 patients in the UK with an isolate producing the NDM carbapenemase, 100 had a travel history, with half of these having travelled to the Indian subcontinent.[184]

Table IV
Infection prevention and surveillance by organism: recommendations by organism/resistance

Recommendation	Application in respect of		
	Resistant Enterobacteriaceae (AmpC, ESBL and carbapenem-resistant organisms)	MDR non-fermenters	
		Acinetobacter baumannii	*Pseudomonas aeruginosa*
1,2. Laboratory test for susceptibility to meropenem for all significant Gram-negative isolates	Test susceptibility to meropenem + cefpodoxime	Test susceptibility to meropenem. Usually confined to ICU	Test susceptibility to meropenem + ceftazidime. Most carbapenem resistance is via loss of OprD, and is less important for infection control than carbapenemases. Carbenicillin and ceftazidime sensitivity indicates OprD loss
3. Request international travel history for patients with carbapenemase-producing Gram-negative bacteria	Find and record	Not usually required — local acquisition	Find and record
4. Diagnostics: detect and report all MDR Gram-negative organisms (at least three resistance mechanisms) in clinical samples and screens in <48 h	Early recognition and infection control intervention to reduce transmission	Early recognition and infection control intervention to reduce transmission	Early recognition and infection control intervention to reduce transmission
5. Active screening rather than monitoring of laboratory reports for high-risk specialities	Case finding/screening for carbapenemase for ICU and other high-risk patients but not routinely recommended for ESBL/AmpC	In outbreaks, case finding/screening for ICU and other high-risk patients. Otherwise, monitor laboratory reports	Poor evidence for screening — may be appropriate in high-risk units (e.g. cystic fibrosis units, burns units, haematology units) or in context of outbreak. Sporadic and epidemic strains co-exist, so tracking of outbreaks may be problematic without typing unless there is a clear phenotype (e.g. metallo-β-lactamase)
6. Risk assessment on admission to ICU and from long-term care facility	Risk assess on admission for carriage of carbapenem-resistant Enterobacteriaceae. ESBLs — not recommended but may be considered on admission from long-stay units	Not recommended on admission except when outbreak in referring ward or hospital	Not recommended on admission except when outbreak in referring ward or hospital
7,8. Screen patients at risk for carbapenem-resistant Enterobacteriaceae	Screen patients assessed as at risk/coming from endemic settings. Screening not recommended for family contacts or staff	Screen in outbreaks. Screening not recommended for family contacts or staff	Screen in outbreaks. Screening not recommended for family contacts or staff
9. Type of sample for screening	Rectal/stool	Skin sites or, if a catheter or endotracheal tube is present, urine, rectal or respiratory secretion	Rectal/stool

10. Screen patients with stay in healthcare facility with endemic carbapenemase-producing organisms in last year	Carbapenem-resistant — targeted screening of patients with history of health care in high-risk areas [i.e endemic, not just sporadic cases (e.g. India, Manchester in UK)]	Carbapenem-resistant — targeted screening of patients with history of health care in high-risk areas (i.e. based on local knowledge of referring centres)	Carbapenem-resistant — targeted screening of patients with history of health care in high-risk areas (i.e. based on local knowledge of referring centres)
11. Monitor SICPs and contact precautions during outbreaks; repeat screening of negative patients weekly and on discharge until no new cases for seven days	Carbapenem-resistant — during outbreak, screen all patient contacts in ward of a new case	Carbapenem-resistant — during outbreak, consider screening all patient contacts in bay/ward of non-isolated case. No evidence for regular admission, ongoing or discharge screening except in outbreaks	No high-quality evidence for patient contact screening, but consider screening all patient contacts in bay/ward in outbreak. No evidence for regular admission, ongoing or discharge screening except in outbreaks
12. At admission, screen patients with previous carbapenem-resistant or other MDR Gram-negative bacteria	Screen all with known previous carriage or infection	Screen all with known previous carriage or infection	Screen all with known previous carriage or infection
13. Contact precautions for patients who present an infection risk	Carbapenem- resistant — pre-emptive isolation of previous positive patients pending screening. Restrict unnecessary patient movements where possible	Carbapenem-resistant — pre-emptive isolation of high-risk patients pending screening. Restrict unnecessary patient movements where possible	No evidence for pre-emptive isolation. Extrapolation from evidence for other MDR organisms suggests that isolation or cohorting of known cases with contact precautions and restrictions on unnecessary movement are appropriate
14. Patients colonized with MDR Gram-negative organisms in single room for duration of stay	No recommendations for tests of clearance — assume long-term carriage during the same inpatient stay	No recommendation for test of clearance	No recommendation for test of clearance
15. Personal protective equipment: use disposable gloves and gown/apron in caring for patients	Apron/gown and gloves for all patient interactions. No requirement for facemasks or respirators	Use apron/gown and gloves for all patient interactions. No requirement for facemasks or respirators	Apron/gown and gloves for all patient interactions. No evidence for the effectiveness of respiratory precautions except for patient-to-patient spread by droplet nuclei in patients with cystic fibrosis
16. Prioritize single-room accommodation (local risk assessment to determine priority against other pathogens, but carbapenem-resistant Enterobacteriaceae usually higher than *Clostridium difficile* or meticillin-resistant *Staphylococcus aureus*)	First priority: carbapenem-resistant Enterobacteriaceae. Carbapenem-resistant Enterobacteriacae: single room, preferably with en-suite facilities, throughout admission. Other MDR Enterobacteriaceae: isolate where possible according to assessment of risk of spread; otherwise, contact precautions	Second priority: carbapenem-resistant *Acinetobacter* spp. These are usually confined to ICU. Carbapenem-resistant: single room, preferably with en-suite facilities, throughout admission. Other MDR *Acinetobacter* spp.: room if available	Third priority: carbapenemase-producing *P. aeruginosa*. Other MDR *Pseudomonas* spp. (e.g. permeability variant): use single room if available
17. Cohort isolate if there are insufficient single rooms	Consider cohorting patients whose isolates have the same phenotypic resistance pattern. Consider staff cohorting where feasible, and education of staff in infection control	Consider cohorting patients whose isolates have the same phenotypic resistance mechanism. Level of evidence for staff cohorting is low	Extrapolation from other infections suggests that staff cohorting may be useful in controlling outbreaks

(*continued on next page*)

Table IV (*continued*)

Recommendation	Application in respect of		
	Resistant Enterobacteriaceae (AmpC, ESBL and carbapenem-resistant organisms)	MDR non-fermenters	
		Acinetobacter baumannii	*Pseudomonas aeruginosa*
18. Hand hygiene before and after direct patient contact	Contact precautions; ensure high awareness of need for attention to hand hygiene, especially with soap and water	Contact precautions and high awareness of need for hand hygiene, especially with soap and water	Low-level evidence. Ensure high awareness of need for attention to hand hygiene, especially with soap and water
19. Environmental screening when unexplained transmission	Persistence in environment in wet areas and respiratory equipment	Environmental persistence, particularly in dust and dry surfaces. Bed rails, bedside tables, hygroscopic bandages, HEPA filters and extract vents implicated	Association with persistently colonized water systems (e.g. taps, filters, aerators, sink traps). Screening of tap outlets in augmented care areas according to local risk assessment. Outbreaks associated with contamination of ventilator equipment
20. Decontaminate equipment in designated cleaning sinks	Indirect evidence for transmission via equipment	Some evidence for transmission through equipment	Evidence for transmission through equipment contamination (e.g. ventilators) demonstrates importance of dedicated and single-use equipment, and decontamination of re-usable equipment by appropriate agents
21. Risk assess point-of-use filters for taps if *P. aeruginosa* colonization/ infection is increasing	Not applicable	Not applicable	Effective in reducing infection but need monthly replacement
22. Terminal disinfection with hypochlorite in outbreak control	Increase cleaning frequency to at least twice daily and every 4 h for high-contact surfaces	Increase cleaning frequency to at least twice daily and every 4 h for high-contact surfaces	Some evidence that cleaning protocols have a role for controlling spread in outbreak settings
23. Consider hydrogen peroxide vapour as adjunct to cleaning	Effective in reducing reservoirs	Effective in reducing reservoirs	Effective in reducing reservoirs on surfaces but not taps or sink traps
24. Routine use of selective digestive decontamination not recommended	Not normally recommended as contrary to antibiotic stewardship	Not recommended	Not normally recommended as contrary to antibiotic stewardship
25. Monitor hand hygiene of all shared staff in cohort isolation	Self-contained nursing unit is effective in control of spread	Self-contained nursing unit is effective in control of spread	No direct evidence

ESBL, extended-spectrum β-lactamase; ICU, intensive care unit; MDR, multi-drug-resistant; SICPs, standard infection control precautions; HEPA, high-efficiency particulate arrestor.

All patients with epidemiological links (same hospital unit or care home) to an index and secondary cases should be screened to determine the extent of secondary transmission. However, carriage may be prolonged in the community (especially in patients with urinary catheters), and the chronology can be difficult to determine. As such, isolation is started on re-admission. Admission screening by rectal swab (or axilla/groin swab for *Acinetobacter* spp.) is required for patients transferred from countries or institutions (including those in the UK) with a prevalence of epidemic or endemic carbapenem-resistant Gram-negative pathogens, as well as those patients with previous colonization or infection. However, that assumes the receiving area (infection control practitioner) has been informed appropriately of prior hospitalization and carriage data, and where endemic or epidemic problems are present.

Given reported prolonged gastrointestinal carriage of MDR Gram-negative organisms, clearance samples are not recommended. Patient isolation should continue for the duration of the inpatient stay unless there is extensive spread and large numbers of colonized or infected patients. Cohorting affected patients together may then be necessary. Colonized or infected patients should be isolated if re-admitted as emergency cases, and should then be screened. Previously colonized or infected patients should be screened as outpatients if admission is planned, and isolated on admission if screening yields the relevant organism. A method of flagging records is needed.[185]

9.4.2.3.2. How to screen. As the intestinal flora is the main source of MDR Gram-negative bacilli (except *Acinetobacter* spp.), a rectal swab (or stool) is preferred for ease of collection, handling and processing,[162,186] but faecal material must be visible on the swab before putting it into transport medium. A stool sample may be used if there is a risk of mucosal trauma. Rectal or perirectal swabs or stool samples have higher yield than testing of other body sites.[116] In patients with indwelling devices, specimens from the related site should be screened. Skin swabs, urine and sputum should be checked in those with chronic wounds, indwelling urinary catheters or endotracheal intubation. *Acinetobacter* spp. are best detected in axillal, groin or wound swabs.[187]

Screening tests should have a turnaround time of less than 48 h. Confirming the specific carbapenemases is important, but requires molecular methods that often limit availability to reference laboratories. Nevertheless, locally performed phenotypic tests can be extremely helpful as the report is available without delay. These tests are easy to implement for most laboratories, provided that the resources are available and laboratory staff have been trained.[162,168] If carbapenemase confirmation is not possible, isolates should be sent to reference laboratories, although infection control precautions should not be delayed. These tests can prove to be even more useful if they are interpreted in conjunction with data on the background prevalence of carbapenem-resistant organisms in a specific region. A rapid diagnostic turnaround time and timely communication of laboratory results to physicians, nurses and the infection control team are extremely important for infection prevention and control and clinical therapy.

Commercial media for detection of carbapenemase-producing Enterobacteriaceae are increasingly available. In a comparison of four chromogenic media used to detect carbapenemase-producing Enterobacteriaceae, chromID Carba had the best sensitivity and specificity, although this may not be adequate for OXA-48.[148] Disc or tablet diffusion synergy tests use meropenem combined with boronic acid to inhibit KPC carbapenemases, or EDTA to inhibit metallo-carbapenemases (IMP, NDM and VIM). Cloxacillin inhibits AmpC but not KPC, facilitating discrimination between isolates with these types of enzyme in an Etest.[143] High-level temocillin and piperacillin/tazobactam resistance without potentiation of meropenem by EDTA is a marker of OXA-48. Molecular confirmation tests show high sensitivity and specificity, and are used in reference laboratories but are expensive and will not detect novel genes. Although several pseudomonas-selective media are marketed, there are no specific data on screening methodology, frequency or duration with respect to *P. aeruginosa*.[161] *P. aeruginosa* resistant to carbapenems but susceptible to other β-lactams can be assumed not to have carbapenemases, and do not warrant reference investigation.

The accuracy of carbapenemase detection may be affected by the species and origin of the pathogen, type of carbapenemase and other resistance properties, such as porin loss or ESBL production. Phenotypic confirmatory tests such as the modified Hodge test are within the capability of most local laboratories, but depressed AmpC enzymes (and sometimes ESBLs) are associated with weak false-positive modified Hodge tests, especially with ertapenem. The test can be difficult to interpret. Colorimetric and MALDI-ToF methods can be used.[188] Some organisms with OXA-48-like carbapenemases only exhibit low-level carbapenem resistance without cephalosporin resistance, thus escaping the standard identification methods.[188]

High sensitivity and specificity in detecting ESBLs can be achieved using chromogenic selective media, despite mixed flora in catheter urine or faeces. However, competitive bacterial flora resistant to multiple antibiotics, especially cephalosporins, can reduce the specificity of selective media. The use of CTX-M Chromagar (CHROMagar, Paris, France) is superior to ESBL chromogenic agars if seeking cases with a CTX-M ESBL in an outbreak, but the medium is less suitable where, for example, TEM 10 ceftazidimase is present.

Screening for carriage of MDR *A. baumannii* has been described using a variety of media with samples from various body sites including axilla, groin, wounds, rectum or pharynx.[104,116,189–192] There is no consensus on site or method of screening for *Acinetobacter* spp., and sensitivity is poor.[193] Most carbapenem resistance involves OXA-23/40/51/58/143-like carbapenemases, whilst a few isolates have metallo-carbapenemase.[194,195]

9.4.2.3.3. When to screen. There is insufficient evidence to mandate routine screening of all patients for colonization by all MDR Gram-negative organisms. However, screening of high-risk patients is used in control efforts for carbapenem-resistant Enterobacteriaceae (e.g. patient transfers from hospitals where these organisms are prevalent). The contribution of this practice to decreasing transmission is unknown. Nevertheless, identifying patients who are at high risk of colonization or infection with MDR organisms (including carbapenem-resistant organisms) and performing screening by rectal swab (or skin for *Acinetobacter* spp.) on admission to healthcare facilities is recommended, and is now becoming more widespread in healthcare settings.[169] Patients at high risk include patients admitted to ICU and from long-term care facilities (e.g. care homes or endemic areas).

Screening for carriage of ESBL Enterobacteriaceae can identify patients in whom empirical treatment with meropenem may be justified, thus supporting antimicrobial stewardship. Discharge screening for ESBL or carbapenem-resistant organisms is appropriate when admission screening is practised, or if a colonized patient is likely to be re-admitted for further procedures or is going to a long-term care facility. Patients with carbapenem-resistant organisms should have notes flagged pending re-admission or if they transfer to long-term care facilities, where there is a risk of further spread. Long-term care facilities should be informed of positive results of discharge screening on their transferees, and may need to consider if their routine SICPs are sufficiently robust for caring for these patients.

Good Practice Recommendations

Effective communications between healthcare settings will help to facilitate efficient patient transfers, and are crucial in reducing spread.

Local screening policies should be developed to define those patients at high risk of carriage of, for example, carbapenemase producers.

9.4.2.4. What can be done in the case of patients unable or unwilling to consent to a rectal swab? On being admitted to hospital, a patient consents to receive those diagnostic and screening tests that are deemed necessary to the management of their presenting problem. In situations where a patient is incapacitated, those giving care may proceed with any interventions deemed necessary to provide medical treatment for the patient's well-being. This follows the principles of 'implied consent' (i.e. it is reasonable to assume that the person would consent if they were not incapacitated and unable to do so). Implied consent is already used for meticillin-resistant *Staphylococcus aureus* (MRSA) screening, even for patients who have the capacity to consent for themselves.

Screening as part of the ward/hospital policy to guide antimicrobial therapy and/or prevent disease transmission does not require specific written consent, but verbal agreement from the patient before sampling is conducted is required whenever possible. Individual, religious and societal concerns have to be respected. Patients should be informed, whenever possible, of the need and reason for screening (i.e. that it is for their benefit and that of other patients, and what it involves). They should be given the option of who carries it out, including self-screening, but only after assessment of their ability and willingness to comply, and safety of the procedure. The option of a same-sex healthcare practitioner should be provided. Some patients may be unwilling to accept a rectal swab but will provide a stool sample, although this may result in delay or absence of a sample. Ideally, patients should be placed pre-emptively in an isolation room while the screening results are awaited, but this is unlikely to be practicable in many high turnover wards. Patients having chemotherapy or with an underlying bowel condition (stoma, colon cancer, recent anal or rectal surgery) may be more easily screened using stool. Nevertheless, rectal swabs can be collected safely in haematology patients.[196]

9.4.2.5. How frequently does screening need to be performed? Extensive active screening during outbreaks due to carbapenem-resistant organisms is recommended[168] (e.g. follow-up screening of negative cases at weekly intervals and/or for all inpatient contacts with confirmed cases). Although such accounts must be interpreted with caution, experience from outbreaks of MDR Gram-negative organisms, including carbapenemase- and ESBL-producing Enterobacteriaceae, in acute healthcare settings suggests that the implementation of screening for early detection and isolation of colonized patients coupled with contact precautions can help to control transmission.[77,169,197] Screening of those not known to be carriers of carbapenem-resistant organisms in an endemic situation is advisable at least weekly and on discharge.

9.4.2.6. Is there evidence for effective interventions on positive patients (i.e. can carriage be cleared)? A number of studies have evaluated the duration of colonization with MDR Gram-negative bacteria. Studies of hospital inpatients suggest that they tend to remain colonized for the duration of their stay.[104,198–200] Most studies evaluating the duration of colonization outside of acute settings for a range of MDR Gram-negative bacteria have identified mean durations of colonization of months rather than days.[11,201–204] This duration is likely to reflect the particular strain, not its resistance.

Several studies have investigated the duration of colonization with carbapenem-resistant Enterobacteriaceae following discharge from acute care facilities. Risk factors for prolonged carriage of MDR Gram-negative bacteria tend to be associated with healthcare contact, underlying medical conditions and the presence of invasive devices.[11,47,199,205] For example, Lubbert *et al.* evaluated prolonged colonization following an outbreak of carbapenem-resistant *K. pneumoniae* following discharge from an acute hospital.[205] Although 26 (31%) of the 84 patients included tested negative for carbapenem-resistant *K. pneumoniae* at one month post discharge, 45% remained colonized at six months and one patient remained positive for almost 40 months. Two other studies found that approximately half of patients colonized at the time of hospital discharge were spontaneously free by six months.[11,47] However, a number of studies identified patients who retested positive after negative screens, suggesting that gastrointestinal colonization is suppressed rather than eliminated in many cases.[47,205] For this reason, the authors of these studies recommend at least three consecutive negative screens separated by at least 24 h before a patient can be considered 'decolonized'.[47,200,205] In practice, colonized inpatients should be considered 'carriers' during the rest of their hospital admission. The risk period from previous hospitalization exceeds one year.

There is no effective equivalent of the topical suppression used to reduce shedding of MRSA in the healthcare environment. Attempts at eradication of MDR Gram-negative organisms from the gastrointestinal tract have not been successful.[206–209] Selective decontamination of the digestive tract (SDD) can produce some temporary reduction in the number of organisms in faeces (see Section 9.4.6).

Evidence-based criteria for discontinuing contact precautions for carbapenem-resistant Gram-negative organisms in acute care settings have not been developed. Given the likelihood for prolonged gastrointestinal carriage by these organisms and risk of spread, organizations should be cautious in discontinuing contact precautions (patient isolation). In most cases, contact precautions should continue for the duration of the hospitalization

during which the organism was first found on culture. Patients re-admitted within 12 months of that hospitalization should be considered probably colonized, and managed with contact precautions until at least one negative screen is available.

Evidence

Early recognition of patients infected with MDR Gram-negative organisms and implementation of rigorous infection control interventions is usually associated with reduced secondary transmission. 3

Screening (except *Acinetobacter* spp.) is most sensitive when performed on rectal (or perirectal) swabs or stool specimens. 3

Patients transferred from, or who have received medical care in, a healthcare facility in an endemic area of the UK or abroad are at high risk of carriage of carbapenemase-resistant organisms. 2++

Recommendations

A rectal swab (with visible material) or stool sample (and urine sample if catheter present) should be used for screening for multi-resistant Enterobacteriaceae and *P. aeruginosa*. For *Acinetobacter* spp., sample skin sites or (if a catheter or endotracheal tube is present) urine or respiratory secretions. Conditional

Each healthcare organization should have access to robust microbiological arrangements for detecting and reporting MDR Gram-negative organisms in routine clinical samples, and for screening using highly-sensitive tests with a rapid diagnostic turnaround time of $<$48 h. Conditional

All patients transferred from, or with a history in the preceding year of admission to, healthcare facilities with known endemic carbapenemase-producing Enterobacteriaceae should be screened. Strong

In the event of secondary cases of carbapenem-resistant Enterobacteriaceae, SICPs and contact precautions should be monitored and re-inforced with clinical staff. Screening of patients not identified as carriers should be repeated weekly and on discharge from affected units until no new cases are identified for more than seven days. Strong

Where possible, single-room isolation should be provided for patients with MDR Gram-negative bacterial infection/colonization, and contact precautions should be continued for the duration of their stay. Conditional

Patients with previous samples with carbapenem-resistant or other MDR Gram-negative bacteria should be screened at the time of admission. Conditional

9.4.3. Isolation and segregation

A long-standing principle of infection prevention and control is to physically segregate those known to be infected or colonized with a pathogen of epidemiological importance from those who are not infected or colonized. However, critical appraisal is difficult as segregation is usually assessed as part of a package of measures. This physical separation can be achieved through placing patients with known/suspected infection/colonization in single rooms; and/or identifying and isolating patients with the same, confirmed pathogen in a cohort room/area. An additional cohort measure (nursing staff numbers permitting) is to identify staff to care for those patients placed in cohorts. The implementation of screening cultures at the time of admission or during a patient's stay on a particular ward is a way to improve the impact of physical segregation by identifying those who are colonized with the pathogen of concern.

Placing patients known to be infected or colonized with MDR Gram-negative bacteria in single rooms reduces transmission. Several studies have reported the impact of converting a unit from multi-occupancy to single rooms on rates of MDR Gram-negative infection/colonization.[210–214] A Canadian study reported the acquisition rate ratio of various Gram-negative bacteria, comparing an intervention unit that had been converted into single rooms with a control unit in a sister hospital that had not been converted into single rooms.[210] The number of *Acinetobacter* spp., *Klebsiella* spp. and *Enterobacter* spp. fell significantly, but the number of *Pseudomonas* spp. and *E. coli* did not. A 20-year before–after study from a US burns ICU that was converted into single rooms reported a significant reduction in Gram-negative bacteraemia, the time to a first positive Gram-negative culture and mortality.[212] Significant reductions were also reported in bloodstream infections due to *P. aeruginosa*, *K. pneumoniae*, *E. cloacae*, *E. coli* and *Providencia stuartii*. However, there was no control unit, and improvements in burns care during the study may have contributed to these reductions. A separate study from the same renovation reported an overall reduction in infection rates, mortality and non-enteric Gram-negative species.[213] One study from a US ICU reported no significant reduction in overall infection rates, or in rates of *E. coli*, *Pseudomonas* spp., *Acinetobacter* spp., *Klebsiella* spp. or *Serratia* spp.[211] Again, this study did not include a control ward. Hand hygiene compliance was low and did not increase when the unit was converted into single rooms, in contrast to other studies.[215,216]

The impact of enhancing patient isolation aside from other interventions has been evaluated. A French study in 2001 found that introducing patient isolation to care for ESBL carriers resulted in a sequential reduction in ESBL incidence and hospital acquisition.[217] However, this preceded the emergence of CTX-M and *E. coli* as dominant factors. A study in a Vietnamese ICU found that improving patient isolation by re-inforcing hand hygiene, and limiting exchange of equipment, materials and staff between patients did not reduce exogenous transmission of various Gram-negative bacteria (gentamicin-resistant *K. pneumoniae*, ESBL Enterobacteriaceae, amikacin-resistant *Acinetobacter* spp. and *P. aeruginosa*), whereas rates of MRSA fell significantly. However, this study did not include physical segregation of patients or the use of gowns or aprons.[218]

Various studies have evaluated switching from a multi-occupancy ward to a single-occupancy ward. An Israeli study showed that there were significantly fewer acquisitions of resistant organisms when an ICU was converted from a multi-occupancy bay to single rooms.[215] The study included a control ward which had not been converted. Patients in the single-room ICU had a significantly lower acquisition rate of resistant organisms when compared with the control multi-occupancy ICU over the same period [3/62 (5%) vs 7/39 (18%), respectively, $P = 0.043$]. SICPs were applied throughout, but compliance with hand hygiene was better in the single-room ICU. Although MDR Gram-negative organisms were included, the significant changes related to Gram-positive pathogens. Another study found that the mean number of nosocomial infections and length of stay were reduced significantly when a multi-occupancy paediatric ICU

was converted to single occupancy.[219] However, no control ward was used, and no specific data on MDR Gram-negative pathogens were reported.

Although these studies suggest that converting multi-occupancy wards to single rooms reduces the spread of MDR Gram-negative pathogens, there are several limitations. First, most studies did not include a control ward (although both of the studies that included a control ward found a significant reduction in transmission).[210,215] Second, compliance with hand hygiene is higher in a single-room format compared with a multi-occupancy setting.[215,216] Thus, it could be that improved hand hygiene rather than improved physical segregation is the critical factor for reducing transmission. All of the studies were performed in an ICU setting, limiting their applicability to settings outside of critical care. Converting wards to single rooms often includes other changes, such as the size of each bedspace, and the location and number of hand hygiene facilities, which could influence transmission rates.[215] Single rooms are associated with a number of drawbacks, particularly an increased risk of adverse events due to reduced observation and psychological effects, so the requirement for patient observation is a key consideration when deciding on the optimal configuration of wards.[220] Finally, patients are increasingly moved around the hospital for procedures and investigations, challenging their segregation.

9.4.3.1. Cohorting staff. No studies have evaluated the impact of cohorting staff aside from other interventions, but several studies have reported cohorting staff as an element of a successful multi-faceted strategy.[77,104,221,222]

9.4.3.2. Disposable aprons and gloves. Data are limited in terms of the most appropriate personal protective equipment to use when caring for patients with MDR Gram-negative bacteria.

Studies have evaluated interventions that have included the use of gloves and gowns or aprons as an element of contact precautions.[137,217,223,224] Hands and uniforms (or gloves and gowns or aprons if worn) can become contaminated with MDR organisms.[126,127,225–230]

The use of gloves is an essential part of prevention of transmission of infection, and the evidence has been reviewed elsewhere.[176] While they protect hands from contamination with biological fluids and micro-organisms, gloves are not a substitute for hand hygiene, and unnecessary use can result in increased cross-contamination. Loveday *et al.* recommended that gloves should be removed immediately after the activity has been completed, and the hands then decontaminated to prevent transmission as they may be contaminated during glove use or during removal.[176]

Evidence

Units composed of single rooms have less transmission of MDR Gram-negative bacteria: *A. baumannii*, ESBL-producing (and, by inference, carbapenemase-producing) Enterobacteriaceae, *P. aeruginosa*. 3

Recommendation

Use disposable gloves and gowns or aprons to care for patients with MDR Gram-negative bacteria: *A. baumannii*, carbapenem-resistant and ESBL Enterobacteriaceae, *P. aeruginosa*. Strong

9.4.3.3. What is the role of isolation in care home/hospital settings? Current practices for the identification and isolation of patients with MDR Gram-negative bacteria (in either single rooms or cohorts) vary widely among healthcare facilities.[231,232] A survey of 66 hospitals in 26 US states and 15 other countries found that 74.2% isolated patients with ESBLs, 93.9% isolated patients with carbapenem-resistant organisms, 81.8% isolated patients with MDR *Pseudomonas* spp. and 84.9% isolated patients with MDR *Acinetobacter* spp. There was considerable variation in the duration of isolation, and few facilities performed screening. Isolation of patients in long-term care facility rooms may not be practicable for psychological reasons.

A number of studies have evaluated the impact of isolating patients with ESBL Enterobacteriaceae aside from other interventions.[217,233–236] A six-year Canadian study evaluated the impact of placing patients with ESBL Enterobacteriaceae in single rooms for the duration of their stay, and applying contact precautions for symptomatic patients.[233] There was an overall increase in ESBL Enterobacteriaceae colonization/infection, but a relative decrease in cases attributable to the hospital, suggesting that local transmission was reduced. A 2-year before–after study in France before the proliferation of CTX-M β-lactamases found that the introduction of admission and weekly surveillance combined with isolation of carriers resulted in a significant reduction in the percentage of patients infected or colonized with ESBL Enterobacteriaceae.[234] There was a significant reduction in ESBL-producing *K. pneumoniae* but not MDR *E. aerogenes*. The study has a number of important confounders, including an intervention to reduce the use of imipenem, encouraging prompt discharge and chlorhexidine bathing for isolated patients. A study in a French paediatric hospital evaluated a sequential change in isolation policy from placing patients in a single room to placing them in a cohort block, applying modelling to test the impact on transmission of ESBL producers.[235] No significant difference was identified between the two isolation protocols, but the model suggested that single-room or cohort isolation reduced transmission of ESBL producers. Finally, a 12-month cluster randomized study in 13 European ICUs evaluated chromogenic agar screening for ESBL Enterobacteriaceae on admission and isolation of carriers vs no admission screening.[236] A hand hygiene improvement programme for staff and chlorhexidine body washing for patients preceded the trial. Of the 2129 Enterobacteriaceae resistant to third- and fourth-generation cephalosporins found on screening, 29% were resistant to carbapenems. Screening and source isolation was not associated with any trend (during the intervention period) or step change (compared with a baseline period) in rate of ESBL transmission. However, individual species were not analysed separately.

Two studies have evaluated the impact of isolation on the transmission of *A. baumannii* and *P. aeruginosa*.[137,223] A seven-year before–after study in France evaluated the introduction of hospital-wide contact precautions, which included placing the patient in a single room or cohort with other patients, and the use of gloves and gowns or aprons, on the transmission of *A. baumannii*.[223] Isolation precautions were implemented for two years, then stopped for three years, then re-implemented for two years; the incidence of *A. baumannii* was significantly lower during the two periods when isolation precautions were in use. The implementation of isolation precautions was the only variable associated with lower incidence of *A. baumannii*

in multi-variate analysis. A follow-up study from the same group reported similar findings.[237] A study from an ICU in Brazil evaluated the introduction of contact isolation, including the use of gloves and gowns or aprons, cohorting of medical items (stethoscopes etc.), daily surface cleaning and disinfection on the rates of MDR *A. baumannii* and *P. aeruginosa*.[137] Bloodstream infections reduced significantly during the intervention, but species were not analysed separately. The study compared rates of infection at two points during the intervention, with no baseline period.

A number of other studies have implemented complex interventions that included increased isolation of patients.[116,221,222,224,238] One study in a US ICU implemented a multi-faceted intervention centred on improved isolation of patients, including admission screening for carbapenem-resistant *K. pneumoniae* but not for *A. baumannii* or *P. aeruginosa*.[221] There was a significant reduction in the rate of carbapenem-resistant *K. pneumoniae,* but no change in the rate of *A. baumannii* or *P. aeruginosa*. A study of various interventions in six US hospitals found that the only consistent predictor of successful control of *K. pneumoniae* with KPC carbapenemases was a shorter length of stay.[238] Three studies have evaluated the impact of a multi-faceted intervention to control the spread of *A. baumannii*. An intervention at US field hospitals in Iraq including improved hand hygiene, contact precautions, and cohorting patients and staff resulted in a significant reduction in *A. baumannii* ventilator-associated pneumonia.[222] A bundle of interventions including contact precautions, screening (on occasion) and regular staff briefings reduced the rate of MDR *A. baumannii* infections significantly overall, particularly bloodstream infections due to the organisms, in a Spanish hospital.[116] Finally, a study in a Thai ICU reported a significant reduction in MDR *A. baumannii* associated with the introduction of contact precautions, cohorting colonized patients, screening and environmental disinfection using bleach.[224] However, acinetobacter infections are more common in Thailand than in the UK.

Studies that have evaluated the impact of isolating patients in either single rooms or cohorts generally lack a concurrent control unit, making it difficult to be certain that changes in rate are attributable to isolation alone. The one study that included a concurrent control ward demonstrated no significant decrease in transmission of ESBL-producing Enterobacteriaceae.[236]

Evidence

Transmission of MDR Gram-negative bacteria is reduced by identifying patients who are infected or colonized, and placing them in single rooms or cohorts. 3

Recommendations

Identify and place infected and colonized patients in single rooms where available in this order of priority: carbapenem-resistant Enterobacteriaceae, carbapenem-resistant *A. baumannii,* ESBL *Klebsiella* spp., carbapenemase-producing *P. aeruginosa*, ESBL *E. coli* and other Enterobacteriaceae, AmpC Enterobacteriaceae. Strong

If insufficient rooms are available, cohort isolate following local risk assessment. Conditional

Good Practice Recommendation

Establish a flagging system for patient notes. Conditional

9.4.4. Hand hygiene

Hand hygiene is an essential part of prevention of transmission of infection in health care, and it has been reviewed by Loveday *et al*.[176] Transient flora, including MDR Gram-negative bacteria, is acquired from touching the patient or environment, and is easily transferred to the next patient or surface. In turn, this causes colonization and later (potentially) infection. Use of alcohol hand rub (or liquid soap and water if hands are visibly soiled) has been shown to reduce the carriage of potential pathogens on the hands, and therefore is likely to reduce the number and likelihood of healthcare-associated infections.[174,176] Hand decontamination is considered to have a high impact on outcomes that are important to patients.[239] Training of all care workers, combined with audit and feedback of compliance rates, is central to current guidance on prevention of infection. The WHO Five Moments for Hand Hygiene has been widely used and supported by NICE, and describes the points at which hand hygiene is required.[239] Hand hygiene is often missed as the worker enters or leaves the patient environment, and on contact with potentially contaminated surfaces[240–242]

Despite many activities around the improvement of hand hygiene products, the introduction of alcohol-based hand rubs/gel, improving environmental factors, and extensive marketing and education campaigns, evidence of sustained compliance improvement is lacking. Globally, hand hygiene compliance is variable, with Creedon[243] and Larson *et al*.[244] suggesting a rate of approximately 50%. Therefore, improving compliance with hand hygiene is reliant upon an understanding of the interactions within health care between the individuals, the practices and procedures they perform, the environment that they work in, and the culture and safety awareness of the organization. These human factors should be applied to the infection prevention agenda to ensure that meaningful, sustainable interventions are adopted reliably to produce the greatest impact.[245]

Evidence

Hand hygiene is associated with reduction of carriage of potential pathogens on the hands. 2+

Recommendation

Hand hygiene is required before and after direct patient contact; after contact with body fluids, mucous membranes and non-intact skin; after contact with the immediate patient environment; and immediately after the removal of gloves. Strong

9.4.5. Environmental hygiene

9.4.5.1. When should the environment be sampled? The role of the environment in the transmission of healthcare-associated infection remains controversial and difficult to study. In recent years, much of the research around this has focused on high-profile Gram-positive pathogens such as MRSA, *Clostridium difficile* and glycopeptide-resistant enterococci, where a significant body of evidence for the importance of environmental sources has started to accumulate.[246,247] Reservoirs can be identified when infection control has failed to control an outbreak.[161] The general view has been that Gram-negative bacteria, particularly members of the Enterobacteriaceae, are not as successful at surviving in the environment for prolonged periods, and generally are relatively easily removed by

appropriate conventional cleaning and drying.[13] Nevertheless, Enterobacteriaceae, including carbapenem-resistant strains, are able to survive on dry surfaces for extended periods, sometimes measured in weeks and months.[248,249] Some strains of *E. coli* carrying ESBLs, for example, can survive for a median of 10 days in the environment.[250] In favourable conditions, *E. coli, Klebsiella* spp. and *Pseudomonas* spp. can survive for even longer.[161] *Acinetobacter* spp. have the capacity for long-term survival on dry surfaces.[14,251,252,253] *Pseudomonas* spp. are more traditionally associated with moist environments, and will be found around handwash basins and respiratory equipment.[35,254] There is considerable evidence that *P. aeruginosa* can contaminate waste water systems and spread from them, with these sometimes acting as reservoirs for carbapenemase-producing strains causing prolonged outbreaks.[255] If not adequately decontaminated (including the hand piece), endoscopes have been found to be responsible for outbreaks.[256]

MDR Gram-negative bacteria, including carbapenem-resistant organisms, Enterobacteriaceae and *A. baumannii*, can be cultured from sites surrounding infected and/or colonized patients.[106,257] Several studies have found that environmental contamination with resistant *K. pneumoniae* is more common than contamination with resistant *E. coli*.[258–260] No controlled studies have shown that an environmental intervention reduces the transmission of MDR Gram-negative rods. However, contamination with MDR Gram-negative bacteria can persist despite cleaning and disinfection.[106,261,262] Epidemiological data suggest that admission to an ICU room previously occupied by patients infected or colonized with *A. baumannii* or *P. aeruginosa* presents an increased risk for acquiring these organisms.[252] A significant correlation was noted between the number of environmental swabs in monthly screening and the number of patients with colonization/infection in the same month ($P = 0.004$).[103] However, this association was not seen for resistant Enterobacteriaceae, suggesting that the environment is less important in their transmission,[252,263] albeit with the caveat that these studies did not stratify by Enterobacteriaceae spp., which may be important given the increased capacity for *K. pneumoniae*, in particular, to contaminate and survive on hospital surfaces.

The evidence for the benefit of environmental screening is limited, and environmental sampling, in itself, will not limit transmission of MDR Gram-negative bacteria.[264] The purpose of screening may be to draw attention to failure of clearance of an outbreak strain by cleaning, or to point to a possible common source for a cluster or outbreak. Most of the evidence surrounding environmental screening is within reports of management of outbreaks, and there is often very little detail on sites sampled, sampling technique or method of culture.[265] When looking for small numbers of organisms or bacteria living in biofilms, the yield can be improved by using enriched culture, but this precludes quantitation. An alternative to specifically seeking the MDR outbreak strain(s) itself is to assess the degree of microbiological contamination by using surface contact plates and undertaking quantitative bacterial culture.[266] Surface contact plates using selective media for specific pathogens can suffer from low sensitivity, but use with non-selective media may be helpful. Choosing sites for sampling remains problematic as any sampling can only reflect a very small fraction of the relevant environment.[267] The general approach should be to choose sites that are likely to be relevant for cross-transmission, such as work surfaces close to the patient and equipment/surfaces that are likely to be touched frequently (e.g. computer keyboards, bed rails and door handles).[264,268]

Given the difficulties with microbiological sampling of the environment, there has been considerable interest in the availability of technologies that can indirectly assess microbial contamination. Adenosine triphosphate (ATP) bioluminescence has been used for many years in the food industry, where visual assessment is considered to be insufficient to assess the risk of infection from contaminated surfaces. It has a number of potential benefits, including simplicity and immediacy of feedback; however, it can give only indirect information on the likelihood of bacterial contamination, and bacteria themselves are not isolated for investigation and comparison with those causing outbreaks. Its use in hospitals can be problematic, as values can be variable and there is little consensus on an appropriate benchmark value to indicate inadequate cleanliness.[166,269,270] Results are prone to interference by different disinfectants.[271] Where ATP bioluminescence has been used most successfully has been on a continuous basis to improve compliance through feedback and improved cleaning.[272,273] Other methods of controlling the process of cleaning, such as the use of fluorescent gel markers, can be useful in auditing the cleaning process and feedback to cleaning staff.[274]

Evidence

Transmission of MDR Gram-negative bacteria, particularly non-fermenters, has been associated with contamination of the environment, water systems or equipment. 2–

Sampling of the environment can be useful in identifying sources of ongoing transmission or a single common source for an outbreak. 2–

Recommendation

Environmental screening should be considered where there is any unexplained transmission of MDR Gram-negative organisms or a possible common source for an outbreak. Strong

9.4.5.2. What is the evidence that respiratory equipment contributes to transmission? The respiratory tract of ventilated patients in critical care units is a frequent site of carriage of MDR Gram-negative bacteria. In one study in India, 87% of samples from ventilators, humidifiers, nebulizers and other respiratory equipment showed bacterial colonization, and 17/42 Gram-negative isolates were multi-drug resistant.[275] Endotracheal suctioning is a potential cause of cross-infection, as disconnection of the system may allow airborne spread to the patient's skin, staff hands and the immediate environment. In a crossover study in the Netherlands, there was no significant difference in acquisition of Gram-negative bacteria during periods of using closed suction vs open suction in ventilated patients.[276] However, antibiotic resistance rates were low and similar in each group. Comparing ventilated with non-ventilated patients in the ICU, non-fermenting and enteric Gram-negative bacilli were reported more frequently in ventilator-associated pneumonia, but this reflected the number of samples cultured per patient. The overall proportions of different pathogenic species were similar.[277]

Inappropriate washing of ventilator or endotracheal tubing in handwash sinks risks the spread of Gram-negative pathogens. Environmental sampling in two outbreaks of MDR *P. aeruginosa* showed it to have colonized the waste

water system, with blockages, splashback and spillage from showers being possible modes of spread.[35] Direction of water directly into the outlet caused spread of organisms from the sink drain trap. Sinks were fitted with a horizontal drain outlet at the back of the basin, resolving the problem. Sterile fluids (not tap water) must be used to clear suction equipment, as the latter may be contaminated with pseudomonads or Enterobacteriaceae, and these can be disseminated when the equipment is next used, including when catheters are changed.

Evidence

Gram-negative bacteria colonize respiratory equipment and may be washed into sink traps. 2+

Recommendation

Respiratory and other contaminated equipment should be decontaminated (or respiratory secretions discarded) away from the immediate bed area in designated cleaning sinks and not in handwash sinks. Strong

Good Practice Recommendation

Do not discard patient wash water, body fluids, secretions or exudates into handwash basins.

9.4.5.3. What is the evidence that sensor taps contribute to transmission? P. aeruginosa, including MDR strains, in water sources in ICUs has long been recognized as being associated with the development of bacteraemia and pneumonia in patients.[278] A recent systematic review demonstrated evidence of transmission of *P. aeruginosa* from water systems to patients and vice versa.[34] Point-of-use filters and increasing chlorine disinfection were effective interventions. Non-touch taps were identified as probable risk factors for biofilm formation and subsequent transmission to patients. Sinks and nurses' hands have been identified as possible vectors. In a neonatal unit, four neonates were infected and 44 were colonized by cross-infection with one clone.[124] In another neonatal unit in Germany, *P. aeruginosa* was isolated from the nasal prongs of 22 babies and from nine respiratory water reservoirs.[279] The hands of staff were the likely means of transmission. Other outbreaks have been due to contaminated detergent-disinfectant solution used in cleaning surfaces.[280] Studies have confirmed the effectiveness of point-of-use filters on water outlets in reducing infection in critical care units, but as they were descriptive cohort studies, they were subject to temporal variation.[281–283] Filters have to be replaced regularly, are expensive and can themselves be the source of contamination. *P. aeruginosa* is found in biofilm in flow straighteners, metal support collars and the adjacent parts of tap bodies. The level of contamination with *Pseudomonas* spp. is highest on complex flow straighteners, integrated mixers and solenoids.[278]

Sensor taps have been implicated in some outbreaks of pseudomonas bacteraemia and other infections in augmented care units as the flow is slow and controlled, and the internal mechanism is complex. Decontamination of sensor taps can be performed[284] and, in one major outbreak, all taps, mixer valves, flexible hoses and flow straighteners were replaced with simpler designs.[278]

Where there are vulnerable patients (i.e. augmented care), the Department of Health in England recommends a regular water-testing regimen; clinical surveillance is sufficient elsewhere. The frequency of testing depends on previous isolation of the organism and proximity to patients at risk (e.g. neonates). The purpose is to prevent colonization before the development of infection. A risk assessment to mitigate risks and a water safety plan are advised, including consideration of removal of thermostatic mixer valves and flow straighteners, and the design of the sink.[36] Infrequently-used taps should be flushed at full flow for 1 min daily or removed altogether. In the event of contaminated supplies, sterile water should be used for neonates, and single-use wipes should be used for other patient hygiene together with additional hand hygiene using alcohol gel after washing.

Evidence

The presence of infections with *P. aeruginosa* in patients is commonly associated with isolation of these bacteria from unit taps. 2–

The installation of point-of-use filters is associated with a reduction in pseudomonal infections. 3

Recommendation

For *P. aeruginosa*, including MDR strains, at a minimum in accordance with the organization's water safety plan, a risk assessment should be made when levels of patient colonization or infection rise, in order to determine if point-of-use filters should be installed or taps changed. Strong

9.4.5.4. Is any cleaning method more effective than others at removing multi-drug-resistant Gram-negative bacilli from the environment? The importance of persistence of transmission of MDR Gram-negative bacteria in the environment remains uncertain.[246,285] However, maintaining a clean environment and appropriately decontaminating all relevant equipment is an essential component of any infection prevention and control programme. The cleanliness of healthcare premises is an important component in the provision of clean safe care.[286] In England, the NHS Constitution pledges 'The NHS commits to ensure that services are provided in a clean and safe environment that is fit for purpose, based on national best practice'.[287] Whilst there have been significant improvements in the cleanliness of English healthcare premises, there is still room for improvement.[286]

The optimal methods for cleaning have been poorly studied with respect to MDR Gram-negative bacteria. Poor cleaning practice, such as inappropriate dilution of cleaning agent or inactivation of disinfectant by organic matter, is more likely to reduce cleaning efficacy than theoretical cross-resistance between disinfectant and antibiotic.[288] In extreme cases, agents used for cleaning can even become contaminated with Gram-negative bacteria, especially pseudomonads.[141,289–291]

Conventional decontamination is carried out by a human operator, and the reliance on the operator to select the correct product, dilution, distribution and surface contact time has the potential for decontamination failure. Debate around the use of chemical disinfectants vs detergents for routine cleaning is gathering momentum with concerns regarding chemical resistance, optimum disinfectant contact times, allergies amongst users and patients, and costs. In short, practice varies widely and monitoring is traditionally by visual inspection, which can be subjective. Efficacy is rarely measured.

Although persistence of Gram-negative organisms on reusable bedpans is a potential mode of spread, there are no

recent reviews of performance with respect to Gram-negative bacteria. In automated washer disinfectors, a combination of alkaline detergent and temperature over 85°C for 1 min is sufficient to eliminate *C. difficile* spores.[292] However, visible faecal soil can remain on 7–33% of bedpans, so appropriate education is important to ensure good practice.[293] Early studies showed that failure to attain 80°C was associated with persistence of *E. coli* and *P. aeruginosa*.[294] Transmission of pathogens via contaminated endoscopes is usually due to failure to comply with appropriate reprocessing practice guidelines.[295] Although some cases of transmission have been known, relatively few have been reported in peer-reviewed journals.

Assessment of the activity of disinfectants against MDR Gram-negative bacteria is hampered by the differences between testing against organisms in suspension and on a surface. *Acinetobacter* spp. and *Pseudomonas* spp. may survive in the ward environment even after bleach disinfection, and increase the risk of acquisition by patients.[106,252] In a prospective cohort study, cleaning the environment with sodium hypochlorite instead of detergent-disinfectant plus chlorhexidine bathing of patients reduced the risk of colonization with MDR *A. baumannii* becoming established beyond that achieved by improved contact precautions, cohorting, screening and antimicrobial stewardship.[296] Termination of acinetobacter outbreaks has been associated with closure and cleaning of units, and removal of a reservoir has been associated with termination of outbreaks for a variety of organisms.[161]

Most interventions to improve cleaning have been accompanied by a package of infection control precautions. Education campaigns and use of audit tools such as marking surfaces with fluorescent dye reduce contamination, but their effect may be transient.

Recently, there has been significant interest in the role of 'no-touch' automated disinfection systems as an additional measure for terminal cleaning of single rooms or hospital areas affected by clusters or outbreaks.[297] Various types of systems are currently marketed, including aerosolized or vapourized hydrogen peroxide, and ultraviolet radiation. Each has distinct microbiological and practical characteristics. A number of studies have shown improved efficacy of killing of various pathogens compared with cleaning alone, particularly in outbreaks, but there are limited data on whether this reduces acquisition rates of pathogens.[298–300] Hydrogen peroxide vapour from 30% H_2O_2 and, in one case, aerosolized hydrogen peroxide from 5% H_2O_2 have been used successfully as part of a bundle of interventions to prevent transmission of MDR *Acinetobacter* spp. in outbreaks,[105,107–109] and hydrogen peroxide vapour has been used to help control outbreaks of resistant Enterobacteriaceae, including those resistant to carbapenems.[262,301,302]

Patients admitted to rooms exposed to hydrogen peroxide vapour were significantly less likely to acquire any MDR organisms than patients admitted to rooms that had not been treated with hydrogen peroxide vapour in a cohort intervention study.[299] *K. pneumoniae*, *P. aeruginosa* and *A. baumannii* in suspension are all susceptible to low concentrations of hydrogen peroxide, but efficacy is significantly reduced when the organisms are in biofilm; some *P. aeruginosa* in biofilm had prolonged survival following hydrogen peroxide exposure in the laboratory.[303] Hydrogen peroxide vapour (from 30% H_2O_2) is more effective in eradicating surface *A. baumannii* than aerosolized hydrogen peroxide (from 5% H_2O_2) (>6 log vs 1-4 log reduction).[304] It is essential to ensure that the area has been thoroughly cleaned first, because efficacy is affected by the presence of organic soiling.

Evidence

Cleaning is important in the control of outbreaks due to MDR *Acinetobacter* spp., and failure to clean specific areas or pieces of equipment has been associated with transmission of other MDR Gram-negative bacteria. However, evidence derived from before–after studies and outbreak reports is open to bias. 2–

Hydrogen peroxide vapour is effective in reducing environmental reservoirs of *Acinetobacter* spp. and other Gram-negative bacteria on surfaces (but not sink traps) if used in addition to standard cleaning. 2+

Recommendations

Terminal disinfection of vacated areas with hypochlorite should be used in the control of outbreaks of MDR Gram-negative infection. Conditional

Hydrogen peroxide vapour should be considered as an adjunctive measure to follow cleaning of vacated isolation rooms/areas. Conditional

Good Practice Recommendation

Increase cleaning frequency to at least twice daily, and every 4 h for high-contact surfaces in the presence of resistant Enterobacteriaece and *Acinetobacter* spp.

9.4.6. Selective decontamination: why is it not used? Is there a role?

SDD is an intervention that aims to reduce mortality and morbidity due to healthcare-associated infection in ICUs. It comprises application of non-absorbable antibiotics to the mouth and stomach together with a course of broad-spectrum intravenous antibiotic(s). A modification uses only the topical element of decontamination [selective oropharyngeal decontamination (SOD)]. The practice has been investigated extensively, largely in the Netherlands, and at least 12 meta-analyses of published papers have been produced.[305] Almost one-third of the trials suggest a significant reduction in the incidence of Gram-negative pneumonia, and one large randomized study demonstrated a small but significant reduction in mortality in a country with low levels of antibiotic resistance.[306] Despite issues with blinding, heterogeneity and compliance, both SDD and SOD appear to be associated with a reduction in pneumonia (OR 0.32, 95% CI 0.26–0.38) and mortality (OR 0.75, 95% CI 0.65–0.87).[307]

Nevertheless, only 5% of UK ICUs use SDD, largely because universal use of prophylactic antibiotics is counter to the tenets of antimicrobial stewardship.[308,309] In some studies with long-term surveillance, both SDD and SOD were associated with an increase in resistance to ceftazidime in Gram-negative flora of the respiratory tract, although systemic antibiotics were also given in many cases.[310–312] In the short term, however, a systematic review found a significant reduction in resistance of Gram-negative bacilli to third-generation cephalosporins during the use of selective decontamination.[208] The relevance of findings from one country to another is unclear when patterns and prevalence rates of resistant Gram-negative bacteria vary so widely. Preparation requires suitable manufacturing units, and administration can be labour intensive.

Recent high-quality studies have provided evidence that daily bathing using chlorhexidine gluconate in ICUs helps to reduce bacteraemia, but there is limited evidence of its specific effect on MDR Gram-negative bacterial infection.[313–316] This has formed part of successful bundles of interventions, but has not been tested as an isolated measure.[236,296,317–319] Some studies that have evaluated chlorhexidine as a single intervention including randomization have failed to demonstrate a reduction in Gram-negative bacteraemia.[314,316,320] There is no strong evidence that daily bathing with chlorhexidine reduces Gram-negative infection or colonization, and there is a risk of development of resistance.[114] The routine use of oropharyngeal chlorhexidine has been associated with an increase in mortality in one systematic review.[321]

Selective decontamination can temporarily suppress excretion of carbapenem-resistant organisms from the gastrointestinal tract and possibly supplement SICPs.[207] In a retrospective analysis of a German outbreak, SDD with colistin and gentamicin as oral solution and gel was used in 14 patients with proven carriage of carbapenemase-producing *K. pneumoniae* KPC-s-KP ST258.[311] Loss of carriage, as defined by three PCR screens 48 h apart, was found at a mean of 21 days in six treated patients (43%), but also in 30% of controls. Resistance to colistin and gentamicin in post-treatment isolates of *K. pneumoniae* rose 19% and 45%, respectively, compared with controls. In a randomized placebo-controlled trial of a regimen based on colistin and neomycin plus treatment of bacteriuria with nitrofurantoin, the detection of ESBL Enterobacteriaceae in rectal swabs was not affected significantly.[322] A randomized trial against placebo used oral gentamicin and topical oropharyngeal gentamicin and colistin for one week, and was directed against carbapenem-resistant *K. pneumoniae* carriage. It produced a significant reduction in carriage at two weeks but not at six weeks.[207] Mortality was not affected significantly, but throat carriage was reduced from 30% to zero in the intervention vs 35% to 30% with placebo ($P < 0.0001$). Isolates did not develop resistance. A lower-quality controlled study reported reductions in faecal and pharyngeal carriage of *Acinetobacter* spp. during colistin-/tobramycin-selective decontamination.[323] Against this, colistin/neomycin/nalidixic acid did not reduce infections or mortality due to MDR Enterobacteriaceae compared with no prophylaxis, but carriage was reduced ($N = 86$, RR 0.28, 95% CI 0.03–2.28).[324]

Evidence

The use of SDD or SOD is associated with a reduction in the incidence of pneumonia due to Gram-negative bacteria. 1+

The use of SDD or SOD is associated with a reduction in the mortality rate. 1+

SOD can be used to reduce excretion of MDR Gram-negative bacteria during an outbreak, but no effect on transmission of infection has been demonstrated, and application can be logistically difficult. 3

Recommendation

The routine use of SDD or SOD is not recommended for control of MDR Gram-negative bacteria. Conditional

9.5. What are the minimum standards to stop spread in public areas, primary care or care homes?

Care homes are recognized as potential reservoirs of MDR pathogens, which can spread among residents, generally as colonizers, and can be re-introduced into hospitals.[325] Publicity may alarm residents, their relatives and carers. Clear information on the standards of infection prevention and control should be available to promote confidence in the quality of care provided. Despite the relatively poor evidence base, guidelines are available for managers and carers.[239,326] In England, the Code of Practice[326] defines what is required to ensure compliance with Care Quality Commission registration requirements for cleanliness and infection control. Following general principles, owners are encouraged to contact the local health protection team in the event of outbreaks of infection, increase cleaning and hand hygiene compliance by patients and staff, conduct root cause analyses, and train staff in infection prevention and control. The prevalence of ESBL Enterobacteriaceae in the care home is usually unknown and sporadic. The need for a urinary catheter, if present, should be reviewed regularly and it should be removed as soon as it is not needed. The appropriate use of such devices to prevent healthcare-acquired infection has been reviewed elsewhere.[166] Residents with diarrhoea should be isolated in their room with a dedicated commode if no ensuite facilities are available. This isolation may require additional psychological support for the resident. Colonization with MDR organisms should not be construed as a reason to isolate or screen other residents. SICPs must continue to be applied.

Evidence

Institutionalized patients/residents are more likely to carry MDR organisms and present a risk on re-admission to hospital. 2+

Good Practice Recommendations

Care homes should adopt national recommendations for environmental and equipment cleanliness, and infection prevention and control.

Clear patient information on MDR Gram-negative infection must be provided in accessible formats to encourage good hand hygiene by patients and staff.

9.6. Are there organizational structures within a healthcare facility that play a role in the successful control of multi-drug-resistant Gram-negative bacilli?

In Israel, with prevalent ST258/KPC *K. pneumoniae*, a self-contained nursing unit with dedicated staff for patients carrying carbapenem-producing Enterobacteriaceae was effective as part of a package of measures including mandatory reporting and a centralized national monitoring system.[77] In the same way, a centralized national system was effective in the control of MRSA in the UK. Outbreaks of carbapenemase-producing *K. pneumoniae* appear to have been controlled by a package of measures, including nursing infected patients in separate units with different staff until discharge or cohorting.[197,262,327–329] The nursing units could be single

rooms, cohorts or wards, but the nurse did not cross between units during the shift. A sequential intervention study found that control was effective when patients were nursed in separate locations with dedicated nursing personnel. The shared medical staff had contact precautions vetted by the dedicated nurse before entering the area.[328] However, the intervention also included education, training, cleaning and screening.

Evidence

A separate unit with dedicated nursing staff rather than part of a ward with shared staff is effective in control packages. 3

Recommendation

Monitor hand hygiene of all staff when patient cohorting is being applied. Strong

10. Further research

- PCR-based tests for swift detection of MDR Gram-negative pathogens require further testing and development to allow cost-effective and rapid screening and detection of carriers.
- Consideration should be given to further investigation of screening patients of long-term care facilities as a means of tracking movement and defining reservoirs of organisms. Longitudinal assessment of patients carrying ESBL-producing organisms, particularly *E. coli* ST131, should be made on admission and discharge to hospitals and nursing homes to detect infection and spontaneous clearance of carriage.
- The risk factors for development of infection, such as urinary catheterization, should be separated from the risk factors for carriage, including hospitalization. Household contacts of cases of infection with *E. coli* ST131 or carbapenem-resistant *K. pneumoniae* should be examined for evidence of spread or subsequent infection.
- Given the recent changes in the prevalence of, for example, ESBL-producing *E. coli* ST131 and *K. pneumoniae* ST258 with KPC carbapenemases, the potential for screening patients for particular clones as means of controlling transmission in hospitals should be assessed. MALDI-ToF, serological and DNA-based detection methods should be developed, together with selective or indicator media for quinolone-resistant Enterobacteriaceae.
- Bacteraemia surveillance including sequence typing for strains resistant to cephalosporins, fluoroquinolones and carbapenems should be expanded and open to public and commissioning groups. This is essential for accurate risk assessment of patients transferred between healthcare facilities. In localities with outbreaks, typing and infection control should be extended to isolates from other anatomical sites.
- Randomized intervention studies of effectiveness measures, including single-room isolation, in the prevention of transmission of Gram-negative bacterial infection.
- The potential for endoscopes to disseminate MDR Gram-negative pathogens requires better understanding with reference to complex instruments such as those with wire-containing channels.

Conflict of interest statement

Appendix 1. Glossary

Active surveillance: Admission regimen that involves testing of patients to detect the presence of multi-drug-resistant organisms.

AmpC β-lactamases: Clinically important cephalosporinases encoded by the chromosomes of many Enterobacteriaceae or (less often) by plasmids. High-level expression confers resistance to penicillins (except temocillin), cephalosporins (except cefepime), aztreonam and penicillin-β-lactamase inhibitor combinations.

Antimicrobial: A substance that kills or inhibits the growth of micro-organisms.

Augmented care area: Units where medical/nursing procedures render the patients susceptible to invasive disease from environmental and opportunistic pathogens (e.g. critical care, neonatal, burns and haematological wards).

Bacteraemia: The presence of micro-organisms in the blood stream.

safety, including exposure to infections (e.g. disposable gloves and disposable aprons).

Porins: Proteins that span the outer membrane of Gram-negative bacteria and mycobacteria forming pores that allow the entry of small water-soluble molecules, including antibiotics.

Screening of patients: Sampling potential colonization sites for multi-drug-resistant Gram-negative pathogens.

Selective decontamination: The prophylactic use of topical and systemic antibiotics to remove pathogenic organisms from the gastrointestinal tract to reduce the incidence of respiratory tract infections.

Standard infection control precautions (SICPs): Basic infection prevention and control measures necessary to reduce the risk of transmission of infectious agents from both recognized and unrecognized sources of infection. Sources of (potential) infection include blood and other body fluid secretions or excretions (excluding sweat), non-intact skin or mucous membranes, and any equipment or items in the care environment that could have become contaminated.

Appendix 2. Guideline development

The subject was identified by the Scientific Development Committee of HIS in February 2011 and approved by HIS in May 2011. The BSAC Council agreed a similar proposal at the same time. The BIA Council agreed to join in September 2011. The members were chosen to reflect the range of stakeholders, and were not limited to members of the three societies. The questions were decided at the first meeting of the Working Party Group in November 2011 from issues presented to the members and patient representatives by staff and patients in the preceding months. Each was debated by the Working Party Group before adoption. Enhance Reviews Ltd was paid for the search and data extraction. Working Party members were not paid, except for travel expenses.

Conflict of interest

Conflicts of interest were registered at the outset and renewed during the process. They are stated in the report. In the event of a potential conflict being identified, the Working Party agreed that the member should not contribute to the section affected.

Infection control: systematic review process

Patient Intervention Comparison Outcome process

Patients: All patient groups were included. The guideline is careful not to make recommendations that may prejudice clinical care based on sex, age, ethnicity or socio-economic status.

Interventions: Interventions were identified in the literature to generate intervention-specific recommendations.

Comparisons: Comparisons between intervention and standard management were used.

Outcomes: Objective referring to length of hospital stay, mortality, rate of acquisition or infection.

Systematic review questions

1. What is the definition of MDR Gram-negative bacilli?

β-lactamases: Enzymes produced by some bacteria that confer resistance to β-lactam antibiotics, such as penicillins and cephalosporins, by breaking down the central structure of the antibiotic.

Carbapenemases: β-lactamases that inactivate carbapenems such as meropenem; most also attack and confer resistance to penicillins and cephalosporins.

Care area: Any portion of a healthcare facility where patients are intended to be examined or treated.

Cleaning: Methods that physically remove soil, dust and dirt from surfaces or equipment.

Cohorting: Imposed grouping within an area of a hospital ward of patients or staff potentially exposed to designated diseases.

Colonization: Situation whereby micro-organisms establish themselves in a particular environment, such as a body surface, without producing disease.

Community-acquired: Infection or colonization that is acquired outside of hospitals.

Community-associated: Usually defined as infection or colonization detected in an outpatient or within 48 h of hospital admission.

Contact precautions: Hand hygiene is performed before touching the patient and prior to wearing gloves, and wearing gloves when touching the patient and the patient's environment. A single room is preferred; otherwise, discussion with infection control personnel to consider cohorting or not moving the patient. An apron/gown is worn for all patient interactions that may involve contact with the patient or potentially contaminated areas in the patient's environment. Donning personal protective equipment on room entry and discarding before exiting the patient room is required to contain pathogens, especially those that have been implicated in transmission through environmental contamination.[173]

Extended-spectrum β-lactamases (ESBLs): β-lactamases that attack cephalosporins with an oxyimino side chain (e.g. cefotaxime, ceftriaxone and ceftazidime), as well as the oxyimino-monobactam aztreonam. Unlike AmpC β-lactamases (q.v.), they are inhibited by clavulanic acid and tazobactam, and unlike carbapenemases (q.v.), they do not attack carbapenems

Healthcare-associated (acquired): Infection or colonization detected in an inpatient more than 48 h after hospital admission.

High-risk: Used to describe those patients or facilities where the risk of acquiring infection is in the upper 10% of the total patient population.

Infection: Invasion by and multiplication of pathogenic micro-organisms in the body, producing tissue injury and disease, requiring treatment.

Long-term care facility (care home/nursing home): Provides accommodation and meets the needs of patients with chronic illness or disability who cannot care for themselves.

Multi-drug-resistant (MDR) Gram-negative bacteria: Bacteria resistant to at least three different antibiotics.

Outbreak: At least two similar (i.e. not distinct) cases related in time and place.

Passive surveillance: Review of routine clinical samples of all patients by microbiologists on reporting results from the laboratory.

Personal protective equipment: The equipment a person wears to protect themselves from risks to their health or

SUMMARY

In 2019—2020, two subsequent outbreaks caused by phenotypically identical ESBL-producing *Enterobacter cloacae* and multi-drug-resistant (MDR) *Pseudomonas putida* were detected in respectively 15 and 9 patients of the haematology-oncology department. Both bacterial species were resistant to piperacillin-tazobactam, used empirically in (neutropenic) sepsis in our hospital, and ciprofloxacin, used prophylactically in selective digestive decontamination for haematology patients. The *E. cloacae outbreak* was identified in clinical cultures of blood and urine. Despite intensified infection control measures, new cases were found in weekly point-prevalence screening cultures. Environmental samples of sinks and shower drains appeared positive in 18.1%. To diminish the environmental contamination burden, all siphons of sinks were replaced, and disinfection of sinks and shower drains was intensified using chlorine and soda on a daily basis. Replacement of shower drains was not possible. The outbreak of *P. putida* remained limited to rectal cultures only, and disappeared spontaneously without interventions. During both outbreaks, multiple strains of the incriminated bacterium were found simultaneously (demonstrated by Amplified-Fragment Length Polymorphism and/or Whole-Genome Multi-locus Sequencing Typing) in patients as well as the environment. It was experimentally shown that a biofilm on the toilet edge may act as a source for nosocomial transmission of Gram-negative bacteria. In conclusion, the drainage system of the hospital is an important reservoir of MDR bacteria, threatening the admitted patients. In existing hospitals, biofilms in the drainage systems cannot be removed. Therefore, it is important that in (re) building plans for hospitals a plan for prevention of nosocomial transmission from environment to patients is incorporated.

Introduction

In recent years, many studies have demonstrated that sink drains, shower drains and toilets in hospitals can serve as a

reservoir of Gram-negative bacterial infections in patients [1—3]. These bacteria reside in biofilms in and on water related devices, which are refractory to disinfection. Bacteria in the biofilm of drainage systems are under a prolonged antibiotic selective pressure, because antibiotics in faeces and urine of patients are absorbed by the biofilm [4]. Within these biofilms, containing several bacterial species, acquired mobile resistance elements are frequently transferred, resulting in highly resistant microorganisms, such as extended-spectrum β-lactamase and carbapenemase-producing Enterobacterales and Pseudomonas species [5,6].

Highly resistant, (as well as antibiotic susceptible), bacteria from biofilms can be transmitted to patients directly or indirectly via droplets, and go on to cause infections [7]. Furthermore, there have been a few reports of transmission via aerosols, but these remain a minority [8]. This transmission results in a serious threat to patients, especially critically-ill patients and immunocompromised hosts, leading to substantial morbidity and mortality, because treatment options are limited. Most Gram-negative healthcare-associated waterborne infections go undetected, unless they occur in outbreaks [2].

In Gram-negative nosocomial outbreaks, isolates found in patients and water-points can be identical, but the direction of transmission is usually unclear (water-point contamination originates from waste-water from the patient, or opposite direction). Therefore, the microbiomes of patients and water-points seem to be a continuum [9].

Usually, biofilms contain several bacterial species. The complete removal of biofilms from drains is often not possible, because they extend into the deeper parts of the water system, which cannot be reached. From this deeper compartment, biofilms grow back to the outlets, even from different patient rooms. Therefore, for infection control, mechanical cleaning and disinfection of the outlets of the system is often the maximum achievable goal.

We describe two subsequent outbreaks in 2019—2020 caused by ESBL-producing *Enterobacter cloacae* and multi drug-resistant *Pseudomonas putida* in the haematology-oncology ward of our hospital, which were related to contaminated water points. Both bacterial species were resistant to the antibiotics used for selective digestive decontamination (SDD), which is used to prevent systemic Gram-negative infection in neutropenic haematology patients, and also to the empirical antibiotic therapy for neutropenic fever.

The *E. cloacae* outbreak involved 15 patients (13 haematology and two oncology), whom were infected or colonized with a phenotypically identical strain (Figure 1), which proved to consist of several genotypes, found in both patients and the environment. Eventually, a bundle of several interventions, including replacement of siphons and intensive disinfection schemes resulted in the termination of this outbreak. The *P. putida* outbreak occurred one year later and involved nine haematology patients (asymptomatic rectal colonization only). This outbreak was also multi-clonal and involved patients and waterpoints, but this ended without interventions.

Methods and materials

Description of water points on the haematology-oncology department

All single and four-person rooms contain a separate sanitary room containing a sink, shower and toilet. The two-person rooms have a sanitary room with a sink and toilet. For these rooms; two extra shower rooms are created on the corridor of the ward (Figure 2). The sinks are situated directly below the outlet with a siphon. The shower drains are situated in such a way that patients do not stand on it. Before and during the outbreaks, all water points functioned properly.

Sampling of patients and environment

Environmental samples

During the two outbreak periods environmental sampling was performed on the ward, using Copan Transswab (108C USE)®. The interior of sink drains and shower drains were sampled by inserting the swab and rotating at a depth of about 6 cm. Toilets were sampled by swabbing under the edge. Furthermore, faucets and refrigerators inpatient rooms were swabbed.

Patient samples

Haematology patients were routinely screened twice a week for colonisation of throat and faeces with Gram-negative

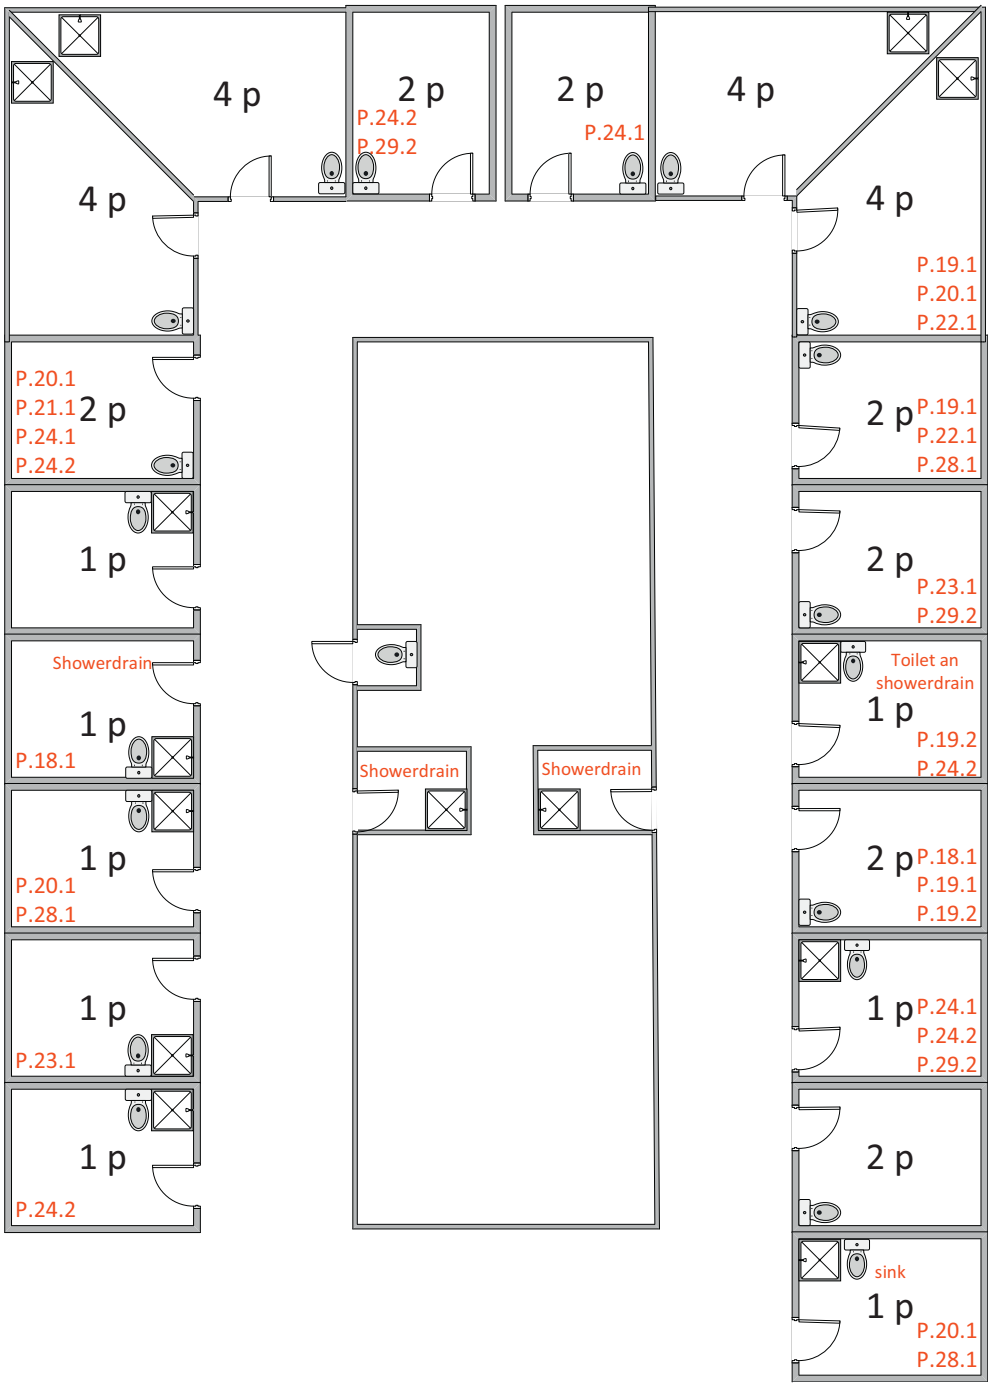

Figure 2. Overview environmental sampling E.cloacae. Situation in the haematology department in week 25. In this figure is indicated where patients and environmental samples tested positive for ESBL-positive *E.cloacae*. **Inner rectangles**: 1p/2p/4p = 1, 2, 4 persons patient room. Orange: environmental samples were positive for other Gram-negative bacteria. Red: environmental sample(s) positive for ESBL-positive *E. cloacae* and other Gram-negative bacteria. In the **outer rectangles** is indicated which patients had been admitted to the room before environmental sampling. **Two shower drains were both positive** at the corridor which were used by multiple patients were all positive for ESBL-positive *E. cloacae*.

bacteria, as a part of their intensive chemotherapy treatment. The oral combination of ciprofloxacin and fluconazole was used prophylactically for SDD, with the aim of preventing systemic Gram-negative or fungal infection during the neutropenic phase of their treatment. If bacteria resistant to ciprofloxacin were cultured from patients, oral colistin was added to bacterial SDD.

During the *E. cloacae* outbreak, present oncology patients were additionally screened weekly by rectal swab for *E. cloacae* carrier status. As no clinical infections occurred during the *P. putida* outbreak, oncology patients were not sampled.

Microbiological methods

Phenotypic investigation

Patient screening swabs were cultured overnight on blood agar and CLED agar at 35°C. As soon as outbreaks were identified, environmental samples and rectal swabs from oncology patients were eluted in Trypton Soya Broth (TSB) and cultured overnight at 35°C. The next day, the TSB was plated and cultured overnight on selective CHROMID® ESBL agar (bioMérieux, Marcy-l'Étoile, France) at 35°C. Bacterial strains were identified and investigated for antibiotic resistance using Vitek-2 (bioMérieux, Marcy-l'Etoile, France). ESBL-production from *E. cloacae* strains was confirmed by the double disk method with cefotaxime, ceftazidime and cefepime with and without clavulanic acid.

Genotyping of bacterial strains

Amplified Fragment Length Polymorphism (AFLP). Cultured isolates were typed by AFLP analysis as described elsewhere [10]. In brief, isolates were resuspended in 10 mM Tris-EDTA buffer pH 8.0. Restriction was performed with *MseI* and *EcoRI* restriction enzymes (New England Biolabs, Massachusetts, USA), adaptors were ligated and fragments were amplified by PCR with primers specific for the ligated adapters. Following restriction and amplification, DNA fragments were separated on an ABI Prism 3500XL Genetic Analyser (Applied Biosystems, Warrington, UK), after which data were analysed using the Pearson correlation coefficient and were clustered by unweighted pair-group matrix analysis (UPGMA) using BioNumerics software v. 7.6 (Applied Maths, St-Martens-Latem, Belgium). Isolates clustering above the threshold were assigned the same AFLP type number.

Whole Genome Multi Locus Sequence Typing (wgMLST). The first cluster of ESL E.cloacae isolates was also typed by whole genome sequencing (WGS). This was performed as described elsewhere [11]. Isolates clustering within an allelic difference of 20 or less were assigned to the same cluster. Sequencing data were deposited at European Nucleotide Archive (ENA) under BioProject PRJEB46126.

Environmental cleaning and disinfection on the ward

The sanitary facilities of the ward were cleaned daily with moist microfiber cloth and toilets with sanitary cleaner containing alkylalcoholethoxylate, aliphatic alcohol and 4-terr-butylcyclohexylacetate (Taski Sani 100, Diversey, Utrecht, The Netherlands). Floor drains of showers were disinfected with chlorine on a weekly basis for a duration of at least 5 minutes, and toilets were cleaned with fluid containing calcium carbonate (CIF, Unilever, Rotterdam, The Netherlands).

Experimental study

We investigated whether toilets might have been a driving force behind transmission on the ward. During flushing, droplets have the opportunity to spread to the environment, because the patient toilets in our hospital do not have a cover lid for practical reasons. The experiments were performed in a toilet room of an unused patient department (all toilets in the hospital are identical). *Experiment 1*: 90 mL Visirub® fluorescent concentrate (Hartmann, Nijmegen, The Netherlands) was mixed with the water present in the flushing cistern (estimated volume 9 L). Photographs were taken before and 5 minutes after flushing the toilet, with illumination of the toilet room using UV-light. *Experiment 2*: 24,25 mL Visirub® concentrate was mixed with 24,25 mL demineralized water and 1.5mL gel-former containing polyacrylamide, C13-14 isoparaffin and laureth-7 (Jojoli, Barendrecht, The Netherlands). The resulting fluorescent mixture was applied underneath the toilet edge. Again, photographs were taken in a similar manner.

Results

ESBL-positive E. cloacae

Description of the outbreak [Figure 1]

In May 2019, a cluster of three patients with multi-resistant ESBL-positive *E. cloacae* was detected on the haematology-oncology department of our hospital. The strains were resistant to the empiric antibiotic regimen on the ward (piperacillin-tazobactam) and had an identical antibiogram (ESBL+, ciprofloxacin R, trimethoprim-sulfamethoxazole R). One neutropenic patient had a positive blood culture with this strain, but recovered after switching the antibiotic regime to meropenem. Two of these patients were roommates and all three patients shared the same shower on the ward.

Six new cases occurred in the subsequent five weeks, despite ongoing enforcement of hand hygiene and contact isolation/cohorting of positive patients in a separate room.

By the end of June, disinfection of sinks and shower drains was intensified by replacing all daily and weekly cleaning products with chlorine at 250 ppm. Patients were instructed not to leave their personal belongings on the rim of the sink bowl, to prevent transmission from splashing water from the drain. In addition, all siphons of sinks on the ward were renewed. As environmental samples remained positive for *E. cloacae*, a weekly treatment with biofilm degrading liquid caustic soda (Senzora BV, Deventer, The Netherlands) for five minutes was added for every sink drain and toilet. After this intervention the incidence of newly colonized patients declined gradually over time.

In the peak of the outbreak, a change in the antibiotic regimen of SDD for neutropenic haematology patients, from ciprofloxacin to colistin, was considered an optional alternative intervention. The epidemic strain was resistant to ciprofloxacin, and more than half of the patients on the ward were treated with SDD, so this might have contributed to the rapid dissemination. Eventually, with the decline of new patient cases, this intervention was not effectuated.

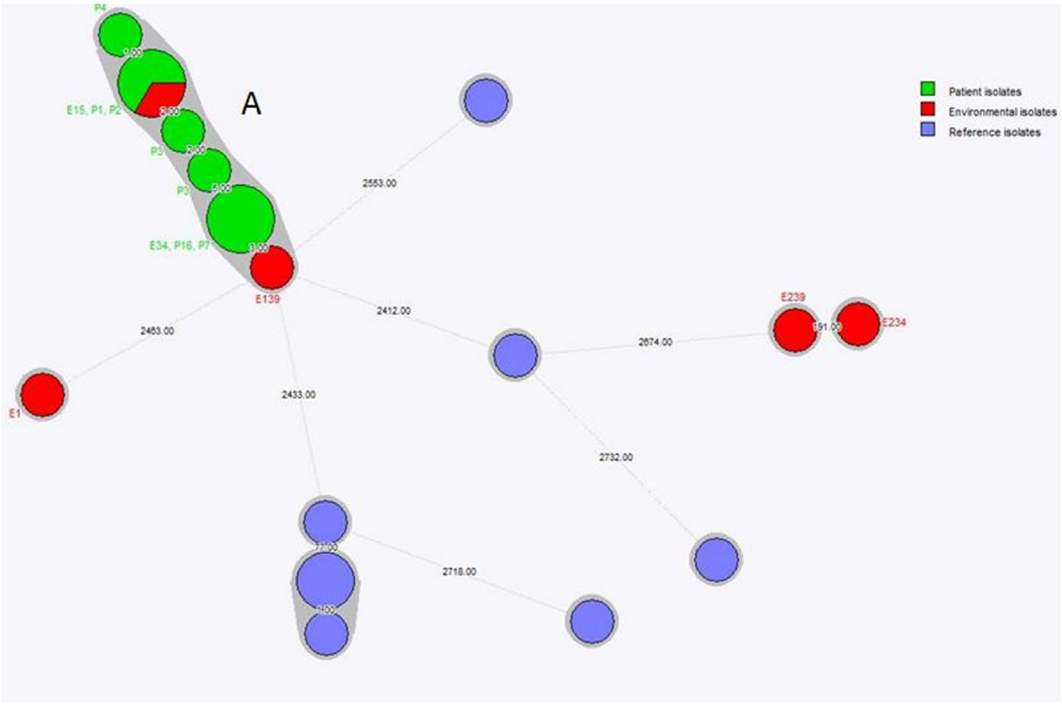

Figure 3. Whole Genome Sequencing results ESBL-*E.cloacae*. Minimum spanning tree of wgMLST of ESBL-positive *E. cloacae*. Each circle represents one or multiple isolates, depending on the circle size and lines between circles indicate the allelic distance between the indicated isolates. Isolates are coloured by origin: patient isolates (green), environmental isolates (red) and reference non-related isolates (blue). Isolates from patients and the environment that cluster together within the cut-off value are depicted with a grey line zone and indicated as cluster A.

A final round of environmental specimens (taken at the end of August) revealed eight positive environmental cultures from which five isolates belonged to genotype A. In retrospect, this could be explained by the suboptimal adherence to the intensified instructions for disinfection by the cleaning personnel. From week 35 on, genotype A *E. cloacae* was not identified in weekly screenings of patients, and environmental samples in November revealed only other genotypes.

Environmental samples and patient samples [Figure 2]

In June and July 2019, 47/241 (19.5%) of environmental specimens cultured *E. cloacae* with an identical antibiogram as the initial epidemic strain, among which three were typed as genotype A (three belonged to other genotypes and 41 were not typed). Positive patients were identified in the majority of patient rooms.

Genotyping [Figure 3]

All patient strains during the initial outbreak period in May (n= 4) appeared to be identical by AFLP and wgMLST (AFLP-type A). Additional isolates were therefore typed by AFLP only. In subsequent AFLP-analysis there appeared to be the simultaneous presence of multiple genotypes on the ward. In the period May—June, six of seven strains were identical (genotype A). In the period July—August three out of six strains were genotype A.

Typing of 18 environmental isolates demonstrated 3/6 genotype A in the period May—July, 7/8 genotype A in August and 0/4 genotype A in November.

Multi-drug-resistant Pseudomonas putida

Description of the outbreak [Figure 4]

In August 2020, a cluster of four patients with MDR *P. putida* was noticed in surveillance rectal cultures of haematology patients. The strains were resistant to the empiric antibiotic regimen on the ward (piperacillin-tazobactam) and had an identical antibiogram (ceftazidime I or R, meropenem R, aminoglycosides R, ciprofloxacin R, colistin S).

New cases (n=5) occurred in the subsequent two months, despite enforcement of hand hygiene and contact isolation/cohorting in a separate room of positive patients.

In contrast to the *E. cloacae* outbreak, no clinical cultures became positive with MDR *P. putida*, and the incriminated strains disappeared from rectal cultures of individual positive patients as soon as SDD was changed from ciprofloxacin to colistin. The incidence of colonization reduced spontaneously, so therefore interventions were not necessary. Suspected environmental sources, such as the shower and sink of a patient room that was shared by several positive patients, and the ice cube machine of the ward, were cultured but were negative.

In October, four new patients became positive with a phenotypically identical *P. putida*. Therefore, the 30 toilet edges in all rooms where positive patients had been admitted, were cultured for *P. putida*. Only one toilet edge was positive with a different genotype. It turned out that the four patient strains were different from each other and only one was colonized with the outbreak strain (genotype 3). Since then, no new patients carrying *P. putida* have been identified. Unexpectedly, in the last week of November four out of five genotyped

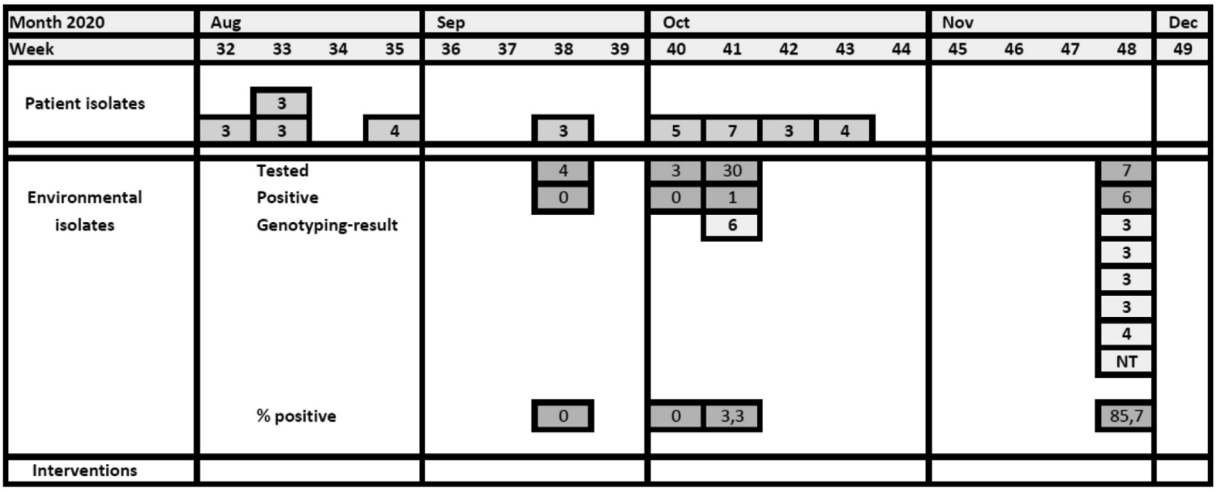

Figure 4. Epidemic curve multi-resistant *Pseudomonas putida* outbreak. Chronologic schematic overview of the epidemic. **Patient isolates**. Only positive cultures from rectal swabs for Selective Digestive Decontamination were involved. **Environmental cultures: *week 38***; shower and sink in patient room frequently occupied by positive patients, ***week 40***; ice cube machine; ***week 41***; various water tap points (water from toilets, siphons of basins, buckets used by cleaning personnel), ***week 48***; ridges of 7 toilets from patient rooms of positive patients (note: these cultures were negative for ESBL+ *E.cloacae*). **Genotyping results (patient and environmental isolates)**: 3–7: genotype of multi-resistant *Pseudomonas putida* strain. NT = not typed. **Interventions**: no interventions were carried out.

environmental strains from toilets were identified as the epidemic *P. putida (*genotype 3).

Environmental samples [Figure 4]

In September–November 2020, 7/44 (16%) of environmental cultures were positive for *P. putida* with an antibiogram identical to the strain found in the cluster in August. From these isolates four belonged to the epidemic genotype 3, two to other genotypes and one was not typed.

Genotyping

Three out of four strains of the initial cluster were determined to be identical by AFLP (genotype 3). During the outbreak different AFLP variants were found, from which some were shared between patients and some between patients and environment. Of the new cases in September–October, 2/5 typed isolates belonged to genotype 3 and of the seven positive environmental samples, four were genotype 3.

Experimental study [Figure 5]

Experiment 1: fluorescent remnants of flushing water were seen throughout the toilet bowl and some droplets outside were identified (Figure 5A). Experiment 2: flushing water was able to remove some fluorescent gel underneath the toilet edge, which could in theory be further transmitted to the environment by successive flushes (Figure 5B).

Discussion

In this study we describe the simultaneous colonization of patients and water related devices with ESBL-positive *E. cloacae* or MDR *P. putida* on the haematology-oncology ward of our hospital. A mix of genotypes were isolated in both cases, but a dominant genotype of either *E. cloacae* or *P. putida* was shared by both patients and environment, suggesting that environmental sources played a role in transmission. This hypothesis was supported by experimental results, which proved that by flushing toilets with a fluorescent dye, droplets were clearly disseminated to the environment in toilet rooms. For *E. cloacae*, various interventions resulted in the discontinuation of transmission among patients. For *P. putida*, transmission disappeared without other interventions beside changing SDD from ciprofloxacin to colistin in individual colonized haematology patients.

While the *E. cloacae* transmission was first discovered in clinical cultures of blood and urine, *P. putida* was only found in rectal surveillance cultures. *P. putida* rectal culture positivity was mainly noticed immediately after admission to the ward and disappeared as soon SDD was changed. For both outbreaks, environmental cultures of wet points remained positive for more than a month after the last positive patient was identified. The latter finding implicates that after disinfection of sink or shower drains, biofilm is still present in the deeper compartment of the hospital drainage system. Moreover, recontamination of the water from a biofilm underneath the toilet rim during flushing is a possibility (Figure 5). Bacteria in this biofilm remain an ongoing threat for colonization of patients during their stay in the hospital. As the drainage systems can often not be replaced, the most efficient solution is to "keep the monster inside" by removing the biofilm at the outlets at regular intervals combined with disinfection of these sites. The most efficient and achievable method is still under debate. Recent technical solutions, such as UV disinfection and ozonisation of water seem promising [12]. Innovative design of sinks can reduce the contamination of the near surroundings with bacteria originating from the biofilm [13]. The introduction of self-disinfecting siphons gave excellent results [14,15]. Furthermore, a critical appraisal of the necessity of all water points in the hospital is indispensable; unnecessary ones should be removed and the remaining points should be strictly divided into incoming and outgoing points to prevent cross-contamination [16]. For transmission prevention of highly resistant opportunistic plumbing premise pathogens, design

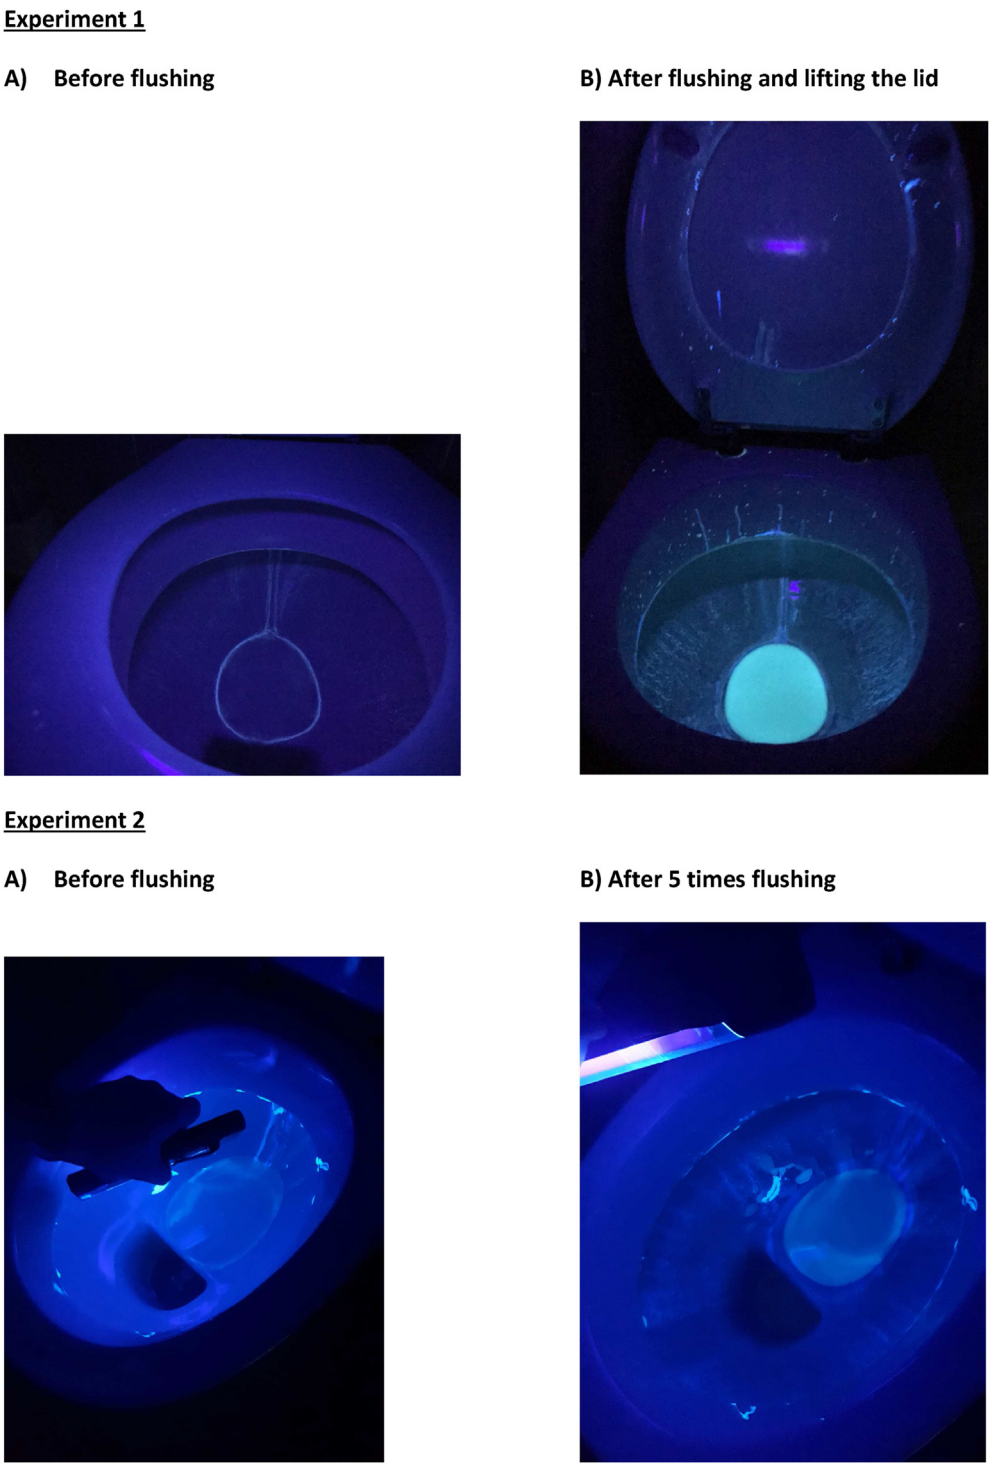

Figure 5. Experimental study flushing toilet. Experiments were performed in a toilet room of a unused patient department. *Experiment 1*: 90 mL Visirub® concentrate (Hartmann, Nijmegen, The Netherlands) was mixed with the water present in the flushing cistern (estimated volume 9 L). Photographs were taken before and 5 minutes after flushing the toilet, with illumination of the toilet room using UV-light. UV-positive remainders of droplets were identified inside as well as outside the toilet bowl. *Experiment 2*: 24,25 mL Visirub® concentrate was mixed with 24,25 demineralized water and 1,5 mL gel-former (Jojoli, Barendrecht, The Netherlands). The resulting fluorescent mixture was applied underneath the toilet edge. Again, photographs were taken in a similar manner. Flushing water was able to remove the gel from the toilet.

and construction of the water system of newly built hospitals is critical [17]. Also the implementation of waterless patient care is an expensive, but effective method to discontinue hospital transmission [18].

For situations wherein the former solutions are not feasible, the most effective intervention for disinfection and removal of biofilm is still under debate. Recently, Ledwoch *et al*. published a novel in vitro biofilm model to investigate this topic. In a study comparing four methods for disinfection, peracetic acid 4000 ppm was superior to alternatives, resulting in a >4 log reduction in viability in all drain sections [19]. Another weak point in manual disinfection is the correct implementation by the environmental services workers. In the *E. cloacae* outbreak, we discovered that the intensified disinfection strategy was not strictly followed by all members of the team, which contributed to the delayed termination of the outbreak. In this context, not only the type of disinfectant but also the contact time with the various parts of the drains is crucial. Education and feedback by regular audit are essential for high standard cleaning and disinfection in the hospital [20]. Furthermore, we concluded that biofilms do not only occur in the drainage system but also underneath the rim of the toilet seats. Technical solutions, such as rimless toilets, are helpful in prevention of biofilms that are difficult to remove.

High antibiotic use is a well-known risk factor for the selection of resistant bacteria. The majority of patients on the ward were haematology patients receiving SDD, as part of their treatment, for prevention of bacteraemia and mortality. In case of resistance in Gram-negative rods, ciprofloxacin is changed to a combination of trimethoprim-sulfamethoxazole and colistin. As a substantial part of the patient population was treated with an antibiotic for which the *E. cloacae* strains were resistant, this was considered as a possible driving force behind the ongoing transmission on the ward, because the colonization resistance in these patients was lowered. Switching to another antibiotic class could be an effective intervention. Frakking *et al*. used the discontinuation of ciprofloxacin prophylaxis in haematology patients in a bundle of interventions which ended a large and persistent outbreak caused by vancomycin-resistant *Enterococcus faecium*, which is less pathogenic than *Enterobacter* spp [21]. Verlinden *et al*. found no significant increase in serious infectious complications with the discontinuation of prophylaxis and a decrease in fluoroquinolone resistant and ESBL-producing Gram-negative bacteria [22]. Furthermore, the effectivity of ciprofloxacin prophylaxis in preventing mortality is questioned by several authors, and it might even cause selection for multi-drug resistant bacteraemia [23,24].

One limitation of our study is worth noting. We did not prove a causal relation as patients and water points were colonized at the same time period. The index-patient with the *E. cloacae* bacteraemia had been infected on the ward with the same strain one year earlier (data not shown), implying that the environment on the ward could have been contaminated for at least a year. This hypothesis is supported by the fact that at the end of our study in November, a part of the investigated environment was still positive for *E. cloacae*, despite the intensified cleaning and disinfection regime. Recently, Volling *et al*. described a tool for assessing the quality of evidence for transmission from water point to patient. In none of the 52 studies that were evaluated with this tool causality was conclusively demonstrated [25].

Conclusions

In conclusion, the patient environment is increasingly considered as a major source of transmission of nosocomial bacteria [26]. The drainage system of the hospital is an important reservoir of multi-resistant bacteria, threatening admitted patients. In existing hospitals, biofilms in the drainage systems can often not be removed. Therefore, it is important that in (re)building plans for hospitals a plan for prevention of nosocomial transmission from environment to patients is incorporated. For existing, maybe older, hospital buildings, a water safety plan for haematology-oncology departments should be instituted [27]. Furthermore, where technical solutions are not available, regular training of cleaning personnel is of utmost importance.

Abstract: This study aimed to establish the clinical features, outcomes, and factors associated with mortality in patients with *Stenotrophomonas maltophilia* (*S. maltophilia*) septicemia. The characteristics and outcome data used in this retrospective study were collected from medical records at Songklanagarind Hospital. Risk factors for survival were analyzed using χ^2-tests, Kaplan–Meier curves, and Cox regression. A total of 117 patients with *S. maltophilia* bacteremia were analyzed. The patients' median age was 45 years, 77 (70%) were male, 105 (90%) had comorbidities, 112 (96%) had previously undergone carbapenem therapy, and over half of the patients were on invasive medical devices. Trimethoprim-sulfamethoxazole (TMP-SMX) and fluoroquinolone showed high susceptibility rates to *S. maltophilia*, with 93% and 88% susceptibility, respectively. Patients who received appropriate empirical antibiotic treatment had significantly reduced 14-day, 30-day, and in-hospital mortality rates than those who did not ($p < 0.001$). The days of hospital stay and costs for those who received appropriate and inappropriate empirical antimicrobial treatment were 21 and 34 days ($p < 0.001$) and 142,463 and 185,663 baht, respectively ($p < 0.002$). Our results suggest that an appropriate empirical antibiotic(s) is significantly associated with lower 30-day mortality in hospitalized patients with *S. maltophilia* septicemia.

1. Introduction

Stenotrophomonas maltophilia is a motile, glucose, non-fermenting, gram-negative bacterium that widely exists in hospital environments [1,2]. In the last few decades, it has been recognized as a significant pathogen responsible for hospital acquired infections in severely debilitated or immunocompromised individuals [3–8]. It usually causes pneumonia and bacteremia and, less frequently, it can cause infections of the urinary tract, intra-abdominal organs, and wounds [2,9].

Due to its inherent resistance to several antibiotic classes, treating *S. maltophilia* infections is difficult. *S. maltophilia* employs a wide spectrum of resistance mechanisms, including reduced permeability, expression of multidrug efflux pumps, and the synthesis of beta-lactamase, carbapenemase, and aminoglycoside-modifying enzymes [10,11]. Moreover, distinguishing between infection and colonization is challenging because of the bacterium's ability to colonize respiratory epithelial cells and invasive medical device surfaces. Hence, the administration of appropriate antibiotics is occasionally delayed, leading

to high mortality [10–12]. TMP-SMX is the preferred antibiotic for treating *S. maltophilia* infections [13,14]. However, fluoroquinolones and minocycline are also alternative management options [15–17]. According to a systematic review, infections with *S. maltophilia* are associated with high rates of mortality, ranging from 21 to 69% [18]. Prior reports have demonstrated the risk factors associated with mortality among *S. maltophilia* bacteremia patients, including septic shock, an Acute Physiology and Chronic Health Evaluation (APACHE) II score more than 15 points, indwelling invasive medical devices, mechanical ventilation, admission to intensive care units (ICU), prolonged hospitalization, and concurrent administration of immunosuppressive agents or broad-spectrum antibiotics [19,20].

To date, information regarding the clinical characteristics and outcomes of patients with *S. maltophilia* bacteremia in Thailand has rarely been reported. Thus, this study reviewed the data of patients with *S. maltophilia* septicemia at Songklanagarind Hospital to establish the clinical characteristics, outcomes, and risk factors associated with mortality. We find that treatment with appropriate empirical antimicrobial agent(s) is significantly associated with a lower 30-day mortality rate, and that a high APACHE II score is a significant independent predictor of mortality, suggesting that *S. maltophilia* bacteremia should always be considered in patients who exhibit potential risk factors.

2. Patients and Methods

2.1. Patients and Setting

This study was conducted retrospectively, using data collected at a tertiary care hospital in southern Thailand from 2010 to 2020. All hospitalized patients aged >15 years who had one or more episodes of infection with *S. maltophilia* isolated from blood culture were eligible for this study. Patients' clinical information was obtained from medical records, while microbiological data were extracted from a laboratory database. Only *S. maltophilia* septicemia as a first episode was included in the analysis to eliminate case duplication.

2.2. Bacterial Identification and Antimicrobial Susceptibility

Conventional biochemical tests, according to Bergey's Manual of Systematic Bacteriology, were performed to identify *S. maltophilia*. Matrix-Assisted Laser Desorption/Ionization-Time of Flight (MALDI-TOF) mass spectrometry (MS) was further employed to confirm the identifications. The Kirby-Bauer disk diffusion method was used for antimicrobial evaluation of TMP-SMX and levofloxacin, while the Broth microdilution method was performed when testing ceftazidime and chloramphenicol. The results were interpreted according to the Clinical and Laboratory Standards Institute (CLSI) [21,22]. Regarding polymyxin susceptibility testing, there are no currently established polymyxin breakpoints for *S. maltophilia*, but Minimal Inhibitory Concentration (MIC) of $\geq$4 μg/mL is often considered resistance [23].

2.3. Study Design and Data Collection

Data Retrieval

Patients' electronic medical records were reviewed. Demographic and clinical variables including age, sex, body mass index, comorbidities, and immunocompromised status were obtained. Comorbidities included cerebrovascular disease, cardiovascular disease, chronic kidney disease, and diabetes mellitus. Immunocompromised status was defined as those who had an absolute neutrophil count $< 0.5 \times 10^9$/L for >two weeks or were on immunosuppressive therapy (chemotherapy within six weeks or corticosteroids at a dosage greater than 15 mg of prednisolone daily for >two weeks or disease-modifying antirheumatic drugs within four weeks after bacteremia). Clinical information included instances of pneumonia, initial ICU admission, the patient's APACHE II score, their history of previous exposure to antibiotics, and the use of invasive medical devices. Microbiological data included MICs. Treatment data included the appropriateness of empirical antimicrobial therapy and the duration of antibiotic treatment. An appropriate empirical

antibiotic was defined as the prescription of drug(s) that are effective against *S. maltophilia* isolates within 72 h of blood culture collection. TMP-SMX and fluoroquinolones are considered treatment options for infections with *S. maltophilia* [24]. The primary outcome was 30-day mortality, whereas secondary outcomes were in-hospital mortality, 14-day mortality, length of hospital stay, and hospital expenses. The length of in-hospital stay was defined as the duration of hospital stay after *S. maltophilia* septicemia was diagnosed. Hospital expenses were divided into two categories: antimicrobial pharmaceutical costs and hospitalization-associated costs.

2.4. Statistical Analysis

Data on demographics and clinical outcomes were analyzed. Continuous variables were reported as means ± SD (standard deviation), and categorical variables were reported as percentages (%) or frequency counts (n). Continuous variables were tested using the D'Agostino-Pearson test to check for normality, and if data were normally distributed, Student's *t*-tests were conducted and data were presented as means ± SD. Otherwise, the Mann–Whitney test was performed, and data were presented as medians (IQR). For categorical variables, χ^2-tests or Fisher's exact test were used. Univariate analysis was used to determine the crude odds ratio (OR) for mortality. A multivariate logistic regression model was used for 30-day mortality-related variables and variables with *p*-values ≤ 0.2. The significance level was set at $p \leq 0.05$. The adjusted OR and 95 percent confidence interval were used to express the relationship between variables and outcomes. A survival analysis using Cox proportional hazard regression was done to determine the factors associated with survival.

2.5. Ethical Statement

The institutional review board of the Faculty of Medicine, Prince of Songkla University, Thailand, approved this retrospective study (REC: 58368144). The authors were given permission to retrieve clinical and microbiological data from the hospital database with a consent waiver. Before being assessed and used, all data were anonymized. The researchers confirm that we conducted this research in line with the Declaration of Helsinki principles.

3. Results

From 2010 to 2020, 129 blood samples from 129 patients yielded positive cultures for *S. maltophilia*. Two or more organisms were isolated from one blood culture of 12 (9.3%) patients; therefore, they were excluded from the study. Figure 1 depicts the patient enrollment in this study. Of 117 patients with *S. maltophilia* septicemia, 54 (46.2%) received appropriate empirical antibiotic(s).

The records of 117 *S. maltophilia* bacteremia patients were included in the analysis. Table 1 reveals the baseline demographic characteristics and comparison of features between patients receiving and not receiving appropriate empirical antibiotics.

The patients' median age was 45 years (range, 40–51 years), and 66% (77/117) were men. *S. maltophilia* was predominantly found in hospitalized patients, with comorbidities in 90% of patients with underlying diseases. However, only six (5%) patients were immunocompromised. Most patients (70%) had a body mass index $\geq 30\,kg/m^2$, reflecting a high incidence of obesity among patients with *S. maltophilia* bacteremia. Also, 54 patients (46%) were critically ill, with an average APACHE II score of 19. In addition, over half (55%) of the patients had pneumonia and bacteremia. Most patients (96%) had a recent history of carbapenem exposure before *S. maltophilia* bacteremia, followed by cephalosporin, fluoroquinolone, beta-lactam/beta-lactamase inhibitor, and aminoglycoside exposure, with rates of 73%, 62%, 59%, and 34%, respectively.

We found significantly higher APACHE II scores, intensive care unit admission rates, rates of intravascular device and urinary catheter, and rates of empirical antimicrobial therapy with TMP-SMX, fluoroquinolone, and colistin for *S. maltophilia* bacteremia in patients who received appropriate antibiotic(s) than in those who did not. Other base-

line characteristics, including demographic data, did not significantly differ between the two groups.

Table 1. Characteristics of *S. maltophilia* bacteremia patients and comparison of features between patients receiving and not receiving appropriate empirical antibiotics.

Parameter	*S. maltophilia* Bacteremia Patients (n = 117)	*S. maltophilia* Bacteremia Patients Receiving Appropriate Empirical Antibiotics (n = 54)	*S. maltophilia* Bacteremia Patients Not Receiving Appropriate Empirical Antibiotics (n = 63)	*p*-Value [A]

[A] Comparison between *S. maltophilia* bacteremia patients receiving and not receiving appropriate empirical antibiotics. Boldface entries indicate values that reached the significance level set at 0.05.

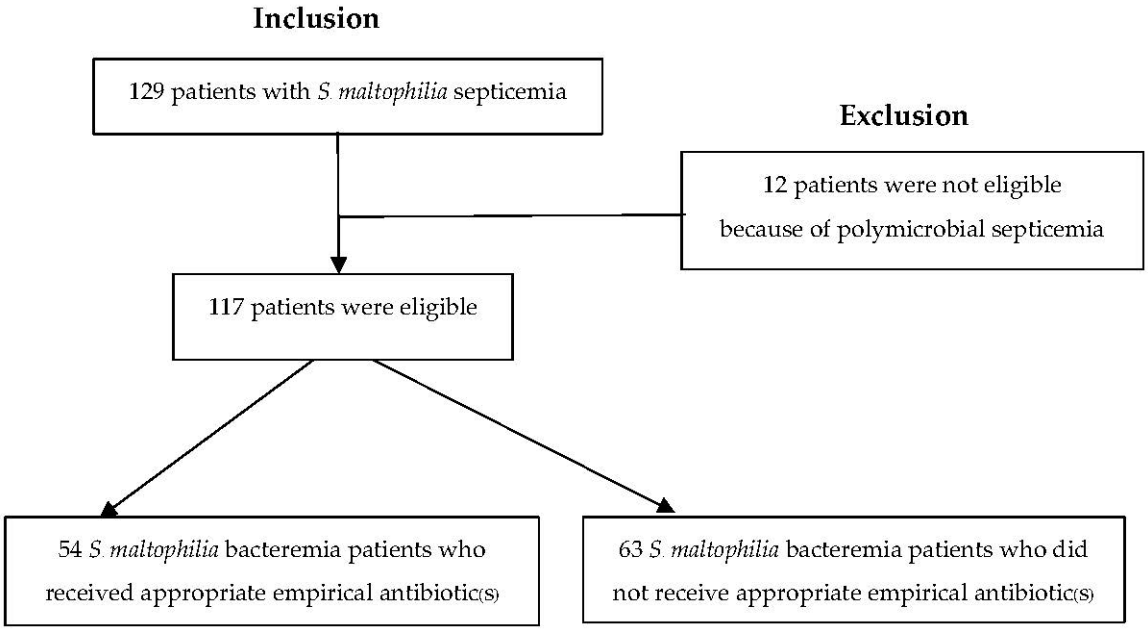

Figure 1. Study enrollment flow chart.

Only 54 (46.2%) patients received appropriate empirical antimicrobial agents, whereas 63 (53.8%) received inappropriate empirical antimicrobial agents. The majority of patients (94%) received empirical antibiotic therapy with carbapenem, which is ineffective against *S. maltophilia*, whereas one-third (34%) received empirical antibiotic treatment with colistin, and only one-fourth had received TMP-SMX or fluoroquinolone for empirical therapy. The duration of antibiotic treatment did not differ between the two groups.

Antimicrobial susceptibility testing of the *S. maltophilia* isolated from the 117 patients is shown in Table 2**.** The results indicated that TMP-SMX, levofloxacin, and chloramphenicol showed the highest susceptibility rate against *S. maltophilia*, with susceptibility values of 93%, 88%, and 82% respectively, compared with the 65% and 35% non-susceptible rate of ceftazidime and colistin. Thus, TMP-SMX was adopted as the most effective antibiotic against *S. maltophilia* bacteremia, followed by fluoroquinolone.

Table 2. Antibiotic-resistant profiles of 117 *S. maltophilia* isolates were obtained from the patients with bacteremia.

Antibiotics	No. of Resistant Isolates (%)
Chloramphenicol	21 (18)
Colistin	41 (35)
Levofloxacin	14 (12)
TMP-SMX	8 (7)
Ceftazidime	76 (65)

The clinical outcomes of the patients treated for *S. maltophilia* bacteremia are shown in Table 3**.** The 14-day, 30-day, and in-hospital mortality rates of those who received appropriate empirical antimicrobial treatment were significantly lower than the rates of those who received inappropriate treatment, with values of 7%, 7%, and 9% and 33%, 48%, and 51%, respectively ($p < 0.001$). Antimicrobial and non-antimicrobial expenses were the highest for patients who received appropriate antibiotic(s). The length of hospital stay from *S. maltophilia* bacteremia onset was significantly lower for patients who received appropriate empirical antibiotic (s) at 21 days, compared to 34 days for patients who did not ($p < 0.001$). Moreover, hospital costs were significantly lower for patients who received appropriate empirical antibiotic(s) (142,463 and 185,663 baht, respectively; $p = 0.002$).

Table 3. Comparison of outcomes between patients with *S. maltophilia* bacteremia who did or did not receive appropriate empirical antibiotic(s).

Outcomes		***S. maltophilia* Bacteremia Patients Who Received Appropriate Empirical Antibiotic(s) (n = 54)**	***S. maltophilia* Bacteremia Patients Who Did Not Receive Appropriate Empirical Antibiotic(s) (n = 63)**	***p*-Value [A]**

[A] Comparison between patients with *S. maltophilia* bacteremia who did and did not receive appropriate empirical antibiotic(s). Boldface entries indicate values that reached the significance level set at 0.05.

The factors associated with 30-day mortality in patients with *S. maltophilia* bacteremia are shown in Table 4. A high APACHE II score was significantly associated with 30-day mortality (OR, 1.19; $p = 0.012$). The appropriate empirical antibiotic reduced 30-day mortality significantly (OR, 0.04; $p = 0.001$).

Table 4. Factors associated with 30-day mortality in 117 *S. maltophilia* bacteremia patients.

[A] Comparison between survivors and non-survivors. Boldface entries indicate values that reached the significance level set at 0.05.

The 30-day Kaplan–Meier survival rates among patients with *S. maltophilia* who received appropriate empirical antibiotic(s) differed significantly from those of patients who did not ($p < 0.001$, log-rank test), as illustrated in Figure 2.

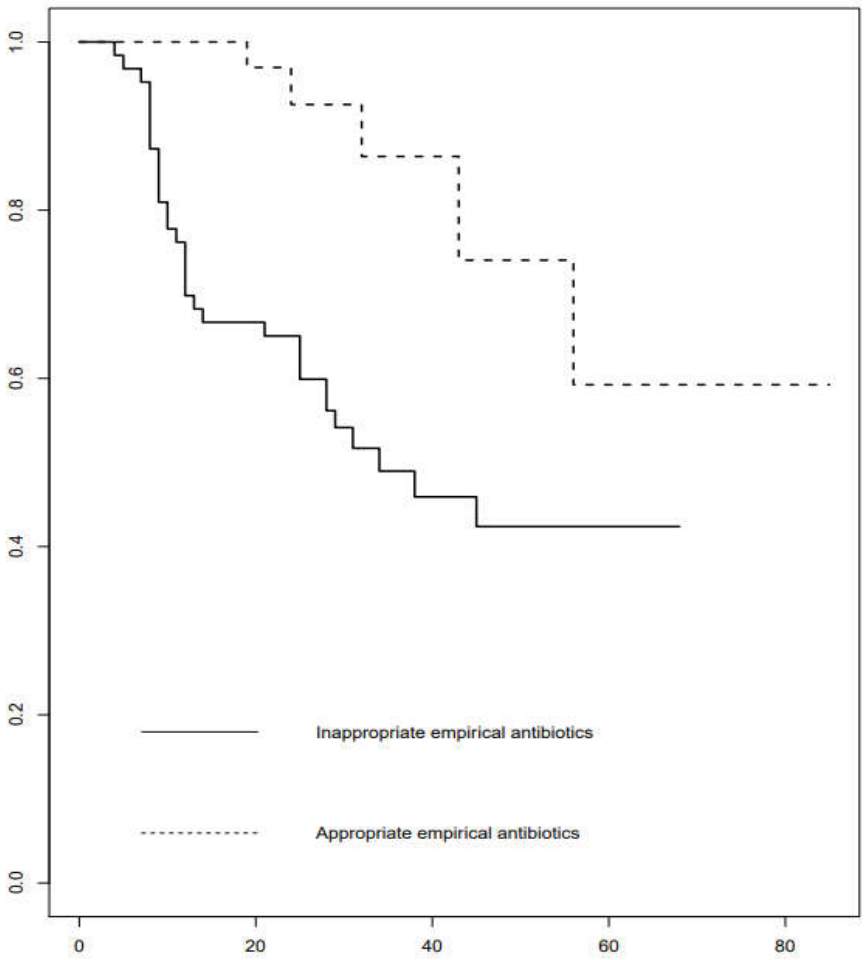

Figure 2. Kaplan–Meier survival curves of *S. maltophilia* bacteremia patients who received and did not receive appropriate empirical antibiotic(s).

4. Discussion

Since the extensive prescription of antimicrobial agents in the past decade, *S. maltophilia* has become the third most prevalent non-fermentative gram-negative bacterial isolate causing hospital acquired infections, preceded by *Pseudomonas aeruginosa* and *Acinetobacter* spp. *S. maltophilia* infections. These are associated with high mortality rates ranging from 21 to 69%, and the overall 30-day mortality rate of 29% observed in this study is comparable to previous reports.

Several characteristics of *S. maltophilia* bacteremia patients were similar to previous reports. Several reports showed that infection due to *S. maltophilia* commonly occurred among the critically ill patients who were admitted in ICUs, while less than half (46%) of the patients in this research were primarily admitted in ICUs [3–8,12]. This can be explained with the constrained ICU capacity in our setting. The patients in this study had relatively severe illness with a median APACHE score of 19, and most were subjected to a mechanical ventilator (82%), intravascular devices (62%) and urinary catheterization (86%), respectively. Thus, the acquisition of this organism frequently occurred among mechanically ventilated patients [12]. Most of the patients in this study (90%) had several medical morbidities. Similarly, risk factors of this infection including multiple debilitating illnesses were described in a previous report. Additionally, previous exposure to several broad-spectrum antibiotics were previously demonstrated to be a risk factor for infection due to *S. maltophilia*. This study shows that *S. maltophilia* mostly affects patients with prior use of antibiotics, especially carbapenem (96%). This suggests that the use of carbapenem in patients who are hospitalized may lead to the emergence of nosocomial infections

A53210128

caused by *S. maltophilia* as its intrinsic resistance to carbapenem and the selective growth of non-susceptible isolates. An antimicrobial susceptibility test in this study showed unfavorable resistance to commonly-used antimicrobial agents for nosocomial infection including ceftazidime and colistin. These findings are similar to previously published data [10,11]. The resistance seemed relatively low among levofloxacin (12%) and TMP-SMX (7%). The appropriate choices in our setting included TMP-SMX and fluoroquinolones. It is interesting that the resistance of colistin is relatively high at 35%. This finding is in line with the reports in several regions of the rising of colistin-resistant *S. maltophilia* [10,11,14]. Unlike the in vitro study of Enterobacteriaceae, the data on combination therapy of *S. maltophilia* remains unclear [25].

Previous reports have demonstrated that risk factors associated with mortality among *S. maltophilia* bacteremia patients include septic shock, APACHE II score ≥15 points, the indwelling of central venous catheters, mechanical ventilation, ICU admission, prolonged hospitalization, and receiving concurrent immunosuppressive agents or broad-spectrum antibiotics [19,20].

In our study, we identified that a high APACHE II score was also associated with higher rates of mortality, similar to previous literature [3,26–28]. Moreover, this study found that the appropriate empirical antibiotic(s) were a protective predictor to reduce mortality, based on the multivariate analysis results. However, some reports found that the inappropriate empirical antimicrobial treatment did not have a significant impact on mortality [12,18]. These discrepancies were probably due to the different antimicrobial susceptibility patterns. This study reported that TMP-SMX and levofloxacin remain highly active against isolates of *S. maltophilia* (93% and 88%, respectively), whereas the susceptibility rates of TMP-SMX and fluoroquinolones have varied in some previous reports (81–85%, and 21–82%, respectively) [18,29].

With regard to the emergence of infections of *S. maltophilia*, particularly in individuals who were admitted in ICUs, a previous report demonstrated the economic burdens among those patients with this infection including prolonged length of stay in hospital and hospital costs [30]. This current study did not only demonstrate only clinical benefits of appropriate antibiotics but also non-clinical benefits including length of hospital stay and hospital expenses. These findings suggest that the appropriate empirical antibiotic yielded an approximately 40% shorter length of hospital stay and an approximately 25% lower hospital cost. Even with the addition of appropriate empirical antimicrobial agents including fluoroquinolones and TMP-SMX into the commonly used regimens, the antimicrobial cost among those with appropriate empirical antimicrobial agents were still lower than those with inappropriate empirical antibiotics.

This study shows that *S. maltophilia* mostly affects patients with a history of the prior use of antibiotics, especially carbapenem (96%), reflecting the widespread but potentially problematic use of carbapenem in hospitalized patients, which may lead to the emergence of *S. maltophilia* infections due to its intrinsic resistance to carbapenem and the selective growth of non-susceptible isolates. Because *S. maltophilia* infections continue to increase worldwide and therapeutic options are limited, antimicrobial stewardship is essential to reduce the emergence of drug-resistant organisms and hospital costs.

Study Limitations

This study has some limitations. First, we enrolled patients from a single hospital, which could make it difficult to generalize our findings to other contexts. Second, the lack of data addressing the clinical judgment of physicians regarding antimicrobial therapy may have limited the scope of the analysis. Third, our study focused only on bloodstream infections and pneumonia, whereas other infection sites were not evaluated. Variations in the infection site might be associated with the outcome of *S. maltophilia* septicemia. Lastly, the design of this study was a retrospective cohort analysis, which may have contributed to information and selection biases. A well-designed prospective study should

be conducted to establish the impact of appropriate antimicrobial therapy on mortality outcomes more precisely.

5. Conclusions

Bacteremia due to *S. maltophilia* causes relatively high mortality and high resource utilization. This infection should of concern among patients with several medical comorbidities, comparatively severe clinical manifestations, with previous admission to intensive care units and previous exposures to broad-spectrum antimicrobial agents, particularly carbapenems. Appropriate empirical antimicrobial treatment yields a significant benefit on clinical outcomes including 14-day, 30-day and in-hospital mortality. Additionally, the patients who received appropriate empirical antimicrobial treatment had a substantially shorter length of hospital stay and lower hospital costs. According to antimicrobial susceptibility testing in this current study, the appropriate empirical antimicrobials agents include TMP-SMX and fluoroquinolone.

Evaluation of a *Stenotrophomonas maltophilia* bacteremia cluster in hematopoietic stem cell transplantation recipients using whole genome sequencing

Stefanie Kampmeier[1*], Mike H. Pillukat[1], Aleksandra Pettke[2,3], Annelene Kossow[1], Evgeny A. Idelevich[2] and Alexander Mellmann[1]

Abstract

Background: *Stenotrophomonas maltophilia* ubiquitously occurs in the hospital environment. This opportunistic pathogen can cause severe infections in immunocompromised hosts such as hematopoietic stem cell transplantation (HSCT) recipients. Between February and July 2016, a cluster of four patients on the HSCT unit suffered from *S. maltophilia* bloodstream infections (BSI).

Methods: For epidemiological investigation we retrospectively identified the colonization status of patients admitted to the ward during this time period and performed environmental monitoring of shower heads, shower outlets, washbasins and toilets in patient rooms. We tested antibiotic susceptibility of detected *S. maltophilia* isolates. Environmental and blood culture samples were subjected to whole genome sequence (WGS)-based typing.

Results: Of four patients with *S. maltophlilia* BSI, three were found to be colonized previously. In addition, retrospective investigations revealed two patients being colonized in anal swab samples but not infected. Environmental monitoring revealed one shower outlet contaminated with *S. maltophilia*. Antibiotic susceptibility testing of seven *S. maltophlia* strains resulted in two trimethoprim/sulfamethoxazole resistant and five susceptible isolates, however, not excluding an outbreak scenario. WGS-based typing did not result in any close genotypic relationship among the patients' isolates. In contrast, one environmental isolate from a shower outlet was closely related to a single patient's isolate.

Conclusion: WGS-based typing successfully refuted an outbreak of *S. maltophilia* on a HSCT ward but uncoverd that sanitary installations can be an actual source of *S. maltophilia* transmissions.

Keywords: *Stenotrophomonas maltophilia*, Outbreak investigation, Whole genome sequence-based typing, Immunocompromised hosts

Background

Stenotrophomonas maltophilia, an intrinsically multidrug resistant gram negative pathogen, is widely distributed in aqueous habitats such as, sink drains, endoscopes and hemodialysis water within clinical settings [1, 2]. Usually, this pathogen is not highly virulent in immunocompetent individuals but can cause severe infections including bacteremia, peritonitis and meningitis in immunocompromised hosts resulting in complications, e.g. septic shock, respiratory failure, tissue necrosis and septic thrombophlebitis [3]. Recipients of hematopoietic stem cell transplantations (HSCT) are especially at risk and suffer from pulmonary hemorrhage resulting in higher mortality rates compared to non-HSCT patients [4].

In recent years, an increasing incidence of *S. maltophilia* is reported on oncologic wards [5]. Moreover, several outbreaks and pseudo-outbreaks caused by this pathogen have been reported [6, 7]. In addition to epidemiological

investigations, different typing methods, e.g. pulse field gel electrophoresis (PFGE) and multi locus sequence typing (MLST) are used to identify the genetical relationship among different *S. maltophilia* isolates [8–11]. These techniques are useful in excluding outbreak scenarios, if MLST sequence types (ST) or PFGE patterns of isolated pathogens differ. In case of identical STs or highly similar PFGE patterns both methods reach their discriminatory limits. In these cases an outbreak is assumed, although more precise methods uncover and accidental cluster. Additionally, inter-laboratory comparability is limited using PFGE. Therefore, whole genome sequence-based typing (WGS) approaches are increasingly seen as gold standard method for highly discriminatory typing [12] and the superiority of WGS in comparison to other typing methods was already demonstrated for several bacterial pathogens [13–17]. Moreover, we could recently demonstrate the high reproducibility of WGS, which is another prerequisite for the applicability in clinical routine [18].

Here we evaluated a cluster of *S. maltophilia* bacteremia in recipients of allogeneic stem cell grafts using WGS-based typing.

Methods

Cluster detection, epidemiological investigations and infection control measures

The 1500-bed University Hospital Münster includes two HSCT-units each comprising 10 patient rooms, which are all HEPA-filtered and equipped with separated bathrooms for each patient (Fig. 1). In total, 193 patients were admitted to the HSCT-units during 2016. Patients usually receive an allogenic HSCT.

S. maltophilia bloodstream infections (BSI) were defined as one or more blood cultures positive for *S. maltophilia* obtained from patients with clinical signs of infection (fever >38 °C, chills, hypotension) according to the critieria given by the European Centre for Disease Prevention and Control [19]. Four *S. maltophilia* BSI were detected in patients (P1, P3, P4, P6) in the HSCT ward between February and July 2016. As this number exceeds the average baseline of 0.5 *S. maltophilia* BSI per year detected during 2011–2015, an epidemiological investigation was initiated. Routine environmental screening of aqueous habitats (shower heads, shower outlets, washbasins and toilets) within patients' rooms in the HSCT unit, normally focusing on multidrug resistant

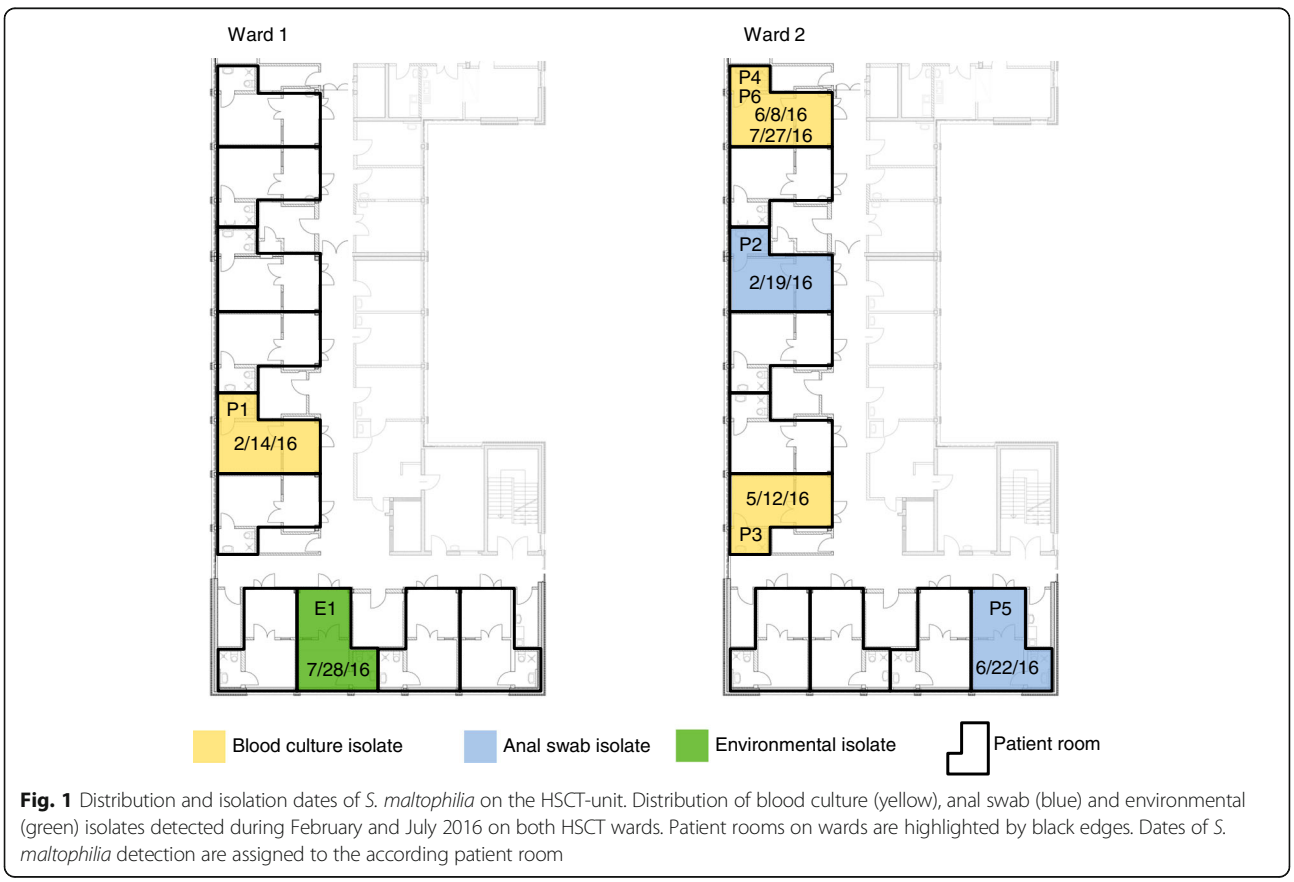

Fig. 1 Distribution and isolation dates of *S. maltophilia* on the HSCT-unit. Distribution of blood culture (yellow), anal swab (blue) and environmental (green) isolates detected during February and July 2016 on both HSCT wards. Patient rooms on wards are highlighted by black edges. Dates of *S. maltophilia* detection are assigned to the according patient room

Pseudomonas aeruginosa, was expanded to *S. maltophilia.* Patients colonized with *S. maltophilia*, coincidentally detected in anal/rectal swabs or stool samples (as screening of HSCT-patients concentrates on multidrug resistant *Pseudomonas aeruginosa*), were retrospectively identified. Moreover, hand hygiene and surface disinfection measures were intensified.

Identification and susceptibility testing

Positive blood culture samples were detected using an automated blood culture system (BACTEC™ 9240, Becton Dickinson GmbH, Heidelberg, Germany). Environmental samples were plated on Columbia sheep blood agar (Oxoid, Wesel, Germany) and MacConkey agar (Becton Dickinson, Heidelberg, Germany) after enrichment in Tryptic Soy Broth (Becton Dickinson) for 24 h at 36 °C. Subsequent species identification was performed by Matrix-Assisted Laser Desorption/Ionization-Time of Flight-Mass Spectrometry (MALDI-TOF MS; Bruker, Bremen, Germany). Susceptibility testing for trimethoprim-sulfamethoxazole (TMP-SMX) was performed using disk diffusion method in accordance with the European Committee on Antimicrobial Susceptibility Testing (EUCAST) standards and interpreted using EUCAST clinical breakpoints (version 6).

Whole genome sequencing (WGS) based typing

To determine the clonal relationship of *S. maltophilia* strains isolated from blood cultures, the isolates were subjected to WGS using the Illumina MiSeq platform (Illumina Inc., San Diego, USA) as described previously [13]. Retrospectively identified colonization isolates were not subjected to WGS as they were no longer available in contrast to BSI isolates, that are stored for a longer time period. Using SeqSphere$^+$ software version 2.0 beta (Ridom GmbH, Münster, Germany), all coding regions were extracted and compared in a gene-by-gene approach (core genome multilocus sequence typing, cgMLST) using *S. maltophilia* K279a strain (GenBank accession number AM743169.1) as a reference sequence. Instead of a published cgMLST scheme, which is not yet available, this ad hoc scheme was used to differentiate the cluster. SeqSphere$^+$ software was used to display the clonal relationship in a minimum-spanning tree (MST). For backwards compatibility with classical molecular typing, i. e. MLST, the MLST sequence types (ST) were extracted from the WGS data in silico.

Results

Epidemiological investigation and susceptibility testing

Chronological order and spacial distribution of isolated *S. maltophilia* is displayed in Fig. 1. Isolates were obtained from blood culture samples of patients on both wards. Two of the four isolates (isolated from P4 and P6) were detected within short intervals in two patients both admitted to room 1 on ward 2. Of the four patients suffering from *S. maltophilia* bacteremia, three (P1, P4 and P6) were previously tested positive for *S. maltophilia* in stool samples or anal swabs. Additionally, two colonized patients (anal swabs; P2, P5) admitted to ward 2 were uncovered by the retrospective analysis (Table 1). One environmental isolate (E1) could be detected in a shower outlet of a patient room that was a patient with *S. maltophilia* infection. Susceptibility testing revealed all patient isolates to be susceptible to TMP-SMX, except isolate P3. The environmental isolate was resistant to TMP-SMX (Table 1).

Clinical characteristics and outcome of patients with *S. maltophilia* bacteremia

All patients with *S. maltophilia* BSI suffered from acute myeloid leukemia as the underlying disease. P2 and P5, who were only colonized by *S. maltophilia,* suffered from chronic lymphatic leukemia and myeloproliferative neoplasm. Except P1, all patients had already received allogenic SCT at the time of *S. maltophilia* detection. P1 and P6 developed an acute respiratory distress syndrome. P1, P3, and P6 died due to *S. maltophilia* bacteremia.

WGS-based typing

We analyzed four bloodstream isolates and the environmental isolate by WGS. Comparison via cgMLST, based on 1876 genes present in all isolates, revealed no genetical relationship among isolates originating from patients (Fig. 2). In contrast, *S. maltophilia* strains isolated from P3 and E1 showed a similar genotype with only four alleles difference, suggesting a relationship between these two isolates. P3 and E1 harbored the MLST ST 94. All other isolates harbored new MLST STs.

Discussion

S. maltophilia has emerged as an important nosocomial pathogen associated with increased mortality rates in patients suffering from hematological malignancies and receiving hematopoietic stem cell transplantations [20, 21]. In this study, WGS was used to evaluate a cluster of four *S. maltophilia* BSI in patients partially suffering from pulmonary dysfunction associated with the infection due to this

Table 1 Patients with *S. maltophilia* colonizations and blood stream infections during February and July 2016

Patient no.	Anal colonization	Blood stream infection	Strain susceptibility to TMP-SMX	WGS performed
P1	+	+	S	+
P2	+	–	S	–
P3	–	+	R	+
P4	+	+	S	+
P5	+	–	S	–
P6	+	+	S	+

TMP-SMX – trimethoprim-sulfamethoxazole, WGS – whole genome sequencing

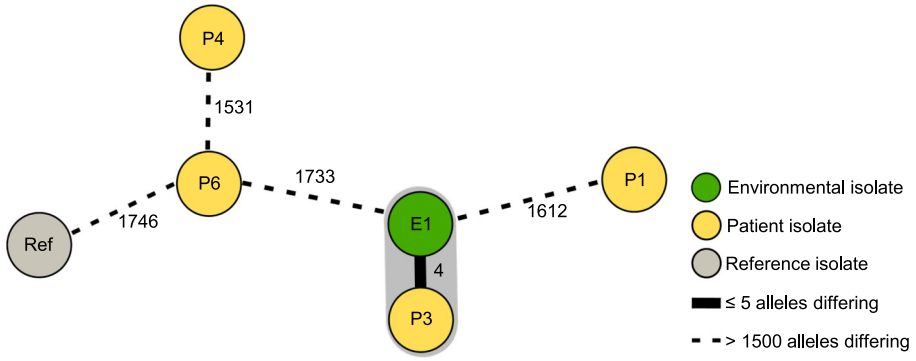

Fig. 2 Minimum spanning tree of *S. maltophilia* isolates. Minimum spanning tree of four blood culture isolates (P, *yellow*), one environmental isolate (E, *green*) from the HSCT unit and one outgroup isolate (Ref, non-HSCT unit, isolated in May 2016, *grey*) based on up to 1876 target genes, pairwise ignoring missing values. Genotypes are consecutively numbered, starting with P1 (isolated in February 2016). Each dot represents one genotype and is colored according to its origin. Different connecting lines and numbers on these lines show the number of alleles differing between two genotypes

pathogen [4]. Susceptibility testing, normally used as a first indication of nosocomial transmission of bacterial strains, could not exclude a spread of one single clone. WGS and subsequent cgMLST analysis, methods that have shown to provide detailed information in evaluating the epidemiology in nosocomial clusters of other pathogens [22], excluded a genetical relation and therefore an outbreak scenario.

A number of different sources are possibly responsible for the increasing number of *S. maltophilia* BSI. Due to its multidrug resistant nature, selection of this pathogen can easily occur in patients after receiving broad-spectrum antibiotics [23]. Moreover, *S. maltophilia* infections occur frequently in combination with the distinct immunocompromised status of HSCT recipients [24]. On the other hand, several environmental sites such as sink drains could be detected as sources of *S. maltophilia* within hospital settings [25].

To what extent these habitats are origins for hospital-acquired colonizations or infections of *S. maltophilia* could not yet be shown in detail. In this study we documented a genetical relation between an environmental and a patient blood stream infection isolate by analyzing WGS data. Although there was no local proximity, *S. maltophilia* could be transmitted from the environment to a patient or vice versa, at least giving the possibility of further spread via aqueous habitats in the HSCT unit.

Conclusion

WGS- analysis can be used to precisely refute an outbreak of *S. maltophilia*. Additionally, WGS- based typing documented sanitary installations in HSCT units to be an actual source or result of transmission between environmental and human habitats. Hence, in addition to classical infection control strategies, monitoring of aqueous habitats has to be established within the rooms of HSCT recipients in order to prevent transmission of these multidrug resistant organisms, as recently also shown for *P. aeruginosa* [26].

Wang N, Tang C and Wang L (2022) Risk Factors for Acquired Stenotrophomonas maltophilia Pneumonia in Intensive Care Unit: A Systematic Review and Meta-Analysis. Front. Med. 8:808391. doi: 10.3389/fmed.2021.808391

Background and Aims: *Stenotrophomonas maltophilia* is increasingly found in critically ill patients, but it is considered a pathogen of limited pathogenicity and therefore it is not often targeted. We systematically evaluated risk factors for *S. maltophilia* pneumonia in ICU patients for better clinical management.

Methods: Prospective and retrospective studies of *S. maltophilia* infection in the ICU from database establishment to August 8, 2021, were searched through PubMed, web of science, Cochrane Library Embase and CNKI. The literature was independently screened and extracted by two authors according to inclusion and exclusion criteria, evaluated for quality by the NOS scale, and meta-analyzed by stata 14.0 software.

Results: A total of eight studies with a sample size of 2,320 cases were included. Meta-analysis showed that APACHE-II score > 20 (OR = 10.98, 95% CI: 5.67 ~ 21.26), COPD (OR = 3.97, 95% CI: 2.39 ~ 6.61), malignant tumor (OR = 2.15, 95% CI: 1.03 ~ 4.50), mechanical ventilation (OR = 8.75, 95% CI: 2.59 ~ 29.58), tracheotomy (OR = 6.12, 95% CI: 2.06 ~ 18.18), endotracheal intubation (OR = 4.25, 95% CI: 2.30 ~ 7.84), β- Lactamase inhibitors (OR = 9.98, 95% CI: 1.51 ~ 65.96), aminoglycosides (OR = 4.01, 95% CI: 2.06 ~ 7.80), carbapenems (OR = 2.82, 95% CI: 1.49 ~ 5.31), and quinolones (OR = 2.17, 95% CI: 1.21 ~ 3.89) were risk factors for ICU-acquired *S. maltophilia* pneumonia.

Conclusion: Many risk factors are associated with *S. maltophilia* pneumonia in ICU patients. Clinical workers should pay more attention to assessing the risk of infection in ICU patients and enhance the prevention and management of high-risk groups, which will help reduce their risk of *S. maltophilia* infection.

INTRODUCTION

S. maltophilia is a non-fermentable Gram-negative bacterium that is an opportunistic agent. It is naturally resistant to many commonly used antibiotics, such as carbapenems and aminoglycosides (1, 2). It is due to such characteristics, in the context of drug resistance, that *S. maltophilia* is becoming an important pathogen of hospital infections in the ICU, which can lead to infections in the lungs, bloodstream and many other important parts of the body, even life-threatening (3, 4).

According to the CHINET bacterial resistance surveillance data in 2020, *S. maltophilia* accounted for 2.98% of all strains and ranked 9th, 7th among Gram-negative bacteria, and 3rd among non-fermentative bacteria, after *Bacillus immobilis* and *Pseudomonas aeruginosa*. *S. maltophilia* has the highest resistance to ceftazidime (38.5%), followed by levofloxacin (10.8%), compound sulfamethoxazole (6.7%) and tigecycline (2.7%), and the lowest resistance to minocycline (2.3%) (5). Clinically, it often causes mixed infections with other bacteria, mainly *Pseudomonas aeruginosa*, *Klebsiella pneumoniae*, and *Acinetobacter baumannii*, so *S. maltophilia* infections are difficult to be treated and the mortality rate is high. Muder et al. (6) reported a mortality rate of 21% in patients with *S. maltophilia* bacteremia. Paez et al. (7) reported a direct mortality rate of 26.7% due to *S. maltophilia* infection and a mortality rate of 21–69% associated with *S. maltophilia* infection.

The study of risk factors for ICU-acquired *S. maltophilia* pneumonia is of great practical significance for the in-depth study of the hazards of this bacterium and the adoption of appropriate preventive and control measures. Currently, Several studies at home and abroad have investigated the risk factors for the occurrence of *S. maltophilia* infection in ICU patients, but there are drawbacks such as small sample size and incomplete risk factor indicators, and the significance of clinical guidance is limited. This study aims to systematically evaluate the risk factors of hospital-acquired *S. maltophilia* pneumonia by Meta-analysis, and provide a theoretical basis for clinical formulation of prevention and control strategies to reduce the morbidity and mortality of *S. maltophilia* infection.

MATERIALS AND METHODS

Literature Search Strategy

PubMed, Web of Science, Cochrane Library, Embase and CNKI were searched from the time of database establishment to August 8, 2021. A combination of subject terms, free words, and Boolean logical operators was used for the search terms: *Stenotrophomonas maltophilia*, hospital-acquired pneumonia, ventilator-associated pneumonia, intensive care, risk factors, etc. The English databases were searched for the following terms: (*Stenotrophomonas maltophilia* OR *S. maltophilia* OR SMA) AND (nosocomial infection OR hospital infection OR hospital acquired infection OR cross infection OR VAP OR ventilator associated pneumonia OR ventilator-associated pneumonia) AND (ICU OR Intensive Care OR NICU OR PICU OR CCU) AND (risk factor OR factor). A manual search of relevant content reviews and references of included literature was conducted to identify potential studies that met the inclusion criteria.

Literature Inclusion and Exclusion Criteria

The inclusion criteria were as follows: (1) The type of literature was a cohort study or case-control study published nationally and internationally; (2) The study population was divided into two groups based on whether they were infected with *S. maltophilia*, and the diagnosis criteria for *S. maltophilia* pneumonia in this study were described below; (3) Risk factors for *S. maltophilia* pneumonia in ICU patients were present in the literature, such as comorbid underlying diseases, invasive procedures undergone, and use of broad-spectrum antibiotics; (4) Outcome indicators for risk factors for *S. maltophilia* pneumonia in ICU patients could be expressed as odds ratios (OR), and their 95% confidence intervals (CI) were calculated. Studies were excluded when meeting one of the following criteria: (1) duplicate reports, conference reports, and reviews; (2) abnormal or missing data; (3) low quality of literature [Newcastle-Ottawa Scale (NOS) score≤3].

In this study, infection and colonization were considered ICU-acquired if they were diagnosed more than 48 h after ICU admission. Pneumonia was defined as follows: (1) new or progressive pulmonary infiltrates. (2) Temperature > 38°C or <36.5°C, leukocyte count >12,000 μl^{-1} or <4000 μl^{-1}, purulent endotracheal aspirate or sputum. (3) Positive respiratory sample. (4) Decreased oxygenation.

Data Extraction and Quality Evaluation

The retrieved literature was screened by two authors independently according to the inclusion and exclusion criteria, and the following data information was extracted: name of the first author, time of publication, source of the literature, basic characteristics of the included cases, and possible risk factors for *S. maltophilia* pneumonia in ICU patients. If the opinions of two reviewing authors do not agree, they discuss. If there was still disagreement after discussion, a third party opinion was sought. The quality of the included literature was also evaluated according to NOS score (8), and the evaluation items include three aspects of population selection, comparability and exposure evaluation, with a score out of 9. A score of 7 and above was considered as high-quality literature, 4–6 as moderate quality literature, and 1–3 as low-quality literature.

Data Analysis

Statistical analysis was performed by stata14.0 software. I^2 was used to determine the heterogeneity of the included literature, and the fixed-effects model was used when $p > 0.1$ and $I^2 < 50\%$; otherwise, the random-effects model was applied. OR and its 95% CI were calculated for count data, while weighted mean difference (WMD) and its 95% CI were calculated for measurement data, and differences were considered statistically significant at $p \leq 0.05$. Sensitivity analysis was performed by calculating the OR and 95% CI for both fixed-effects and random-effects models and comparing the results of the two groups. Sensitivity analysis was performed by changing the data analysis model. If there was no substantial change after the model change (no opposite conclusion was reached after changing the model), the consolidated result was considered to be stable. Begg's test was used to test for publication bias when the number of included papers for individual risk factor analysis was ≥3.

RESULTS

Literature Search

Firstly, 1,156 papers were initially searched in the database through the search strategy, and then 43 papers were selected through title, abstract and keywords, etc. Finally, eight papers

A53210128

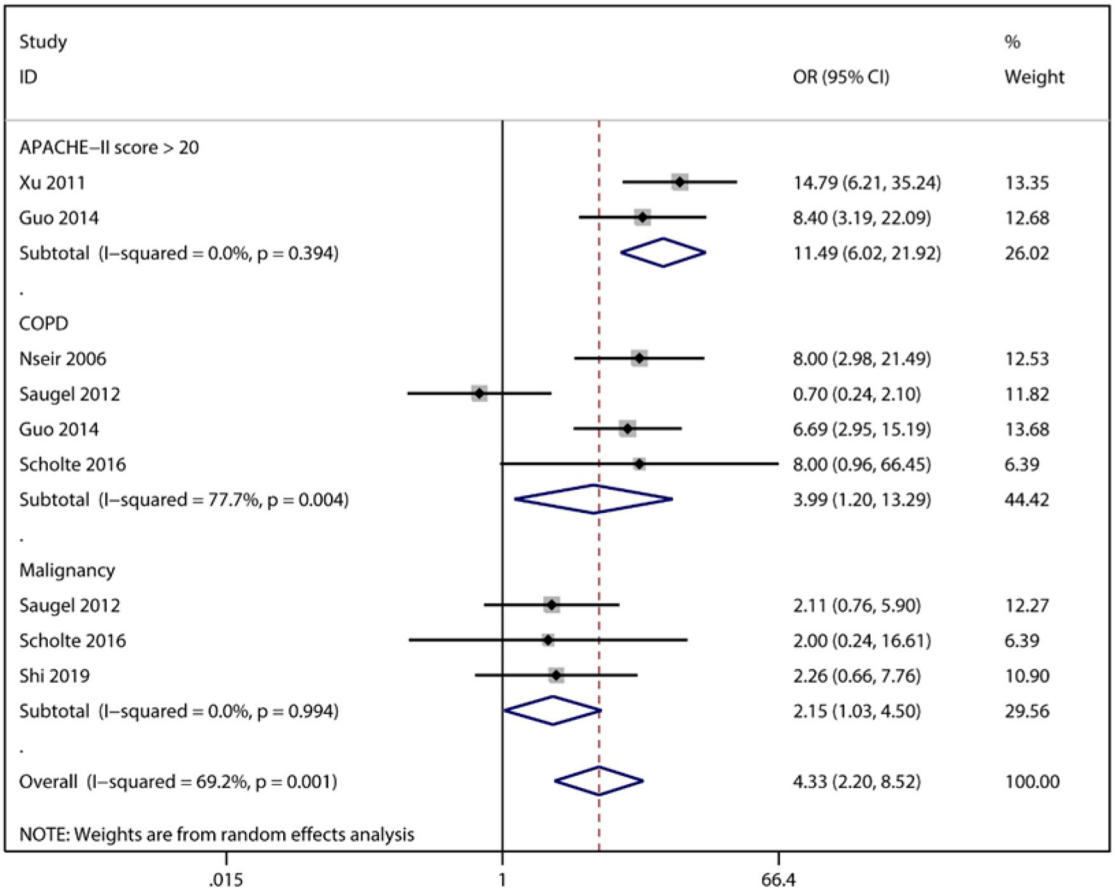

FIGURE 2 | Meta-analysis results of impact of general condition and combined underlying diseases on risk factors for acquired *Stenotrophomonas maltophilia* in intensive care unit.

(9–16) were further screened by reading the full text, including five papers in English and three papers in Chinese (**Figure 1**).

Baseline Characteristics of the Studies

The eight included papers included in the study were published between 2002 and 2020, seven of which were case-control studies and one was a cohort study involving 2320 patients, 306 in the *S. maltophilia*-infected group and 2014 in the non-infected group, and 25 exposure factors for *S. maltophilia* infection were extracted. The quality of the eight papers was evaluated using the NOS scale, including five high-quality papers and tree moderate-quality papers. The basic characteristics of the included literature are shown in **Tables 1**, **2**.

Meta-Analysis of Exposure Factors for *S. maltophilia* Pneumonia

Heterogeneity was tested for exposure factors such as age, gender, APACHE-II score, length of ICU stay, Glasgow score, glucocorticoid use, diabetes, malignancy, cardiovascular disease, renal insufficiency, immunodeficiency disorders, tracheal intubation, indwelling catheters, surgery, and use of carbapenems, quinolones, and aminoglycosides. Heterogeneity was acceptable ($p > 0.10$, $I^2 < 50\%$), and effect sizes were combined using a fixed-effects model. heterogeneity was present for APACHE-II scores >20, COPD, tracheotomy, mechanical ventilation, indwelling nasogastric tube, central venous line, use of β-lactamase inhibitors and nitroimidazole antibiotics ($p < 0.10$, $I^2 > 50\%$), random-effects model combinations of effect sizes were performed.

The meta-analysis showed that risk factors for *S. maltophilia* pneumonia in the ICU included APACHE-II score > 20 (OR = 10.98, 95% CI: 5.67 ~ 21.26), COPD (OR = 3.97, 95% CI: 2.39 ~ 6.61), malignant tumor (OR = 2.15, 95% CI: 1.03 ~ 4.50), mechanical ventilation (OR = 8.75, 95% CI: 2.59 ~ 29.58), tracheotomy (OR = 6.12, 95% CI: 2.06 ~ 18.18), endotracheal intubation (OR = 4.25, 95% CI: 2.30 ~ 7.84), β- Lactamase inhibitors (OR = 9.98, 95% CI: 1.51 ~ 65.96), aminoglycosides (OR = 4.01, 95% CI: 2.06 ~ 7.80), carbapenems (OR = 2.82, 95% CI: 1.49 ~ 5.31), and quinolones (OR = 2.17, 95% CI: 1.21 ~ 3.89). There was no obvious correlation between risk factors and *S. maltophilia* pneumonia, such as age, gender, APACHE-II score, length of stay in ICU, combined diabetes, combined cardiovascular disease, combined renal insufficiency, combined immunodeficiency disease, indwelling

A53210128

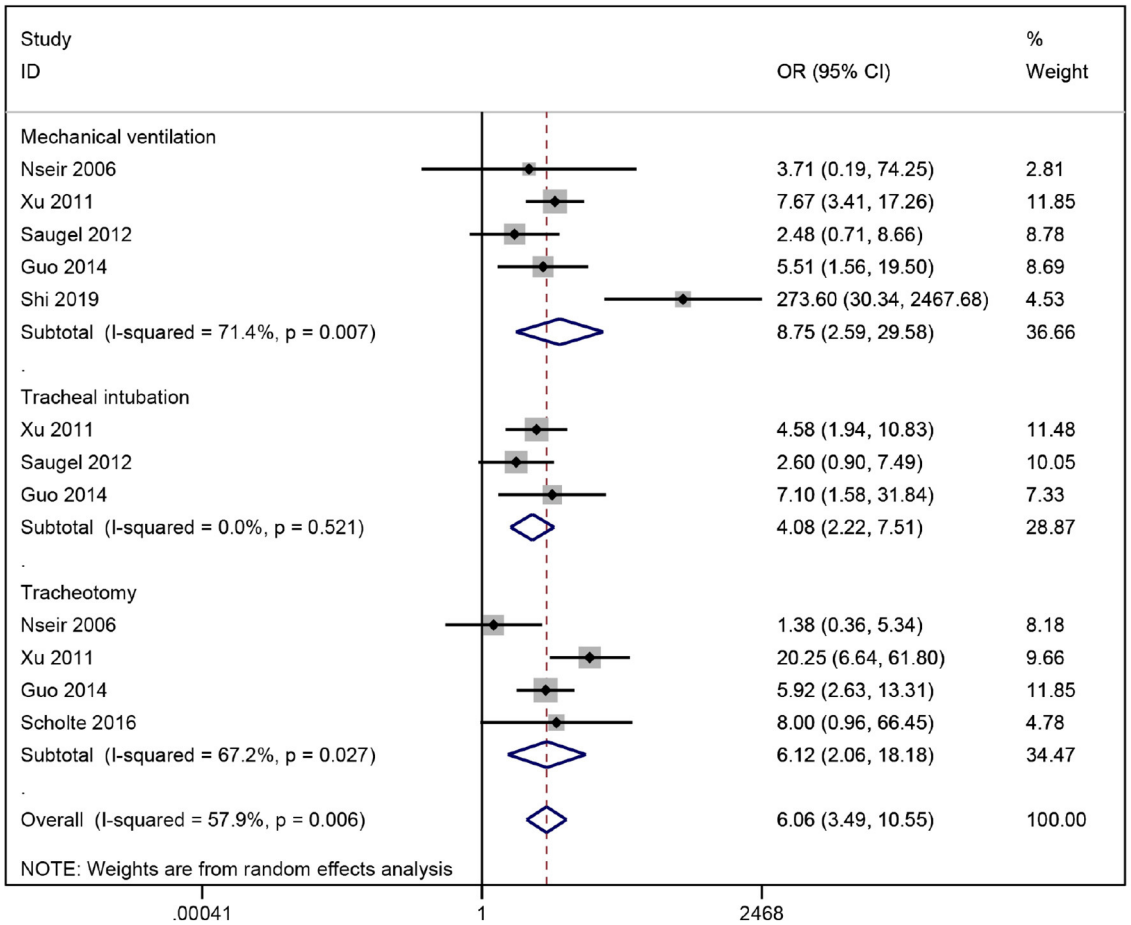

FIGURE 3 | Meta-analysis results of impact of invasive operations on risk factors for acquired *Stenotrophomonas maltophilia* in intensive care unit.

catheter, operation, central venous line, indwelling nasogastric tube, corticosteroids, and nitroimidazole antibiotics.

Sensitivity Analysis and Publication Bias

Sensitivity analysis suggested that the results of the meta-analysis were stable for all outcome indicators except for two exposure factors, central venous placement and indwelling nasal cannula (**Table 3**). Begg's test was used to test for publication bias when the number of included papers for individual risk factor analysis was $\geq$3. The results showed $p > 0.05$, indicating that the publication bias of included papers was not significant.

DISCUSSION

Stenotrophomonas maltophilia is widely distributed in natural environments, such as soil, water, and hospital environments, and can also parasitize the human skin, respiratory and digestive tracts. It is a very common conditional pathogen. The results of studies over the past few years have shown that the detection rate of *S. maltophilia pneumonia* is increasing year by year and has become an important pathogen of ICU infections. ICU-acquired infections associated with *S. maltophilia* are an independent risk factor for mortality in the ICU, and therefore knowledge of the risk factors for *S. maltophilia* pneumonia in the ICU and early targeted empirical treatment are key to reducing mortality from *S. maltophilia* pneumonia. In this study, we conducted a meta-analysis to screen the risk factors for *S. maltophilia* pneumonia in the ICU regarding general condition, co-morbid underlying diseases, invasive procedures, and use of antibiotics.

Correlation of the Patient's General Condition, Co-morbid Underlying Diseases and ICU-Acquired *S. maltophilia* Pneumonia

S. maltophilia pneumonia was associated with the patients' underlying disease status, and among the various underlying diseases, patients with COPD had the highest risk of infection (OR = 3.99), followed by malignant tumor (OR = 2.15). In contrast, underlying diseases such as immunodeficiency disorders, diabetes mellitus, and renal insufficiency were not associated with *S. maltophilia* pneumonia in ICU patients

A53210128

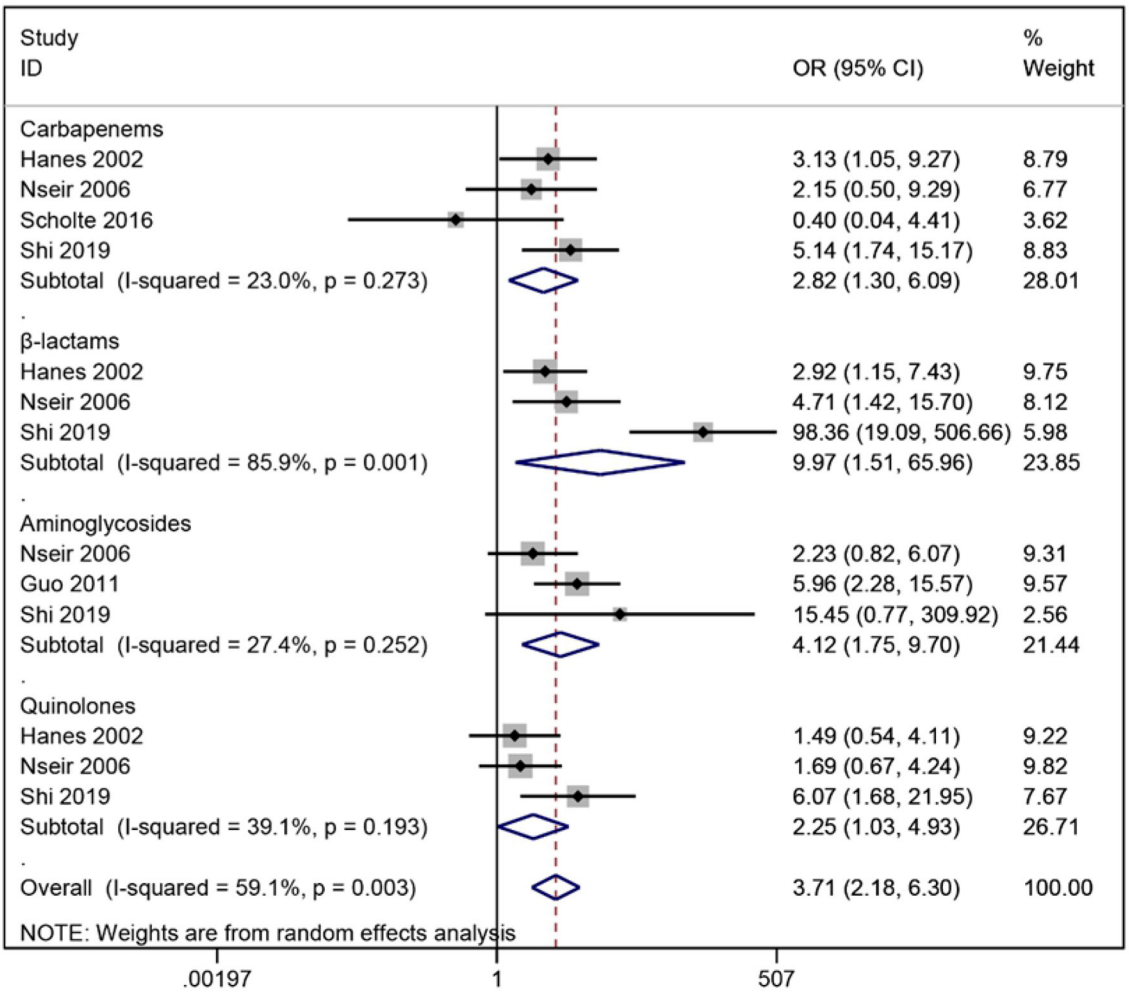

FIGURE 4 | Meta-analysis results of antimicrobial drug impact of on risk factors for acquired *Stenotrophomonas maltophilia* in intensive care unit.

(**Figure 2**). Severity of illness is also an important factor in *S. maltophilia* pneumonia, and APACHE-II score is one of the most widely used tools for critical illness assessment (17). Furthermore, by combining the APACHE-II score of the experimental and control groups, we did not find a statistical difference between the two groups, unlike that reported by a few individual studies (9, 15). However, further analysis informed that there was a hierarchical effect between APACHE-II scores and *S. maltophilia* pneumonia, suggesting that *S. maltophilia* pneumonia is closely related to the severity of the disease. In recent years, the trend of glucocorticoid abuse in clinical practice has become more serious, and related studies have reported that long-term high-dose glucocorticoid use is a high-risk factor for multi-drug-resistant bacteria and fungal infections (18–20). However, we did not find that glucocorticoids increased the incidence of *S. maltophilia* pneumonia in the ICU, there may be bias due to different doses of glucocorticoids, course of treatment and patients' treatment response.

Invasive Procedures and ICU-Acquired *S. maltophilia* Pneumonia

Our meta-analysis indicated that among the risk factors involved in invasive maneuvers, mechanical ventilation was strongly associated with ICU-acquired *S. maltophilia* pneumonia (OR = 8.75), followed by tracheotomy (OR = 6.10) and tracheal intubation (OR = 4.25), demonstrating that invasive procedures such as mechanical ventilation, tracheal intubation and tracheotomy are high risk factors for *S. maltophilia* pneumonia in the ICU (**Figure 3**). Invasive procedures can breach the body's basic defense barriers. *S. maltophilia* colonized in the oral pharynx tends to form bacterial biofilms in the lining of indwelling catheters and tends to enrich at oxygen storage sites, increasing the risk of pulmonary *S. maltophilia* infection (21). In addition, the longer the duration of invasive procedures such as mechanical ventilation, the greater the risk of *S. maltophilia* infection. Guo et al. (12) have reported that the duration of invasive ventilator ventilation (>14 d) is an independent risk factor for ICU-acquired *S. maltophilia*

A53210128

infection. Therefore, clinical practitioners need to strictly follow the indications for invasive procedures and reduce unnecessary invasive operations, while tracheal intubation should be removed as early as possible when conditions allow to help reduce the risk of *S. maltophilia* infection. In our study, the combination of two exposure factors, central venous cannulation and indwelling nasal cannula, was more heterogeneous and less robust than other invasive procedures, and the combined results should be viewed with caution.

The Association Between Antimicrobial Drug Use and ICU-Acquired Pneumonia With *S. maltophilia*

At present, for the treatment of antibiotic-resistant *S. maltophilia* infection, Chinese experts recommended three combined treatment modes, which are based on compound sulfamethoxazole, combined with ticarcillin clavulanate potassium, cefoperazone sulbactam, fluoroquinolone, minocycline, ceftazidime or polymyxin. Or ceftazidime-based fluoroquinolones, ticarcillin clavulanate potassium or cefoperazone sulbactam regimen; Alternatively, a polymyxin-based regimen combined with ticarcillin clavulanate potassium can be adopted (22). However, the use of antibiotics is a double-edged sword. *S. maltophilia* is naturally resistant to carbapenems, while its AAC(6')-lz acetyltransferase and pumping system make it highly resistant to aminoglycosides, and these characteristics could explain the use of both drugs to passively screen the bacterium for hospital-acquired infections due to the proliferation of dominant bacteria (23). Nseir et al. (10) found that broad-spectrum antibiotics such as fluoroquinolones and cephalosporins can also increase the rate of *S. maltophilia* pneumonia and concluded that broad-spectrum antibiotic use is more significant than carbapenems alone. This study showed that the use of β-lactamase inhibitors had the largest combined OR associated with *S. maltophilia* pneumonia (OR = 7.88), followed by aminoglycosides (OR = 4.01) and carbapenems (OR = 2.82), suggesting that the possibility of *S. maltophilia* pneumonia should be considered when clinical treatment with these three drugs is not effective (**Figure 4**). The long-term heavy use of broad-spectrum antibiotics is an important medical factor for hospital-acquired infections of *S. maltophilia.* Broad-spectrum antibiotics increase the risk of infection by killing other pathogens while screening out dominant species, including *S. maltophilia*. A study by Xu et al. (11) concluded that the use of ≥3 antibiotics for more than 1 week was an independent risk factor for *S. maltophilia* pneumonia in ICU patients, and therefore care should be taken to monitor the risk of infection in ICU patients using multiple antimicrobials simultaneously.

Limitation of this Study

There are a few limitations in this study: (1) Due to the limited number of domestic and international studies on risk factors for *S. maltophilia* pneumonia in ICU and the uneven quality of the literature. Eight papers were screened strictly according to the inclusion and exclusion criteria, including five in English and three in Chinese, which may have a certain degree of publication bias. (2) Due to limited literature, some risk factor indicators in this study were not combined effectively, which may affect the study results. (3) At present, the research on related risk factors in China is not deep enough, and there is a lack of relevant prospective cohort studies. Therefore, more rigorous design, large samples, and multicenter studies are needed to clarify the risk factors for *S. maltophilia* pneumonia in the ICU.

CONCLUSION

In recent years, the disease burden of hospital-acquired *S. maltophilia* pneumonia in ICU patients has been high, and resistance to the organism is increasing. *S. maltophilia* pneumonia occurs in patients with severe disease, comorbid COPD, malignancy, high APACHE-II scores, undergoing invasive procedures, and in ICU patients on broad-spectrum antibiotics due to a combination of host and medical factors. From the host side, these patients are characterized by impaired immune function, severe disease, and the need for prolonged hospitalization, which objectively contributes to the infection of conditional pathogens such as *S. maltophilia* (24). Therefore, strengthening the monitoring, prevention, and control of patients with risk factors of *S. maltophilia* infection is beneficial to reduce the risk of infection and death in ICU patients.

Abstract: The aim of this review is to synthesise the key aspects of the epidemiology, current microbiological diagnostic challenges, antibiotic resistance rates, optimal antimicrobial management, and most effective prevention strategies for *Stenotrophomonas maltophilia* (SM) in the intensive care unit (ICU) population. In recent years, resistance surveillance data indicate that SM accounts for less than 3% of all healthcare-associated infection strains, a percentage that doubles in the case of ventilator-associated pneumonia (VAP). Interestingly, SM ranks as the third most isolated non-glucose fermenter Gram-negative bacilli (NFGNB). Although this NFGNB genus has usually been considered a bystander and colonising strain, recently published data warn about its potential role as a causative pathogen of severe infections, particularly pneumonia and bloodstream infections (BSI), not only for the classical immunocompromised susceptible host patients but also for critically ill ones even without overt immunosuppression. Indeed, it has been associated with crude 28-day mortality as high as 54.8%, despite initial response following targeted therapy. Additionally, alongside its intrinsic resistance to a wide range of common antimicrobials, various worldwide and local surveillance studies raise concerns about an increase in ICU settings regarding resistance to first-line drugs such as cotrimoxazole or tigecycline. This scenario alerts ICU physicians to the need to reconsider the best stewardship approach when SM is isolated in obtained samples from critically ill patients. Despite the coverage of this multidrug-resistant bacterium (MDRB) provided by some traditional and a non-negligible number of current pipeline antimicrobials, an ecological and cost-effective strategy is needed in the present era.

1. Introduction

The genus *Stenotrophomonas* comprises at least eight species, of which *Stenotrophomonas maltophilia* (SM) is the most predominant and the only one known to cause human disease [1]. SM is an environmental non-glucose fermenter Gram-negative bacillus (NFGNB) isolated from aqueous-associated sources both inside and outside the hospital setting [2]. It is ubiquitous and often encountered as a coloniser of plants and medical devices owing to its site adhesion and biofilm formation abilities [3]. Not typically found in the common gut flora, it can colonise the oral cavity and the respiratory tract epithelial cells of cystic fibrosis (CF) and hospitalised patients, causing chronic infection of the airways in this population that contributes to inflammation, lung damage, and premature mortality.

Interestingly, although understudied, SM ranks as the third most isolated unusual NFGNB (after *Pseudomonas aeruginosa* and *Acinetobacter baumannii*) in various reports [4,5].

Most SM isolates are hospital-acquired, with a median delay of 8–14 days of hospital stay, but community-acquired isolates have also been described [4,6].

To date, distinguishing between SM colonisation and true infection represents a significant challenge, especially when more than one pathogen is isolated. This yet unresolved issue needs to be elucidated because although other host and severity clinical factors enable physicians to tailor management decision-making, finding a balance between antimicrobial overuse and the risk of worse prognosis due to absent or delayed treatment remains complicated [7]. SM infection rates have been confirmed to range from 13 to 60% according to definitions for surveillance of healthcare-associated infection established by the National Healthcare Safety Network managed by the Centers for Disease Control and Prevention (CDC/NHSN) [8,9]. Moreover, in a prospective multicentre cohort (33% ICU patients), Fihman V et al. observed that SM caused infection more often than colonisation [RR 1.74 (95% CI 1.15–2.63), p = 0.01] [4]. In a previous review of 13 cohort studies, a considerable mortality rate (up to 37.5%) was attributed to SM infection. These authors warned clinicians against underestimating its clinical significance, even redefining the term "SM colonisation" [10].

As an unusual NFGNB, SM has often been considered less pathogenic than many other nosocomial organisms. However, this is without considering immunocompromised patients or those with chronic respiratory diseases such as CF, who represent a debilitated population at high risk of suffering from severe and mainly nosocomial infections from this opportunistic pathogen [4,11].

Furthermore, SM infections are notable in the ICU population. All patients admitted to ICU are at high risk of infection by MDRB, even without a known immunosuppressed status, and when infected, need timely appropriate treatment due to an increased risk for mortality. In an earlier, classic study in 1995, Laing FPY et al. found that ICU patients were more frequently infected than those in non-ICU settings [12]. Although ICU-acquired colonisation and/or infection related to SM was considered uncommon among immunocompetent ICU patients (two patients per 1000 ICU days) [6], it was nonetheless recognised as a potentially worrisome emerging ICU pathogen; indeed, an ICU-acquired infection related to SM was independently associated with ICU mortality in this study. A recently published study confirms this ominous SM infection prognosis. It has been associated with crude 28-day mortality as high as 54.8% despite initial response after targeted therapy, especially if respiratory-focused [13].

Several studies have investigated the risk factors for SM infection in ICU patients, some of which are related to illness severity and underlying comorbidities such as APACHE-II score > 20, older age, and chronic obstructive pulmonary disease (COPD). Other risk factors that are concerned with invasive procedures at ICU admission include indwelling intravascular catheter devices, mechanical ventilation, tracheotomy, and tracheal intubation. Finally, SM isolation within 30 days, hospitalisation within the last three months, and prolonged antibiotic treatment (specially carbapenems [CP], but also β-lactamase inhibitors, antipseudomonal cephalosporins and aminoglycosides) have been associated with SM infections; COPD and CP use have been demonstrated as independently predictive factors [4,6,7,11,14–16].

Defining the clinical risk factors for SM infection is, therefore, a challenge, but one that would be highly beneficial for adequate antimicrobial treatment in the current MDRB era. Initial CP regimens covering extended-spectrum beta-lactamase-producing *Enterobacteriaceae* (ESBL-PE) bacteria causing community and healthcare infections could lead to inappropriate SM treatment due to its intrinsic CP-resistant profile. Indeed, an association between inappropriate initial antimicrobial treatment and mortality has previously been reported in SM-infected, either critically ill or non-critical cases [4,6,10].

This current situation is a challenge for doctors, who need to raise the index of suspicion. Moreover, knowledge about local epidemiology is essential to become familiar with antibiotic resistance rates and accordingly plan an optimal antimicrobial stewardship strategy. Finally, updated infection control measures such as those included in the Spanish

"Zero Resistance" program [17] should accompany these bundles to improve the prognosis of SM infections in ICU patients.

This review aims to highlight key issues over the last twenty years to help provide clinical guidance for when SM is isolated in critically ill patients.

2. Relevant Sections

2.1. Commensal vs. Pathogenic Status of SM: Relevant Aspects

2.1.1. Why Should We Consider Highlighting the Importance of Colonisation by SM?

While microbial culture isolation of a putative pathogen in the laboratory is often associated with infectious syndromes such as BSIs and other sterile body site infections, the correlation is not well defined for NFGNB when the cultured specimen is from body sites with a high colonisation/contamination potential, especially when more than one pathogen is isolated [7].

In contrast, colonisation by an MDRB has been associated with a significantly higher frequency of subsequent infection with the same MDRB and increased mortality in the ICU population. A meta-analysis including a total of 13 studies (with 15,045 ICU patients) found the risk for subsequent ESBL-PE infection to be almost 50-fold higher in colonised than non-colonised patients. These authors concluded that ESBL-PE colonisation of the digestive tract could be a useful marker to predict ESBL-PE infection [18]. In a single-centre retrospective observational study including 3463 surveillance cultures from 250 haematological patients (11 from ICU), Torres I and colleagues documented MDRB colonisation in 33.7% of admissions, most frequently by NFGNB (55.7%). Colonisation by any MDRB was independently associated with an increased risk of MDRB-BSI (HR, 3.70; 95% CI, 1.38–9.90; $p = 0.009$) [19].

SM is rarely present in the oropharynx microbiome of healthy patients but can often be recovered from the oropharynx of hospitalised and CF patients. In the specific case of SM, infection was predicted (96% sensitivity and 93% specificity) by a relative abundance of 36% of oral *Stenotrophomonas*, as assessed via 16SrRNA gene quantification in a cohort of 90 acute myeloid leukaemia (AML) patients receiving remission induction chemotherapy [14]. An SM infection incidence of 9% was reported in this immunosuppressed non-ICU population. In a previous similar study, which analysed SM colonisation during allogeneic hematopoietic stem cell transplantation, the authors observed that SM colonised patients had a worse prognosis, with a poorer overall survival from 6 to 60 months due to higher non-relapsed mortality after allo-transplant (6 months: 15% vs. 4.8% and 60 months: 40.1% vs. 16.2%, $p = 0.003$) [20]. SM colonised in the oral pharynx tends to form bacterial biofilms in the lining of indwelling catheters, increasing the risk of pulmonary SM infection. The results obtained from immunosuppressed non-ICU patients are quite different from those described with *Enterobacterales*, non-SM NFGNB, and *Enterococcus* spp., which usually involve the importance of negative predictive value for suspected infection, frequently BSI caused by gastrointestinal translocation due to rectal colonisation [18,19].

Several classic prospective case-control studies in the ICU population contain significant findings and suggestions focused on the patient risk profile and outcomes of SM infection. Regarding the former, four studies stand out. First, research performed by the Grupo Andaluz para el Estudio de Enfermedades Infecciosas (GAEI) in six tertiary hospitals (with one-third of patients in ICU) revealed a pooled incidence of SM colonisation or infection of 5.7 cases per 10,000 admissions. About half were considered infected, with pneumonia as the most frequent type of infection in ICU patients (two-thirds VAP). The results of qualitative and quantitative analysis of variables independently associated with an increased risk of acquiring SM pointed to SM as a potential cause of nosocomial infections in patients who had previously received a prolonged course of a carbapenem, ceftazidime, or quinolone, particularly if they were under mechanical ventilation [9]. Second, a more recently published meta-analysis including 2320 ICU patients, of which 306 (13%) were SM-infected, showed a particular risk profile with highly suspected SM origin in ICU-acquired pneumonia, specifically including the above-mentioned criteria. These authors

drew attention to a subset of critically ill patients with underlying comorbidities (COPD, malignancy, and high APACHE-II score) who had undergone invasive procedures related to artificial airways and were on broad-spectrum antibiotics due to a combination of host and medical factors [15]. Third, during the pandemic period, a systematic Japanese review of COVID-19-associated SM infection (most patients requiring ICU admission) reported these patients as having similar risk factors as in the above-mentioned studies of patients without COVID-19 [21]. Finally, revisiting the risk factors for the second most common SM infection, bacteraemia, a retrospective study comparing 54 SM with 167 *P. aeruginosa* and 69 *Acinetobacter* species bacteraemic patients showed SM isolation within 30 days prior to infection onset as an independent risk factor for SM bacteraemia, with earlier SM isolation in 66.7%. Nearly half of these patients were considered to have secondary bacteraemia. The thirty-day all-cause mortality of 33.3% among the SM group was significantly higher than that of the other NFGNB groups, and catheter-related infections were associated with survival [16].

Likewise, the outcomes of SM infections acquired during ICU stay have prompted clinical physicians to consider antimicrobial treatment. In a prospective observational case-control study among immunocompetent cases with ICU-acquired infection related to SM (2% of overall incidence), 80% of patients had prior colonisation related to this microorganism [6]. The study reported a significantly higher mortality rate in cases with ICU-acquired SM infection than those with ICU-acquired SM colonisation (70% vs. 25%, OR = 2.5 [1.2 to 4.9], $p = 0.029$). Furthermore, ICU-acquired SM infection was independently associated with ICU mortality. Despite evidence suggesting that clinicians should consider the importance of the predictive value of proven colonisation by SM in critically ill patients, there is no evidence supporting the benefit of antimicrobial use; instead, it likely incurs an ecological cost in this scenario. Therefore, close monitoring of these colonised patients should be considered a daily best practice.

2.1.2. Why and When Should We Consider SM as a Real-Life Pathogen in the ICU? The Importance of VAP Cases in the Critically Ill

SM can cause serious infections, including bacteremia, tracheobronchitis, pneumonia, meningitis, endocarditis, endophthalmitis, skin and soft tissue, urinary tract, and oral cavity infections. Although this bacterium is normally nosocomial, community-onset infections have also been reported [3]. Worldwide, the most common clinically observed specimen is blood, with a frequency of 36.84%, followed by the eye and respiratory tract (19.29% and 15.78%, respectively) [11]. In the classic multicentre case-control study from the GAEI group, the authors underline a difference between ICU and cancer patients, with the most frequent infections being respiratory (especially VAP) in the former and primary or catheter-related bacteriemia in the latter [9].

From a global perspective, according to CHINET bacterial resistance surveillance data, in 2020, SM accounted for 2.98% of all strains and ranked third among NFGNB [5]. In the same way, in the recently published European surveillance, SM accounted for 0.8% of all healthcare-associated infections, rising to 1.9% in cases of pneumonia/lower respiratory infections [22]. Likewise, it is noteworthy that SM is usually linked to pulmonary infections in critically ill patients. In fact, in a 2021 CDC/NHSN updated national summary of pathogens distributions, SM appeared among the most frequently possible VAP pathogens not usually reported from other device-associated infections, accounting for 4% in hospital ICUs and ranking ninth for this type of healthcare infection. Similarly, in the Spanish national surveillance programme of ICU-acquired infection (ENVIN-HELICS registry) in 2023, SM represented 2.68% of isolated microorganisms among the main ICU-acquired infections. SM was especially important in the case of VAP (5.88%), ranking fourth after *P. aeruginosa*, *Klebsiella pneumoniae*, and *Staphylococcus aureus* [23].

Besides the above-mentioned risk factors for SM infections in critically ill patients, some evidence points to the length of ICU stay as associated with acquiring SM during hospitalisation, suggesting that empiric treatment should be considered for this microorganism

in this setting. The GAEI group described a median duration of 17 days (range 0–180) before SM isolation [9]. A subsequent study reported a mean time of 14 ± 11 days between ICU admission and the first ICU-acquired SM [6]. The duration of invasive procedures (such as mechanical ventilation >14 days) also seems important, having been identified as an independent risk factor for ICU-acquired SM infection in a neurological ICU [24].

In a recently published retrospective bi-centre study including 103 ICU patients with SM infection, pneumonia (hospital-acquired pneumonia [HAP] and VAP) was the predominant clinical syndrome (72.8%), while 22% of cases were in haemato-oncology patients. In multivariable analysis, only increasing age and haemato-oncologic disease were shown to be independent risk factors for 28-day mortality SM infection, which was as high as 54.8% despite initial clinical and laboratory response after targeted therapy [13].

The possibility of developing fatal haemorrhagic pneumonia caused by SM has also been observed in the population with hematologic malignancies with SM bacteraemia. It is a rare presentation, with only 91 reported cases worldwide from 1990 to 2023, but with a very high associated 30-day mortality of 90.1%, even after prompt antibiotic treatment [25–27]. Due to its severity and rapid progression, after analysing the few survival cases, some authors emphasise the importance of early suspicion and suggest combination therapy, including TMP-SMX, for this clinical picture in this specific population, although no clinical studies are available [25,26]. The exact mechanism by which SM causes haemorrhage is unknown. Windhorst et al. propose pathogenic factors such as StmPr1, a protease with broad specificity secreted by SM, leading to tissue invasion, destruction, and haemorrhage [28]. Moreover, neutropenia (<500/mm^3) and thrombocytopenia (<50,000/mm^3) have been identified as risk factors for haemorrhagic pneumonia, which could partly explain the bleeding progression in patients with haematologic malignancies with SM bacteraemia [25].

2.2. Antibiotic Resistance Traits and Microbiological Diagnostic Challenges: Clinical Impact on the ICU Population

2.2.1. Basis of SM Antibiotic Resistance

Numerous intrinsic and acquired resistance traits make SM-caused infections notoriously difficult to treat. This bacterium is intrinsically resistant to a wide range of antibiotics, including most β-lactams, fluoroquinolones, tetracycline derivatives (except for doxycycline, minocycline, or tigecycline), chloramphenicol, all aminoglycosides (including kanamycin, tobramycin, amikacin, and neomycin) and trimethoprim [29]. SM employs a wide spectrum of antibiotic resistance mechanisms, which include overexpression/mutation of multidrug resistance efflux pumps, reduced membrane permeability, the chromosomally encoded Sm*qnr* gene (that protects both gyrase and topoisomerase IV from quinolones), and the production of beta-lactamase, carbapenemase, and aminoglycoside-modifying enzymes [11,29]. It is noteworthy that the high carbapenem resistance of SM is primarily caused by the expression of two chromosomally encoded extracellular ß-lactamases, bla_{L1} (a class B metallo-β-lactamase which is not inactivated by aztreonam) and bla_{L2} (a class A clavulanic acid susceptible cephalosporinase, which is susceptible to inhibition by serine-β-lactamase inhibitors such as clavulanic acid and avibactam), which would explain the clinical benefit of combined ceftazidime–avibactam if administered in combination with aztreonam [30].

Among its acquired resistance mechanisms, SM can develop cefiderocol resistance through different genetic pathways, such as mutations in the *tonB* gene or in the *smeT* promoter [29]. An increasing presence has also been noted of *sul*1, *sul*2, and *dfrA* genes that have been found both chromosomally and in plasmids, which contribute to SM resistance to trimethoprim-sulfamethoxazole (TMP/SMX). These genes are often associated with Class 1 integrons, which favour their mobility and even carry multiple resistance genes, which are conducive to multi-resistance.

A53210128

2.2.2. Considerations for Empirical Antimicrobial Decision-Making

This nosocomial pathogen shows low susceptibility to many antibiotics commonly used to empirically treat hospital-acquired infections. In contrast, antimicrobials with a priori in vitro susceptibility, such as TMP/SMX, quinolones, and tetracyclines derivatives (minocycline and tigecycline), are not covered in usual clinical practice in the ICU setting. Gram-negative bacteria are the organisms most commonly responsible for serious infections in the ICU; however, dual empirical coverage usually includes *P. aeruginosa* and *Enterobacteriaceae* as the organisms most frequently involved, whereas SM is responsible for only a minority of cases. SM is, therefore, not typically covered and is likely to be subject to initial inappropriate treatment (ITT). Quinolone is sometimes suggested as an option in empiric combination therapy, such as in the PANNUCI algorithm for nosocomial pneumonia management in the ICU, in which cases SM may be covered [31]. However, quinolones are not always recommended for severe nosocomial infections with sepsis and septic shock, especially given that the resistance rate to ciprofloxacin and levofloxacin in *P. aeruginosa* currently exceeds 30% in most Spanish hospitals [32]. In a large retrospective analysis of ICU patients with bacteraemia and severe sepsis/septic shock caused by a Gram-negative organism, IIT was a key determinant of short-term mortality with a three-fold increase, and MDR was strongly associated with IIT [33]. Notably, SM was specifically identified as a predictor of IIT in this study population.

SM has been associated with infections after various prolonged antimicrobial treatments, especially with carbapenems, which probably would be selected for SM because of its intrinsic resistance to most of them [9,11]. As well as its prior use perse, cumulative exposure to meropenem has been associated with increased infection risk (hazard ratio, 1.17; 95% CI, 1.01–1.35; $p = 0.03$) in non-critically ill patients, resulting in a 17% increased risk of SM infection with each additional day of meropenem use [14]. Furthermore, a study by Xu et al. concluded that the use of three antibiotics for more than one week was an independent risk factor for SM pneumonia in ICU patients [34]. It seems that not only the type but also the time of exposure and the number of antimicrobials can impact SM infection development.

Interestingly, SM has been identified as the most frequent carbapenem-resistant (CR) Gram-negative species in hospitalised patients with HAP and VAP [35]. In this retrospective cohort study, which included 8969 patients, a total of 11.8% of isolates were CR, with nearly 60% of this requiring ICU admission. *P. aeruginosa* was the most common Gram-negative pathogen overall (21.1%) but was second to SM (16.8 vs. 38.7%) among CR species. In terms of clinical impact, it is noteworthy that CR was associated with an excess of 3.0 days (95% CI, 1.4–4.6) in overall length of stay and an excess of $8921 (95% CI, 3864–13,977) in hospital costs [35].

SM production of inducible carbapenemase, which hydrolyses and detoxifies antibiotics, is also involved in polymicrobial infections, especially among SM and *P. aeruginosa*, although the pathogenic role of SM is difficult to ascertain in this scenario. There is limited understanding of the way antimicrobial resistance evolves in the presence of non-targeted microbial species and how ecological interactions likely alter the effectiveness of antibiotic treatment. CF represents the paradigm of this co-infection, which affects up to a quarter of patients and is often associated with increased mortality [36]. A 24-day-long in vitro experimental study with two-species model CF communities highlighted some aspects related to bacterial eco-evolutionary dynamics in the absence of and under clinically relevant β-lactam imipenem concentrations. Firstly, they found that a clinical SM strain protected sensitive *P. aeruginosa* from imipenem. Secondly, the presence of SM led to an equal or increased rate of imipenem resistance development via parallel loss of function mutations in the OprD porin gene. Finally, and unexpectedly, they observed that resistant *P. aeruginosa* drove SM into extinction due to increased production of pyocyanin in the presence of imipenem, which was cytotoxic to SM [37]. Interestingly, there is some clinical evidence illustrating the way interactions between members can affect the prognosis of this specific polymicrobial infection. SM and *P. aeruginosa* can produce biofilm in the lungs,

creating a thriving environment for both. In a Chinese retrospective analysis including severe pneumonia patients, a higher mortality rate and longer hospital stay were reported for those co-infected with *P. aeruginosa* and SM compared with those infected with only one or not infected [38].

2.2.3. Related Microbiological Diagnostic Challenges

Caution should be applied when considering in vitro results of SM susceptibility based on antimicrobial susceptibility testing (AST) guidelines (the Clinical and Laboratory Standards Institute [CLSI], the European Committee on Antimicrobial Susceptibility Testing [EUCAST], and Food and Drug Administration [FDA]), which are not standardised. CLSI has established minimum inhibitory concentration (MIC) interpretation criteria for seven antibiotics, including TMP-SMX, ticarcillin–clavulanate, ceftazidime, cefiderocol, levofloxacin, minocycline, and chloramphenicol. In contrast, the EUCAST has defined MIC and disc breakpoints only for TMP-SMX (an antimicrobial with nearly identical breakpoints for EUCAST (>4 mg/L) and CLSI ($\geq$4 mg/L)). The FDA only recognises ceftazidime breakpoints for SM. In real life, only five agents with interpretable antibiotic MIC data are available to clinicians for clinically relevant application in AST (TMP-SMX, ceftazidime, cefiderocol, levofloxacin and minocycline) [29,39]. As a result, differences among SM resistance rates to these antimicrobials become apparent among prevalence studies, and most importantly, the lack of adequate information available may have a considerable impact on patient treatment.

Accordingly, a recent report including 223 studies in which CLSI recommendations were used evaluated the prevalence of antibiotic resistance in clinical isolates of SM worldwide. The authors observed that the most frequent antibiotic resistance worldwide was against levofloxacin (14.4%) among prevalence studies, with an increased resistance especially in China, and against TMP/SMX (36.84%) among case reports/case series studies, with the highest resistance rate reported in Asia [11]. A more recent worldwide meta-analysis showed a low global prevalence of resistance to TMP-SMX (14.7%), suggesting that this antimicrobial remained effective as a first-line treatment for SM. Other findings were a relatively low resistance rate to levofloxacin (16%), a significant increase in resistance to tigecycline, and the lowest resistance rates documented for minocycline (3%) and cefiderocol (4%) [39]. Regarding the ICU population, the above-mentioned ENVIN-HELICS registry showed a trend towards increased SM resistance to TMP/SMX during the last two years (2022–2023) compared with the pre-pandemic period (2018) (6.2% and 13.5% vs. 0%, respectively), similar to tigecycline (60% and 80% vs. 0%), in contrast to levofloxacin that has remained the same or even decreased (13.65 and 13.3% vs. 15.38%, respectively). Moreover, this report showed an SM resistance of 53.8% to ceftazidime/avibactam and 50% to cefiderocol among 13 and 4 out of 113 tested strains, respectively, within 2022 and 2023 in the participating Spanish ICUs [23].

Despite the MDR profile of SM, clinicians should be aware of the epidemiologic and previous colonisation situation in their local institutions to ensure appropriate treatment. Familiarity with microbiological tests, from the simple Gram stain microscopy to new methods for rapid SM identification (such as Matrix-assisted laser desorption ionisation–time of flight [MALDI-TOF] mass spectrometry), as well as a deeper understanding of the value of syndromic panels to detect causative pathogens by molecular methods, are also essential to avoid ITT in the ICU setting (see Table 1). Regarding molecular detection, there are currently few methods that allow the detection of SM directly from biological samples. For the diagnosis of bacterial infections in the lower respiratory tract, the only platform that allows this detection from a direct sample is Unyvero. Furthermore, a recent randomised control trial involving patients with pneumonia in the ICU observed that the growth of 'off-panel' pathogens was unusual and most commonly due to *Citrobacter* species and SM. The lack of detection of these organisms by the pneumonia panel did not adversely affect patients' antimicrobial treatment in this trial [40]. Accordingly, a stewardship strategy for guiding an adjustment of empirical antimicrobial therapy based on

the results of rapid microbiological testing like Biofire® Filmarray® Pneumonia Panel plus (BioFire Diagnostics, LLC, Salt Lake City, UT, USA) seems imperative in the management of critically ill patients [41]. Likewise, next-generation metagenomic sequencing (mNGS) has emerged as a promising tool in the field of medicine. Although it shows promising diagnostic performance for severe pneumonia in critically ill patients, facilitating precise diagnoses and treatments, the clinical value of this technology remains controversial due to challenges such as the lack of common standards and guidelines. Continued research and the development of standardized protocols are necessary to maximise its potential and ensure its clinical applicability [42].

Table 1. New microbiological diagnostic methods for rapid SM identification.

Diagnostic Test	Pathogen/ Resistance	Sample Type	Time Required to Detection (Hours)	Detection Limit	Sensitivity (%)	Specificity (%)	Robustness	Reference
Unyvero A50 System HPN (Curetis, Holzgerlingen, Germany)	21 Gram-negative and Gram-positive bacteria/17 antibiotic-resistant markers	Sputum, bronchoalveolar lavage, tracheal and bronchial secretions	<5 h	NR	84	98	NR	Sun et al., 2021 [43]
Unyvero A50 System BCU (Curetis)	34 Pathogens, 16 antibiotic resistance markers	Positive blood culture	<5 h	NR	96.8	99.8	NR	Burrack-Lange et al., 2018 [44]
Biofire®Filmarray® BCID2 (bioMeriéux, Craponne, France)	33 Gram-negative, Gram-positive bacteria, Candida spp., and 10 antibiotic-resistant markers	Positive blood culture	1 h	NR	>80 for SM	99.8	NR	Peri et al., 2022 [45]
Sepsis Flow Chip (VITRO Master Diagnóstica, Granada, Spain)	17 Gram-negative and Gram-positive bacteria, 1 yeast, and 19 antibiotic-resistant markers	Positive blood culture	3 h	NR	100 for SM	100	NR	Galiana et al., 2017 [46]
hemoFISH (Miacom Diagnostics, Düsseldorf, Germany)	19 Gram-negative and Gram-positive bacteria	Positive blood culture	>5 h	NR	<80–90 for SM	>95	NR	Reitz et al., 2018 [47]
Magicplex Sepsis Real-Time (Seegene, Seoul, Republic of Korea)	73 Gram-positive, 12 Gram-negative, 6 fungal, and 3 antibiotic-resistant markers	Whole blood	3–6 h	NR	65	92	NR	Carrara et al., 2013 [48]
MALDI Biotyper System (Bruker, Billerica, MA, USA)	Bacterial and fungal species or species groups	A single colony from isolate positive culture or positive whole blood cultures	minutes	-	73 for SM	99	NR	Gautam et al., 2017 [49]
LiDia-SEQ NGS (DNA Electronics Ltd., Carlsbad, CA, USA)	Bacterial and fungal pathogens	Whole blood	>4 h	1 CFU/mL	NR	NR	NR	Not found

Note: SM: *Stenothophomonas maltophilia*; NR: not reported; CFU: colony forming unit.

A53210128

2.3. Best Evidence-Based Approach to SM Severe Infections. Antimicrobial Stewardship in the Critically Ill

As mentioned above, SM infection management can be hampered either by high-level intrinsic resistance to many antibiotic classes and the increasing occurrence of acquired resistance to the first-line drug cotrimoxazole (TMP/SMX) [3] or by a lack of coverage by the most used empirical antimicrobial strategies for ICU infections, which in turn can cast a shadow over its prognosis.

Different treatment guidelines for infections caused by multidrug-resistant Gram-negative microorganisms have recently been published, including recommendations on SM treatment in guidelines by the Infectious Diseases Society of America (IDSA) and the Society of Infectious Diseases and Clinical Microbiology (SEIMC) [30,50,51]. Published data on the optimal treatment for SM infections are limited. Despite the lack of randomised controlled trials comparing TMP/SMX with any other available treatment for SM infections, it is still currently considered the drug of choice based on high in vitro susceptibility rates [52].

For severe infection, the Spanish Society recommends considering combination therapy in immunocompromised patients (strength of recommendation B and quality of evidence II), preferably including TMX/SMX [50]. Likewise, IDSA recommendations from 2022 were recently updated in the 2023 guidelines on the treatment of antimicrobial-resistant Gram-negative infections [53]. The authors directly suggested two approaches: (1) combined use of two of the following agents: TMP-SMX, minocycline/tigecycline, cefiderocol, or levofloxacin, at least until clinical improvement is observed, primarily because of limited and conflicting in vitro and clinical data (limited to observational studies) supporting any individual agent and the need to increase the likelihood of appropriate treatment. (2) The combination of ceftazidime–avibactam plus aztreonam in situations of significant clinical instability following clinical failure with or intolerance to other agents.

It is noteworthy that the authors recommend a second approach, including ceftazidime–avibactam and aztreonam, in situations of significant clinical instability. This has been considered a reasonable treatment option for severe infections despite limited available clinical data and few case reports, based on the above-mentioned explanation that this combination can overcome the activity of both β-lactamases intrinsic to SM. The IDSA panel expressly advised avoiding ceftazidime as a treatment option because of the presence of β-lactamase genes intrinsic to SM that are expected to render this antimicrobial inactive. The panel also changed the aztreonam regimen in terms of suggested antibiotics dosing from the previous publication [30,53]. Regarding the ICU population, in an Italian case series of 26 COVID-19 ICU patients with VAP due to difficult-to-treat NFGNB, with SM isolated in six of these patients (mostly as part of polymicrobial infection), ceftazidime–avibactam was employed in different regimen combinations. The authors suggest that SM appears as a true pathogen in this patient population, promoting the development of haemorrhagic pneumonia or bacteraemia. A surprising finding was a 30-day overall mortality of 60.8% vs. 16% in an SM-specific subgroup [54].

The 2023 American guidelines proposed TMX-SMX and minocycline as the preferred components for combination. Minocycline has slightly more favourable in vitro data, availability of CLSI breakpoints, oral formulation, and likely improved tolerability compared with tigecycline. Moreover, minocycline has been associated with lower adverse effects and mortality than TMP/SMX in a retrospective study dealing with severe patients based on the APACHE-II score [55]. However, tigecycline is also a treatment option for SM infections [30], with extensive penetration into lung tissue at high doses, as demonstrated in critically ill patients [56]. In several series, moreover, the reported MICs for eravacycline are two- to four-fold lower than for tigecycline and frequently mirror minocycline for SM.

Fluoroquinolones are commonly used as an alternative for cases with TMP/SMX-resistant SM or with intolerance due to adverse side effects, especially in HIV-infected patients. Several retrospective observational studies comparing monotherapy with fluoroquinolones and TMP/SMX (with a quarter of patients in the ICU at the time of culture) have suggested that levofloxacin had similar efficacy [57] or even lower OR of death and length

of hospital stay than TMP/SMX in patients with lower respiratory tract infections [50,58]. However, because of suboptimal results with fluoroquinolone monotherapy in in vitro studies, known mechanisms of resistance of SM to fluoroquinolones, the emergence of resistance during therapy, and inherent biases in the observational data, the IDSA panel suggests levofloxacin be used only as a component of combination therapy when prescribed for treatment of SM infections [53]. It is noteworthy that treatments (e.g., quinolones) that select mutants leading to multidrug efflux pump overexpression, such as SmeDEF, can reduce SM susceptibility to several antimicrobials simultaneously. This would explain co-resistance to quinolone and cotrimoxazole. However, it does not appear to affect susceptibility to either minocycline or tigecycline, which could thus be candidate antimicrobials in this context [29,52,59]. This could also be the rationale behind the use of antimicrobial combinations in severe infections.

Regarding second-line agents against SM infections, SEIMC experts have recommended their use for their in vitro activity against the isolate (B-II) [50]. In particular, the IDSA proposes cefiderocol because, despite the limited availability of clinical data, in vitro data and animal models are encouraging for its use in treating SM infections, initially in combination with a second active agent [51,53,60]. Clinically, a Spanish retrospective observational study [61] and a French case series [62] assessing the effect of cefiderocol treatment for severe infections due to difficult-to-treat resistant Gram-negative bacilli in critically ill patients reported a 30-day overall mortality rate of nearly 30%. Among the few patients infected with SM (5 and 4, respectively), mortality increased to 80%, although most were immunosuppressed, and related mortality was not specified. Lastly, the ongoing international retrospective medical chart review PROVE study, with a higher sample size regarding SM infections and with more than 70% of patients admitted to ICU, will soon shed further light on the real-life situation.

2.4. Preventive Measures: Theoretical Basis for Clinical Formulation of Prevention and Control Strategies to Reduce the Morbidity and Mortality of SM Infection in the ICU

SM is widely distributed in natural environments, such as soil, water, and hospital environments, and can also parasite the human skin, respiratory and digestive tracts. Since environmental and clinical strains are genetically closely related, soil might be a likely source for community-acquired infections [2]. Moreover, sink drains, faucets, water, and sponges have also been identified as environmental sources of SM in hospitals, reflecting the ability of this pathogen to survive on any humid surfaces and colonise them over the long term by forming biofilm and resisting commonly used biocides [2,29,36,63]. SM possesses multiple virulence factors that allow it to colonise and produce infection, and among the most important of these is the production of pili, flagella, fimbria structures, and adhesins, which contribute to adherence, auto-aggregation, and colonisation of biotic and abiotic surfaces. This scenario allows SM to become a potentially important pathogen in the ICU setting, where healthcare-associated infections are a global challenge.

Guided by whole genome sequencing analysis, there is provided evidence that sink drains serve as antibiotic-resistant organism persistent reservoirs (in particular, SM and *P. aeruginosa* but not *Enterobacterales* species) in ICUs, and moreover that this was associated with human clinical infections, specifically bacteriemia by some *P. aeruginosa* clones [64]. In another previously published study, patients with SM pneumonia were associated with clones originating from sinks and medical devices in a Swedish ICU outbreak [65]. Therefore, disinfection of all possible sources is imperative to avoid healthcare-associated infections with this pathogen [29]. In addition, SM can be transferred via healthcare providers by hand contact. This reinforces the fact that healthcare personnel need to improve infection control practices and keep a close surveillance system [17,66].

Finally, a hospital-acquired BSI has been observed that is seasonal with summer spikes. A national Belgian cohort study on this infection showed associations between ambient climate variables and hospital-acquired BSI incidence rates per microorganism, with Gram-negative but not Gram-positive incidence increasing by 13% for every 5 °C increase in

temperature. Stenotrophomonas, Acinetobacter, and Klebsiella spp. demonstrated the highest correlation with increased temperature, and Stenotrophomonas and Bacteroides spp. had higher relative humidity. These factors also warrant further examination to improve patient safety in our units [67].

3. Discussion and Future Directions

SM has been identified as a novel nosocomial pathogen associated with life-threatening invasive infections and a high mortality rate in some patient populations, especially those who are severely ill or immunocompromised [10,25]. Clinicians should be made aware of the implications of isolating this organism and should interpret their findings considering clinical settings.

The ICU population is especially vulnerable to this pathogen because of patients' conditions and an environment conducive to SM colonisation and subsequent patient transmission. As mentioned above, SM can often be recovered from the oropharynx of hospitalised and CF patients. We could hypothesise that critically ill mechanically ventilated patients can mimic CF status, as in both cases, SM causes chronic infection of the airways, which contributes to inflammation and lung damage. Moreover, prolonged ICU stays are accompanied by numerous antimicrobial rounds: these induce ecological effects on microbiota that condition the emergence and frequently the coexistence of MDRB. CF represents the paradigm of bacterial–bacterial community interactions, including Pseudomonas spp. and SM, whose prevalence can be correlated with or sometimes be independent of the use of antimicrobials such as carbapenems [7]. Moreover, poor clinical outcomes in co-infected cases warrant further research to find better antibiotic treatment strategies and case management to reduce co-infection mortality [38].

SM diagnosis also raises many challenges. It is imperative to establish a reproducible, accurate, sensitive, and predictive standard method to detect clinically important susceptibility profiles in contemporary isolates. Moreover, molecular rapid methods should be included in guidelines, but these should preferentially be universal and available for all centres.

As previously mentioned, the use of carbapenem in daily practice in the ICU represents one of the most important risk factors for SM infections from a different perspective. Classically, Del Toro MD et al. hypothesised that antimicrobials would select for SM because of its intrinsic resistance to most antibiotics, thus making colonisation easier to detect with clinical cultures and favouring the possibility of infection in patients debilitated by invasive procedures [9]. Therefore, implementing an antimicrobial stewardship program (ASP) in the ICU attending to a combination of measures related to antimicrobial selection, PK/PD optimisation, and short time duration, is one of the main keys to optimising and dealing with the healthcare problem of increasing antibiotic resistance [68]. Furthermore, ASPs are widely accepted in the ICU, and it has been demonstrated that antimicrobials can be administered without compromising patient safety [69].

It is noteworthy that although TMP-SMX is the treatment of choice for SM infections, it is not routinely included in empirical treatment regimens due both to its adverse event profile and the relative rarity of SM infections in comparison to other Gram-negative bacilli. Consequently, a risk stratification strategy seems important. The use of clinical scoring tools while awaiting final culture results may help identify patients at increased risk for a particular infection, with the intent of reducing time to appropriate antimicrobial therapy. Accordingly, a risk score has been developed that predicts hematologic malignancy patients at increased risk for SM BSI to guide early TMP-SMX therapy [70]. Twenty percent of the 337 patients included were admitted to the ICU. The StenoSCORE, incorporating five variables (AML, absolute neutrophil counts, mucositis, central venous catheter, and carbapenem receipt for $\geq$3 days), performed moderately well in predicting this infection. Afterward, it was externally validated with a single-centre cohort study with hematologic malignancy, including 36 patients with SM BSI [71]. The authors also evaluated alternative variables that better predicted SM BSI and ICU admission within 12 h of index culture

included in the so-called StenoSCORE2. ROC curve analysis of the StenoSCORE2 performance produced an AUC of 0.84 (95% CI 0.76–0.92), which was higher than the previously published StenoSCORE. A StenoSCORE2 $\geq$ 4 had a sensitivity of 86%, specificity of 76%, and accurately identified 77% of SM BSIs.

Overall, combination therapy with effective antibiotics has been suggested when SM infections are suspected [53]. Unlike the current recommendation of combination therapy for empiric treatment of suspected or proven septic shock in ICU patients and monotherapy for definitive treatment when culture results and susceptibility tests are available, even for NFGNB, combination therapy could be discussed in patients with proven difficult-to-treat pathogens such as SM or carbapenem-resistant *Enterobacteriaceae* during ASP in the ICU, following clinical practice guidelines [68,72].

Opening further lines of research may help control the spread of SM in the ICU setting, with the optimisation of infection control policies deserving special attention [17].

Table 2 shows the most relevant findings and evidence-based key messages regarding severe SM infections in the critically ill population.

Table 2. Most relevant findings and key messages regarding severe SM infections in the critically ill population.

Scenario	Clinical Evidence
Epidemiology	Recent surveillance data indicate that SM accounts for less than 3% of all strains of healthcare-associated infections, a percentage that doubles in the case of VAP [5,22,23]. Crude 28-day mortality is 54.8% [13], increasing to 90% if hemorrhagic pneumonia is present [25], and it is further increased with co-infection by *Pseudomonas aeruginosa* [38]
Risk factors	Importance of stratification strategy: pre-existing medical conditions (COPD, malignancy); length of ICU stay; invasive procedures and antimicrobial agents, especially CP [15]. StenoSCORE2 for SM bacteriemia prediction [71]
Colonisation	Oral SM relative abundance of 36% predicts infection [14]. Previous SM colonisation was found in 80% of patients with pneumonia and 67% of patients with bacteremia caused by SM [6,16]
Antibiotic resistance	SM is intrinsically resistant to a wide range of commonly used antibiotics [29]. The resistance surveillance data reflect an increase, especially for cotrimoxazole and tigecycline [11,23,39]
Diagnostic challenges	There is no consensus among antimicrobial susceptibility testing guidelines [29,39]. An ICU-ASP for guiding an adjustment of empirical antimicrobial therapy based on rapid microbiological testing seems imperative [41,68]
Empirical therapy	SM predicts initially inappropriate antibiotic therapy [33]
Directed therapy	Combination therapy is recommended until clinical improvement [51,53]
Prevention measures	SM establishes ambiental ICU reservoirs and is related to patient infection [64,65]. Optimisation of infection control policies deserves special attention [17]

Note: SM: *Stenothophomonas maltophilia*; VAP: ventilator-associated pneumonia; COPD: chronic obstructive pulmonary disease; ICU: intensive care unit; CP: carbapenems; ASP: antimicrobial stewardship program.

This paper has several limitations inherent to narrative review methodology, such as potential incomplete coverage, lack of quantitative analysis, and positive results bias. Heterogeneity in study designs and the lack of explicit criteria for study selection may

have also introduced some bias. Nevertheless, to our knowledge, no previous study has comprehensively evaluated evidence on Stenotrophomonas maltophilia infections in critical patients. However, data are limited, and relevant clinical questions remain outstanding, such as the microbiological diagnostic challenges, proper antimicrobial stewardship in the critically ill, and concrete preventive measures in these settings.

4. Conclusions

SM infection remains a challenge for critical care physicians. A high index of suspicion and deep knowledge of both the local epidemiological situation and the new rapid diagnostic tools linked to the implementation of an ICU-ASP in daily practice, as well as control measures, would improve the ominous prognosis of this bacterium's presence in the ICU setting.

Clinical presentation and outcomes of bloodstream infection with intrinsically carbapenem-resistant non-fermenting gram-negative organisms: *Stenotrophomonas maltophilia*, *Elizabethkingia* spp. and *Chryseobacterium* spp. in Singapore, from 2012 to 2024

Matthew Chung Yi Koh[1], Jinghao Nicholas Ngiam[1*], Ka Lip Chew[2*], Nares Smitasin[1,3], Lionel Hon-Wai Lum[1,3] and David Michael Allen[1,3,4*]

Abstract

Background Bloodstream infections with the non-fermenting Gram-negative organisms *Stenotrophomonas maltophilia*, *Elizabethkingia* spp. or *Chryseobacterium* spp. are observed in nosocomial settings. Comparative description of their clinical presentation, microbiological characteristics, treatment options and outcomes remain to be investigated.

Methods We performed a retrospective single-centre analysis of bloodstream infections with the abovementioned three organisms from 1 Jan 2012 to 30 Jun 2024.

Results A total of 349 distinct encounters (from 322 unique patients) were identified with bacteraemia. *Stenotrophomonas maltophilia* was the commonest (197/349, 56.4%), followed by *Elizabethkingia* spp. (127/349, 36.4%) and *Chryseobacterium* spp. (25/349, 7.2%). Prior carbapenem exposure was observed in 59.9% of cases. The majority were related to central lines (58.2%). Most cases were nosocomial in onset (82.5%), and a third were from the intensive care unit (32.1%). A significant proportion of our *Stenotrophomonas maltophilia* (32.8%) and *Chryseobacterium* spp. (22.7%) isolates were resistant to levofloxacin, while a majority of the organisms retained

susceptibility to trimethoprim-sulfamethoxazole (TMP-SMX) and minocycline. Dual antibiotics were used in a minority of encounters (23/349, 6.6%). Mortality was high across infections with the three organisms, but highest amongst those with *Stenotrophomonas maltophilia* bacteraemia (41.6%), followed by *Elizabethkingia* spp. (29.9%) and *Chryseobacterium* spp. (20.0%).

Conclusions *Stenotrophomonas*, *Elizabethkingia or Chryseobacterium spp* bacteraemia was associated with significant mortality. Most cases were nosocomial in acquisition, with prior carbapenem exposure or indwelling central catheters. Fluoroquinolone resistance was common for *Stenotrophomonas maltophilia* and *Chryseobacterium* spp., but less prevalent in *Elizabethkingia* spp., while TMP-SMX and minocycline retained susceptibility. Monitoring these trends would be critical in guiding empiric therapy for these organisms.

Keywords Stenotrophomonas maltophilia, Elizabethkingia spp., Chryseobacterium spp., Clinical outcomes, Bacteraemia

Introduction

Three non-fermenting carbapenem resistant Gram-negative organisms – *Stenotrophomonas maltophilia*, *Elizabethkingia* spp. and *Chryseobacterium* spp. may cause invasive bloodstream infections in certain clinical contexts. These three organisms share common risk factors for the development of infection including prior carbapenem exposure, indwelling central catheters, immunocompromised states or critical illness in the intensive care [1–3]. Historically, there are also specific infections that are associated with each of these organisms. For example, *S. maltophilia* typically causes infections of the respiratory tract and bloodstream infections, while *Elizabethkingia* spp. is an important cause of meningitis in the paediatric population, and *Chryseobacterium* spp. is known to cause nosocomial bloodstream infections, often in the context of indwelling devices [4–6]. These organisms are frequently difficult to treat because they are intrinsically resistant to carbapenems and most beta-lactam antibiotics [1, 7]. They thus require therapy with other antimicrobial agents such as fluoroquinolones, trimethoprim-sulfamethoxazole (TMP-SMX) or tetracyclines (minocycline in particular). In fact, due to difficulty in predicting susceptibility patterns in patients with severe *S. maltophilia* infections, guidance from the Infectious Diseases Society of America (IDSA) recommends dual antimicrobial therapy [8]. However, clinical data is scarce. Similarly, invasive *Elizabethkingia* spp. infections may be fulminant, and some experts also recommend combination therapy initially [9]. Invasive infections with *Chryseobacterium* spp. are less frequent, but can also confer significant mortality and morbidity [4].

From a global perspective, infections with these three organisms are on the rise, with evolving trends in antimicrobial susceptibility. Unfortunately, optimal treatment remains ill-defined and clinical outcomes remain poor. In part, clinical outcomes are poor for patients with bacteraemia with these organisms as they present as invasive infections in immunocompromised hosts [10–12]. In patients with haematologic malignancies, *S. maltophilia* often causes a severe haemorrhagic pneumonia [13]. In other hosts, these organisms can cause invasive infection in those critically ill and also present as part of a co-infection with additional virulent pathogens [3, 4, 8, 14]. Therefore, we aimed to describe and examine the comparative characteristics of the background, clinical presentation of bloodstream infections with *S. maltophilia*, *Elizabethkingia* spp. and *Chryseobacterium* spp., in addition to describing trends in antibiotic treatment regimens and clinical outcomes. This would be informative to guide optimal treatment of infections with these organisms and also form the basis for future prospective study.

Methods

We performed a retrospective single-centre cohort study to describe the clinical characteristics, antimicrobial susceptibility patterns and treatment outcomes for bloodstream infections with *S. maltophilia*, *Elizabethkingia* spp. and *Chryseobacterium* spp. This study included distinct patient encounters with positive blood cultures identifying any of the three organisms from 1st January 2012 to 30th June 2024. All patients were adults (age $\geq$ 21 years old) hospitalised in our tertiary specialist institution (National University Hospital, Singapore). The positive blood cultures were identified through the laboratory information system, for which species level identification was performed using Matrix-Assisted Laser Desorption Ionization–Time of Flight Mass Spectrometry (MALDI-TOF MS) (Bruker MALDI Biotyper, Bruker, Massachusetts, US). We excluded positive cultures from other sites (e.g. respiratory samples) and only examined positive blood cultures. We excluded duplicate blood culture isolates from the same patient hospitalisation encounter within the study period. Relapse of bacteraemia or recurrent bloodstream infection was tabulated separately, if it occurred in a different hospitalisation encounter. Susceptibility testing was performed by Etest. The tested antimicrobials varied during the included time period with the most frequently tested antimicrobials being trimethoprim-sulfamethoxazole (TMP-SMX), levofloxacin,

and minocycline. Ceftazidime testing for *S. maltophilia*, and piperacillin-tazobactam testing for *Elizabethkingia spp.* and *Chryseobacterium* spp. was also performed. The laboratory uses the European Committee on Antimicrobial Susceptibility Testing (EUCAST) breakpoints. However, EUCAST breakpoints were only available for *S. maltophilia* testing for TMP-SMX [15]. Non-species PK/PD breakpoints were used for levofloxacin, ceftazidime, and piperacillin-tazobactam interpretation. As there are no EUCAST non-species breakpoints for minocycline and TMP-SMX (other than for *S. maltophilia)*, Clinical and Laboratory Standards Institute (CLSI) breakpoints were used.

Baseline clinical data was tabulated, including the clinical presentation, demographics, past medical history and outcome data. Nosocomial onset of bacteraemia was defined as bacteraemia occurring ≥ 48 hours into the hospitalisation. We defined prior carbapenem exposure as having received a carbapenem within one month prior to the episode of bacteraemia. Microbiological findings included the speciation of each organism, as well as the antibiotic resistance patterns. Laboratory markers were tabulated if obtained from the same blood draw, or the closest results that were obtained within 48 h of the positive blood culture, including the full blood count, kidney function, liver function testing, and C-reactive protein levels. For each episode of bloodstream infection, antibiotic choice and duration was recorded. The initial empiric antibiotic choice was defined as the antibiotic that was chosen in response to the identification of one of these three organisms in blood culture, prior to antibiotic susceptibility testing results. The empiric antibiotic choice was labelled as an "appropriate" choice, if the clinical isolate eventually demonstrated susceptibility to one or more of the chosen agents. Clinical outcomes such as the length of hospital stay, need for intensive care, mechanical ventilation, vasopressor support, recurrence of bacteraemia within a year from the index episode and in-hospital all-cause mortality were also evaluated. We recorded all episodes of bloodstream infection (bacteraemia). If the same individual had two separate hospital encounters with bacteraemia, they were recorded as two distinct episodes. Co-infection with other pathogens were also recorded if they were concomitantly isolated from blood cultures in the same setting as the positive blood culture with *S. maltophilia*, *Elizabethkingia* spp. or *Chryseobacterium* spp. Adequate source control of infection was recorded if patients had undergone a procedure such as central line removal, debridement of infected tissues, or abscess drainage, where appropriate.

We then stratified the patients into three groups (*S. maltophilia*, *Elizabethkingia* spp. and *Chryseobacterium* spp.) and compared them across clinical, demographic, laboratory parameters as well as clinical outcomes. Continuous parameters were examined by one-way analysis of variance and presented as means ± one standard deviation. Categorical variables were presented in frequencies and percentages, and compared by Chi-squared tests. Where statistical significance across the three groups was observed, post-hoc pairwise comparisons between the groups were conducted, with Bonferroni correction. A p-value of < 0.05 was considered significant. All data analyses for this study were carried out on SPSS version 20.0 (SPSS, Inc., Chicago, Illinois). This study had been approved by the National Healthcare Group Domain Specific Review Board (DSRB 2024–3132) prior to its conduct. The study was done in accordance with the principles laid out by the Declaration of Helsinki. All data was anonymised and a waiver of written informed consent had been obtained from the institutional review board prior to the conduct of the study, as this was a retrospective study and did not involve the human participants directly.

Results

A total of 349 distinct patient encounters involving 322 patients with bloodstream infections caused by *S. maltophilia*, *Elizabethkingia* spp., and *Chryseobacterium* spp. were analyzed. The majority of these infections were attributed to *S. maltophilia* (56.4%), followed by *Elizabethkingia* spp. (36.4%), then *Chryseobacterium* spp. (7.2%) (Fig. 1).

Demographics and clinical presentation

Patients with *Elizabethkingia* spp. bacteremia were significantly older. Immunocompromised status was most common in patients with *S. maltophilia* (62.4%) compared with the other two organisms (*Elizabethkingia* spp. (37.8%) or *Chryseobacterium* spp. (48.0%). Additionally, prior carbapenem exposure within the preceding month was reported in 59.9% of cases, with no significant differences observed among the three pathogens. Central lines were present in most patients, particularly those with *S. maltophilia* (89.8%). Total parenteral nutrition was rare (2.9%) and predominantly associated with *S. maltophilia* as well, although this was not statistically significant. Most infections were nosocomial in onset (82.5%), and 32.1% of cases occurred in the intensive care unit (Table 1).

Microbiological characteristics

Co-infections were observed in 25.8% of cases, most commonly with *Chryseobacterium* spp. (44.0%). Enterococci ($n = 14$) and Coagulase negative Staphylococci were the most common co-pathogens ($n = 13$), followed by *Pseudomonas* spp. ($n = 11$), *Candida* spp. ($n = 7$), and *Acinetobacter* spp. ($n = 7$). Catheter-related infections accounted for a majority (58.2%) of cases. Amongst these

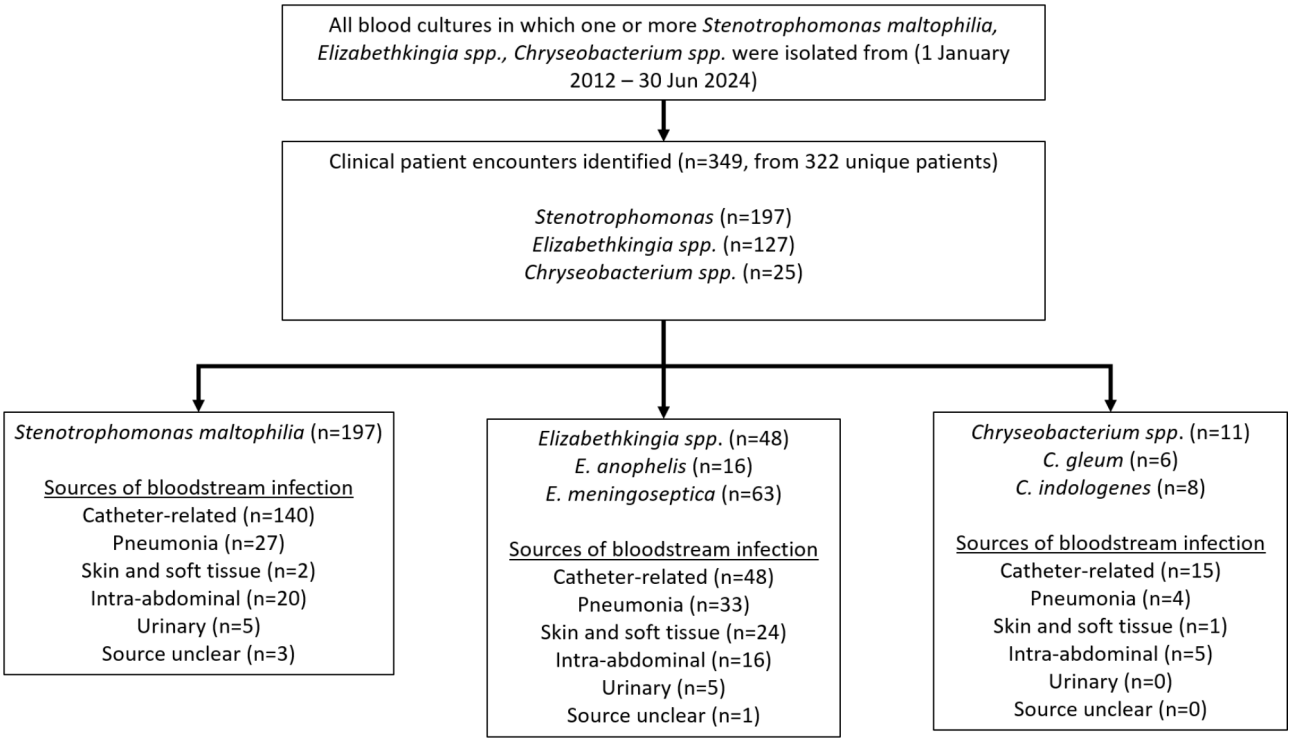

Fig. 1 Flowchart describing patient population by organism and sources of bloodstream infection

three organisms, the organism to present most frequently with skin and soft tissue infection as its source of infection was *Elizabethkingia* spp. A majority of these skin and soft tissue infections were a result of recent peripheral intravenous cannulation and subsequent thrombophlebitis. Intra-abdominal infection had the highest frequency with *Chryseobacterium* spp. (Table 1). Intraabdominal infections tended to occur after surgery or an endoscopic procedure, such as endoscopic retrograde cholangiopancreaticography for biliary obstruction. All episodes of urinary infection were associated with urological procedures or stenting.

Across the three organisms, 23% of isolates were resistant to levofloxacin, and 4.2% were resistant to TMP-SMX. Eight of the 349 isolates (2.3%) were resistant to both TMP-SMX and levofloxacin. Of these, 7 were *S. maltophilia* isolates and the remaining one was a *Chryseobacterium* isolate. Amongst the *S. maltophilia* isolates, resistance to levofloxacin in our institution was high (32.8%), although a majority retained susceptibility to TMP-SMX (93.1%) and minocycline (98.8%). Similarly, amongst the *Chryseobacterium* spp. isolates, 22.7% were resistant to levofloxacin, while a majority remained susceptibile to TMP-SMX (95.7%) and minocycline (100%). For *Elizabethkingia* spp., levofloxacin resistance was observed in 7.9%, while no isolates were resistant to TMP-SMX or minocycline. (Table 2).

Antimicrobial treatment and clinical outcomes

Initial antibiotic regimens commonly included TMP-SMX (37.0%) or levofloxacin (39.0%), with dual therapy used in only 6.6% of cases. Empiric therapy was appropriate in 84.2% of encounters, though 17.5% required regimen changes due to antibiotic intolerance or inappropriate initial choices. Patients received an average of 12 (±7) days of appropriate antibiotics, with no significant differences among the three pathogens (Table 2).

The overall mean length of hospital stay was 48 ± 107 days. Most patient encounters required a procedure for source control (219 out of 349, 62.8%). Of these procedures, 208 patients underwent central line removal, and the remaining 11 patients either had debridement of infected issues, or drainage of intra-abdominal abscesses. In-hospital mortality was high in this cohort at 35.8% (125 out of 349). Mortality was highest amongst patients with *S. maltophilia* bacteraemia (41.6%) versus *Elizabethkingia* spp. (29.9%). and *Chryseobacterium* spp. (20.0%, $p = 0.023$). Recurrence of bacteraemia within 1 year of the index episode was observed in 12 out of 349 patient encounters (3.4%), and a majority of these were in patients with *S. maltophilia* (Table 2).

Discussion

Overall, we described important trends in hospitalised patients presenting with bloodstream infection with *S. maltophilia*, *Elizabethkingia* spp. or *Chryseobacterium*

spp. over the 13 years from 2012 to 2024. Broadly, the risk factors for acquisition of these organisms were similar. A majority (> 80%) were nosocomial in acquisition, and a third were acquired in critically ill patients in the intensive care unit. Furthermore, close to 60% had prior carbapenem exposure before developing bacteraemia with these organisms. Prolonged carbapenem exposure has been associated with invasive infections with these organisms as they are intrinsically resistant to carbapenems. Selection pressure from prolonged carbapenem exposure likely eradicates normal flora and allows for proliferation of these opportunistic non-fermenting intrinsically carbapenem-resistant Gram negative organisms [2–4, 16].

Nevertheless, there were sizeable number of catheter-related bloodstream infections amongst patients with end-stage kidney disease on haemodialysis that presented from the community. Given that they were community acquired infections, a majority of these patients did not have carbapenem exposure prior to infection. Compared with *Staphylococcus aureus* and coagulase negative *Staphylococci*, *S. maltophilia*, *Elizabethkingia* spp. and *Chryseobacterium* spp. are generally thought to be uncommon causes of catheter-related bloodstream

infections patients on dialysis. However, outbreaks in dialysis centres have been reported, which may be related to contaminated water sources [17, 18]. In our cohort these episodes appeared to be sporadic and did not appear to cluster to any specific timeframe. We also did not observe recurrence of bacteraemia in the same patients who would return to visit the same dialysis centre after hospital admission, which may more clearly suggest a contaminated water source.

Solid organ tumours also formed an important risk factor for bloodstream infections with these organisms, accounting for approximately 20% of encounters. These patients often have central lines for delivery of chemotherapy, or biliary obstruction and endoscopic procedures which have been stented. Translocation of bacteraemia from the biliary tree into the bloodstream has been reported after biliary procedures, particularly when the procedure was performed in the context of biliary obstruction [19]. Carbapenem or broad-spectrum antibiotic use peri-procedurally then may have subsequently pre-disposed to bacteraemia with one of these three organisms.

Elizabethkingia spp. bloodstream infections were also observed amongst patients who were immunocompetent and not critically ill. The source of these infections was often pulmonary, in the form of hospital acquired pneumonias, or skin and soft tissue infection, in the context of thrombophlebitis after recent intravenous cannulation [20]. In our adult population, we did not identify meningitis or central nervous system infection, which had been commonly observed in the paediatric setting [5].

Overall, we found these three organisms to be important nosocomial pathogens. The in-hospital mortality in our cohort was high, consistent with data from other observational cohorts [3, 4, 14]. Amongst the three, mortality was highest in *S. maltophilia* bloodstream infections. Optimal treatment approaches for these infections remain unclear. In our centre, for infections with *S. maltophilia*, the first-line empiric antibiotic choice was TMP-SMX, due to the high rates of fluoroquinolone resistance.

S. maltophilia harbour beta lactamases that hydrolyse penicillins, cephalosporins, carbapenems and aztreonam [21–23]. In addition, they also demonstrate intrinsic resistance to aminoglycosides by chromosomal aminoglycoside acetyl transferase enzymes [24]. In addition to the intrinsic antimicrobial resistance, *S. maltophilia* is also known to develop resistance while on therapy, by upregulating efflux pumps [25–27]. Similarly, both *Elizabethkingia* spp. and *Chryseobacterium* spp. in addition to beta-lactamases, can also express efflux pumps which confer resistance to other antibiotics [28, 29]. As such, with the intention to avoid the development of antimicrobial resistance, some experts recommend the use of combination antibiotic therapy [8, 30]. The clinical evidence for this practice remains scarce and controversial. One reasonable approach may have been to stratify patients by disease severity, where it appeared that patients with more severe infection were more likely to demonstrate benefit from the use of combination antimicrobial therapy [31].

In contrast to *S. maltophilia*, clinical outcomes and characteristics are less well studied in *Elizabethkingia* spp. and *Chryseobacterium* spp., probably because they are less frequent causes of invasive infection. Consequently, there are no treatment guidelines for infections with *Elizabethkingia* spp. or *Chryseobacterium* spp. Dual antibiotic therapy is sometimes used for these infections, particularly, when the infection is severe and while susceptibility testing results are pending, to increase the likelihood of at least one appropriate empiric agent. In our retrospective review, dual therapy was rarely used for infections with these three organisms. Therefore, the numbers were too small to conclude or evaluate if outcomes associated with empiric dual therapy were better or worse than with monotherapy.

In addition to antibiotic choice, the optimal duration of antibiotic therapy for bloodstream infections with these organisms also remains to be elucidated. Duration of therapy is likely guided by the patient's clinical syndrome (e.g. pneumonia, skin and soft tissue infection, catheter-related infection, etc.), and clinical progress on antimicrobial therapy. The IDSA guidelines recommend line removal, and 7 to 14 days of antibiotics for catheter-related bloodstream infections with Gram negative organisms [32]. In most of the patients in our cohort, central lines were removed in a timely fashion, which likely provided an adequate degree of source control for the infection. The patients in our cohort received an average of 12 ± 7 days of appropriate antibiotics. With this, we observed that relapse of bacteraemia within a year was low in our cohort (3.4%). Future study is important to define appropriate antibiotic duration for this infection. To examine this, patients may have to be stratified by source of infection. For example, in clinical contexts in which the infection complicated and source control is less adequate (e.g. an infected biliary stent that cannot be removed), a longer duration of antibiotic therapy may be required.

Limitations

Our study reflects a single-centre experience of patients being managed for bloodstream infections with *S. maltophilia*, *Elizabethkingia* spp. or *Chryseobacterium* spp. MALDI-TOF MS could reliably identify *Elizabethkingia* spp. to a genus level, so this group was analyzed as a whole. Species-level identification to further comparing the differences in clinical characteristics and outcomes

among distinct species would require further diagnostic methods (for example, 16s rRNA sequencing) [33]. Source of infections were determined by the primary managing team, as documented in the clinical charts on retrospective review. The clinical and demographic data obtained therefore relied on the quality of documentation in the patients' electronic records. Importantly, this is a cross-sectional study, and we did not prospectively follow-up each of these patients. Furthermore, as this was a retrospective and observational cohort, treatment decisions, such as antibiotic choices and durations were left to the discretion of the managing physicians. As such, we could not systematically study the impact or difference of various treatment options on clinical outcomes as well. Most empiric antibiotics were administered intravenously, but we did not capture the timing of oral switch in therapy. We also only reported the antimicrobial susceptibility testing for the index episode of bacteraemia. There were some subjects with multiple blood cultures that returned positive over time. We did not capture if resistance to antibiotics had developed while on therapy.

Our findings were exploratory and descriptive. As such, we did not build a multivariable model to adjust for confounding variables that may have explained some of the observed trends. For example, although the prevalence of prior carbapenem exposure was common in bacteraemia with these three organisms, we did not have a control group of bacteraemia with other Gram-negative organisms to compare against. Nevertheless, we report real-world observational findings in terms of the clinical presentation and outcomes from these infections.

Furthermore, we also used all-cause in-hospital mortality as an outcome measure. It was not always possible to elucidate if the bacteraemia episode was the main contributor to an individual's mortality. Therefore, an individual's underlying co-morbidities such as underlying metastatic cancer may also have contributed to the adverse outcomes. We did not specifically study the trends in mortality over time. However, our study examined a long period of time (close to 13 years). The changes in critical care practices and other unmeasured factors may also have contributed to differences in clinical outcomes. Furthermore, in some immunocompromised hosts, fluoroquinolone or trimethoprim-sulfamethoxazole prophylaxis may have been used. Understanding the specific antibiotic therapy that the patient had been on prior to the bacteraemia episode may importantly influence the clinical outcomes, as well as the antimicrobial susceptibility profile of infections with these three organisms.

Our study focused only on infections with these three organisms, and we were not able to compare the prevalence of these infections with bloodstream infections with other Gram-negative organisms., although our findings are exploratory, they may form the important basis for randomised controlled trials to evaluate optimal antimicrobial treatment regimens and duration in these infections. Additionally, to understand the evolution and development of antibiotic resistance, future prospective study on the mechanisms of resistance in these organisms are important.

Conclusions

Mortality and morbidity were high in our cohort, particularly in patients with *Stenotrophomonas maltophilia* bloodstream infection. Dual therapy was rarely used as part of the initial treatment regimen, and it remains unclear if this would have an impact on clinical outcomes. Fluoroquinolone resistance was common in *S. maltophilia* and *Chryseobacterium* spp., but was less frequently identified in *Elizabethkingia* spp. isolates. Understanding local trends in resistance patterns may thus help to guide empirical antibiotic choice for infections with these organisms. Monitoring local susceptibility patterns for these three organisms over time would be helpful to guide treatment protocols, and prospective studies evaluating optimal treatment regimens and duration, and evolving resistance mechanisms are warranted.

SUMMARY *Burkholderia cepacia* (formerly *Pseudomonas cepacia*) was once thought to be a single bacterial species but has expanded to the *Burkholderia cepacia* complex (Bcc), comprising 24 closely related opportunistic pathogenic species. These bacteria have a widespread environmental distribution, an extraordinary metabolic versatility, a complex genome with three chromosomes, and a high capacity for rapid mutation and adaptation. Additionally, they present an inherent resistance to antibiotics and antiseptics, as well as the abilities to survive under nutrient-limited conditions and to metabolize the organic matter present in oligotrophic aquatic environments, even using certain antimicrobials as carbon sources. These traits constitute the reason that Bcc bacteria are considered feared contaminants of aqueous pharmaceutical and personal care products and the frequent reason behind nonsterile product recalls. Contamination with Bcc has caused numerous nosocomial outbreaks in health care facilities, presenting a health threat, particularly for patients with cystic fibrosis and chronic granulomatous disease and for immunocompromised individuals. This review addresses the role of Bcc bacteria as a potential public health problem, the mechanisms behind their success as contaminants of pharma-

ceutical products, particularly in the presence of biocides, the difficulties encountered in their detection, and the preventive measures applied during manufacturing processes to control contamination with these objectionable microorganisms. A summary of Bcc-related outbreaks in different clinical settings, due to contamination of diverse types of pharmaceutical products, is provided.

KEYWORDS *Burkholderia cepacia* complex, pharmaceutical contamination

INTRODUCTION

The *Burkholderia cepacia* complex (Bcc) is a group of Gram-negative nonfermenting betaproteobacteria (1) that are broadly distributed in the environment, colonizing diverse niches, whether natural or human-made (2–6). This feature is attributed to their genotypic and phenotypic plasticity and consequent capacity for rapid mutation and adaptation to challenging environments (1, 7, 8). This group of bacteria has emerged as a worrying opportunistic pathogen, with high potential to cause serious respiratory infections in patients with underlying illnesses, namely, cystic fibrosis (CF) (9–11) and chronic granulomatous disease (CGD) (12, 13). Bcc infection also has been reported in immunocompromised patients (debilitated elderly people, HIV-positive individuals, cancer patients undergoing chemotherapy, etc.) (14–16). Bcc bacteria can adapt to the stressful conditions that characterize the CF lung environment, which makes them virtually impossible to eradicate, leading to unpredictable and variable outcomes, ranging from asymptomatic carriage to a quick and sometimes unexpected deterioration of the patient's condition, culminating in a fatal necrotizing pneumonia (termed "cepacia syndrome") (3, 17).

Remarkably, Bcc bacteria also possess the capacity to survive and proliferate in water-based environments, such as water bodies, lakes, rivers, drinking water, and liquids containing small amounts of nutrients (18–21). In addition to this capacity, these bacteria are described as major contaminants of sterile (e.g., intravenous drugs and solutions) and nonsterile pharmaceuticals (e.g., nasal sprays, water-based products, mouthwash, preoperative skin solutions, and hand sanitizers), being the cause of numerous nosocomial outbreaks registered in the last 2 decades (22–26). Many of these contamination episodes have been associated with the ability of Bcc bacteria to thrive in the presence of antimicrobials and disinfectants, particularly the biocides used in pharmaceutical products' formulations (24, 27–31). Benzalkonium chloride (BZK) solutions have been described as one of the most frequent sources of Bcc contamination (32). Bcc bacteria have developed an array of strategies to cope with the presence of biocides, including their active extrusion from the bacterial cell through the action of efflux pumps or the inactivation by catabolic enzymes and subsequent use as carbon sources for bacterial growth (33–36).

Since Bcc bacteria can survive under nutrient-deprived conditions, water constitutes the most common environment in which they can cause contamination, raising a particular concern when the water supplies of pharmaceutical companies are affected (37, 38). The clinical relevance of Bcc bacteria and their status as one of the most prevalent contaminants in pharmaceutical industries has led authorities, namely, the United States Food and Drug Administration (FDA), to propose the inclusion of these bacteria in the "Objectionable Microorganisms" category (39, 40). In addition to the fact that Bcc bacteria are inherently difficult to detect and identify, due to their specific metabolic requirements and low growth rate, the majority of phenotypic and genotypic methods also demonstrate significant limitations in their capacity to detect Bcc organisms. Therefore, it is important to understand and control the presence of Bcc in pharmaceutical settings, including raw materials and finished products, to avoid their propagation into health care settings, which greatly compromises the treatment options and general quality of life of susceptible patients. Figure 1 provides an overview of the main topics that will be addressed in this review, with special focus on pharmaceutical products' contamination and the associated implications in terms of public health.

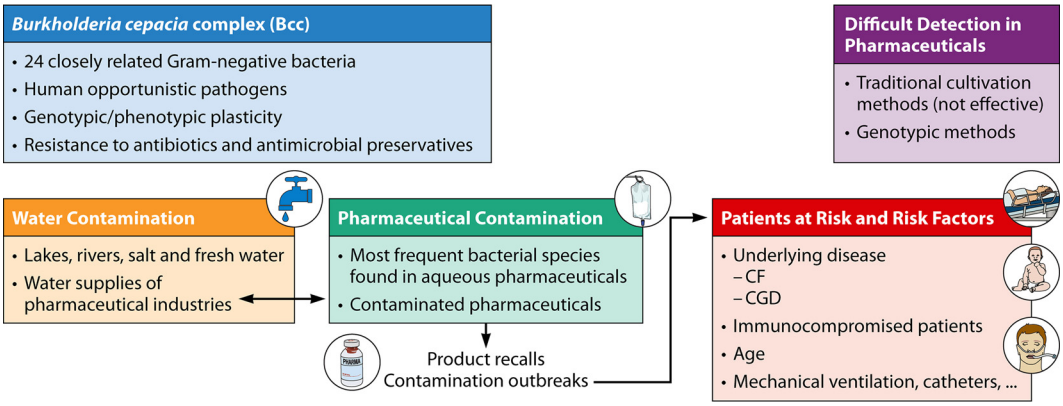

FIG 1 Overview of the main topics addressed in this review, from the description and characterization of *Burkholderia cepacia* complex (Bcc) bacteria and their survival and proliferation in diverse environments, including water supplies and pharmaceutical products, to the related nosocomial outbreaks, especially involving susceptible patients, as well as the difficulty and complexity associated with Bcc detection and identification based on phenotypic and genotypic methods.

Bcc—DIVERSITY AND ECOLOGY

The *Burkholderia cepacia* complex (Bcc) is a group of 24 phylogenetically related Gram-negative betaproteobacteria that are widely distributed in the environment (41–45). They carry complex genomes (with sizes ranging from 6 to 9 Mb and typically 3 chromosomes) and have the ability to rapidly adapt through mutation, which translates into a remarkable genotypic and phenotypic plasticity (1, 3, 7). Consequently, Bcc bacteria are known for their metabolic diversity and capacity to endure environmental stresses (33, 46).

Bcc bacteria are frequently found in natural environments, occupying diverse niches, such as soil, water (including seawater), plant rhizosphere, and agricultural products (2–6). However, the distribution of Bcc species is not homogeneous among these habitats. For instance, *B. cepacia*, *B. cenocepacia*, *B. vietnamiensis*, and *B. ambifaria* are the most representative Bcc species inhabiting the rhizosphere of plants (3–6, 8), while *B. cepacia*, *B. cenocepacia*, *B. vietnamiensis*, *B. anthina*, and *B. seminalis* are commonly found in water-based environments worldwide (6, 19–21). Nevertheless, the precise environmental origin of some Bcc species, namely, *B. multivorans*, is currently unclear, and the reports concerning its presence in different environmental samples are rather contradictory; some describe water as the most common source of this bacterium (19, 21), while others indicate that soil is the most common environmental niche (47). These discrepancies might be due to the limitations associated with the isolation methods (48).

Due to their metabolic diversity and ability to establish mutualistic and symbiotic interactions with plants, the use of *Burkholderia* species for biological control, plant growth promotion, and bioremediation has been attempted, but their pathogenic potential raises concerns (5). Since Bcc species are phylogenetically related, the exchange of genetic material between different strains/species might occur, creating the possibility for apparently innocuous strains to acquire pathogenic characteristics (6). This hypothesis has not yet been described in natural settings but has been demonstrated *in vitro* (6). Field tests have shown that Bcc bacteria can proliferate within the rhizosphere of various economically relevant crops, including rice (where *B. vietnamiensis* has been found in high numbers), pea roots (colonized by *B. ambifaria*), and wheat (with *B. cepacia* and *B. cenocepacia* inhabiting its rhizosphere) (4). Some of these species are also capable of N_2 fixation, thereby contributing to plant growth (8). Another important capacity is the production of biopesticides that protect crops against other bacteria, protozoa, nematodes, and fungal diseases, such as root rot or seed-damaging infections (2, 5). Due to their ability to use complex and diverse carbon sources, some *Burkholderia* isolates potentially can degrade different xenobiotic com-

A53210128

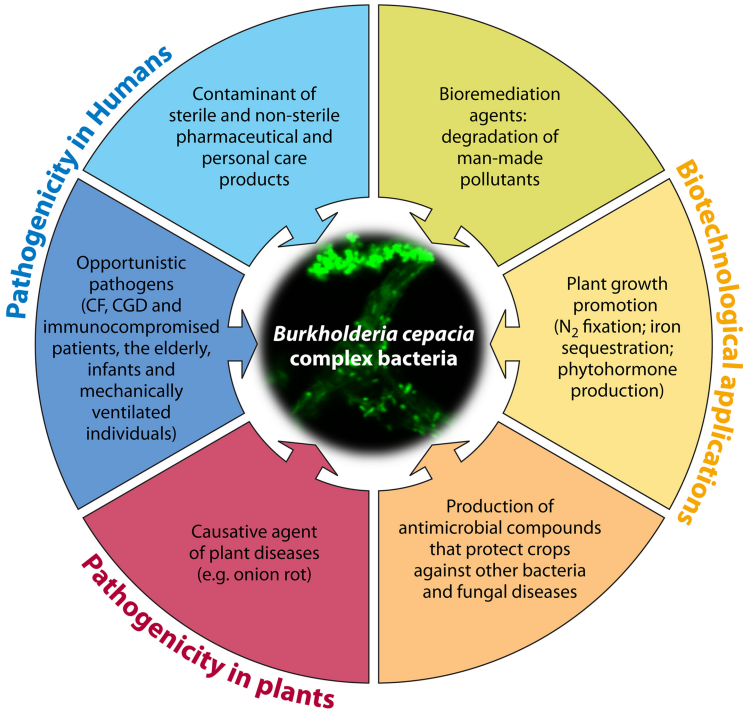

FIG 2 Strains of Bcc bacteria have potentially beneficial ecological and biotechnological applications, including their role in biocontrol, bioremediation, and plant growth promotion. However, their application in environmental settings raises concern, since members of the Bcc are human opportunistic pathogens and have been associated with infection outbreaks due to contaminated pharmaceutical products. These bacteria also can cause disease in plants.

pounds and organic pollutants, including constituents of crude oils, pesticides, phthalates, and solvents, like trichloroethylene (TCE) (3, 8).

Unlike the majority of opportunistic pathogens, members of the Bcc are not prone to commensal carriage, and infections typically are acquired in hospital settings or directly from the environment. In the case of chronically infected CF patients, person-to-person transmission might also occur outside the context of health care facilities (3). In 2002, a soil isolate was proven to be genetically indistinguishable from an epidemic *B. cenocepacia* clone (at the time referred to as *B. cepacia* genomovar III) responsible for widespread infection in CF patients, proving that strains that are pathogenic to humans do not necessarily differ from those found in the environment (49). A number of studies have confirmed the presence of Bcc bacteria in outdoor environments with which people may have regular contact. For example, PCR analysis of DNA extracts from soil and rhizosphere samples, collected from 91 sites located in 3 large U.S. cities (playgrounds, athletic fields, parks, hiking trails, residential yards, and gardens), revealed that around 90% of the samples examined were positive for Bcc (50). Moreover, *B. cenocepacia*, *B. anthina*, *B. multivorans*, and *B. pyrrocinia* strains were isolated from soil and water samples collected in the house and gardens of four CF patients, suggesting that these bacteria are also common in the home environment, possibly acting as a reservoir for infection (51). Therefore, further understanding of the role played by the natural environment in Bcc infection acquisition is of the utmost importance. The positive and negative impacts of the presence of Bcc bacteria in natural and human-made environments are summarized in Fig. 2.

Bcc BACTERIA AS HUMAN OPPORTUNISTIC PATHOGENS

Despite their potential application in bioremediation, the large-scale use of Bcc bacteria deserves attention from the scientific community, especially concerning their release in the environment. This is important, since the multiple bacterial species that

A53210128
Downloaded from https://journals.asm.org/journal/cmr on 04 June 2025 by 194.9.111.110.

constitute the Bcc may lead to serious respiratory infections among CF (9–11) and CGD patients (12, 13). Immunocompromised individuals, infants, and the elderly also are susceptible to Bcc infection (14–16). Bcc strains rarely cause respiratory infection in healthy (immunocompetent) individuals, since they are cleared by normal airway mucociliary activity (8). In the case of hospitalized non-CF patients, the most commonly reported risk factors comprise the use of venous and urinary catheters, endotracheal tubes (in mechanically ventilated patients), hemodialysis, and long hospitalization periods in intensive care units (17). Patient-to-patient transmission is thought to occur through spreading of aerosol particles, direct physical interaction with infected people, or upon contact with contaminated surfaces (3).

The accumulation of mucous secretions is recurrent in CF patients' airways due to a mutation in the CF transmembrane conductance regulator (CFTR) gene (52). The resulting lung environment is prone to colonization by Bcc bacteria and other pathogens (52), often presenting selective pressures that induce phenotypic and genotypic variation, conferring evolutionary and adaptive advantage (53). Such adaptation mechanisms might include increased antimicrobial resistance, the development of alternative metabolic pathways, and marked genomic expression reprogramming (53–55).

Although a smaller proportion of CF patients are infected with Bcc than with *Pseudomonas aeruginosa*, they represent a major concern, since the clinical outcome is very unpredictable, even if patients are infected with clonal strains (3, 17). Although the Bcc comprises 24 bacterial species, the two most prevalent among the CF community are *B. cenocepacia* and *B. multivorans* (4, 10, 17). However, the less represented species, in particular, *B. dolosa*, *B. stabilis*, *B. contaminans*, and *B. cepacia*, also may result in poor clinical outcomes (11, 56, 57).

B. gladioli, although not a member of the Bcc, is a very closely related bacterial species and accounts for a significant percentage of opportunistic respiratory CF infections (56). This pathogen also has been identified in CGD (58) and other non-CF patients (59, 60). However, to our knowledge, there are no reports on *B. gladioli*-related nosocomial outbreaks, and contamination of pharmaceutical products with this species has not been registered. Contamination episodes involving the presence of *B. gladioli* have been registered only in the water supply system of a laboratory mouse housing facility (61) and within endotracheal tubes used for mechanical ventilation (59). Unlike Bcc species, *B. gladioli* is highly susceptible to certain antibiotics, such as piperacillin-tazobactam, aminoglycosides, quinolones, carbapenem, imipenem, and ticarcillin-clavulanic acid (59, 62, 63), which might, to some extent, explain the lack of contamination outbreaks related to this species.

Bcc BACTERIAL SURVIVAL IN WATER AND UNDER NUTRIENT-DEPLETED CONDITIONS

Besides being widely distributed in the soil, Bcc bacteria also can survive and proliferate in water-based environments, such as water bodies, lakes, rivers, drinking water, and liquids containing small amounts of nutrients. This characteristic is mainly attributed to the genetic and nutritional diversity of these species, which might be responsible for the ability of certain Bcc bacteria to metabolize the organic matter present in oligotrophic aquatic environments (18).

Examples of Bcc Survival in Water Environments

In a study carried out in the province of Bologna (Italy), *B. cepacia* was found to be present in 3.5% of the eighty-five samples of drinking water that were collected from public and private buildings, growing at a temperature of approximately 24°C (20). Additionally, it was demonstrated that the organic matter from the biofilm that is normally formed around the inner walls of water pipes was probably metabolized by the bacterial cells (20). When twenty-eight water samples, collected from the European rivers Schelde and Leie, were analyzed, ten of them were positive for the presence of Bcc bacteria, namely, *B. cepacia*, *B. multivorans*, *B. cenocepacia*, *B. vietnamiensis*, and *B. anthina* (19). More recently, the presence of Bcc bacteria in water bodies of the West

A53210128
Downloaded from https://journals.asm.org/journal/cmr on 04 June 2025 by 194.9.111.110.

Lake in China was confirmed, where 40% of the 670 bacterial isolates analyzed belonged to five representative Bcc species: *B. multivorans*, *B. cenocepacia*, *B. stabilis*, *B. vietnamiensis*, and *B. seminalis* (21).

Besides being able to survive and proliferate in water-based environments, Bcc bacteria also have been reported to tolerate substantial temperature variations. Early studies performed on three different strains of *P. cepacia* (now *B. cepacia* or another Bcc species), incubated in distilled water, revealed optimum growth rates at 37°C (64). Nonetheless, high population yields were also observed during long-term incubation at temperatures ranging from 18°C to 42°C (64). Moreover, two other *B. cepacia* strains were able to grow in distilled water at temperatures as low as 10°C and as high as 50°C, even surviving under those conditions for 21 days and 48 h, respectively (64). Another study involving six *B. cenocepacia* strains revealed that all of them were able to proliferate or survive in distilled water for at least 40 days at 18°C and 23°C (18).

Mechanisms of Adaptation to Water and Nutrient Scarcity

Several factors can influence bacterial survival in water, namely, their physiological state, intrinsic tolerance to nutrient scarcity, interaction with other bacteria, and temperature variations (18). However, in the case of Bcc bacteria, the reasons behind their remarkable ability to persist in water environments for long periods of time still have not been thoroughly assessed, and to our knowledge, there are no published studies pertaining to the molecular mechanisms behind Bcc bacterial survival in water. Relevant clues about this topic can be extrapolated only from other bacterial species within the *Burkholderia* genus, namely, *B. pseudomallei*, a pathogen endemic to tropical and subtropical regions and the causative agent of melioidosis disease in humans and animals (65). Despite not being a member of the Bcc, it is the best-studied *Burkholderia* species in terms of survival in water environments. Results suggest that the ability to maintain an intact outer membrane architecture is relevant for *B. pseudomallei*'s prolonged survival in water environments (66). A switch of morphology from typical Gram-negative rods to cocci/coccobacilli and the transition into a viable but nonculturable state were also considered to contribute to *B. pseudomallei*'s survival in distilled water at 25°C for 16 years (67). A recent study also suggested that *P. aeruginosa* is capable of long-term survival in a nutrient-deprived environment by existing in a dormant state (68). During long-term incubation in water, *P. aeruginosa*'s cells were found to exhibit a decreased metabolic activity to convert from a rod to a coccoid shape and to change the membrane lipid composition, leading to decreased outer membrane permeability and consequent increased tolerance to polymyxin B (68). A global expression analysis indicated that the majority of genes were repressed, including those required for DNA replication (68). However, a number of genes had increased expression, in particular, amino acid, fatty acid, and phospholipid metabolism genes, suggesting that these compounds can be used as alternative carbon and energy sources under nutrient starvation (68). Water constitutes a hostile environment, presenting several challenges to bacterial growth, including a lack of nutrients and low osmolarity (66). The fact that Bcc bacteria can persist under such harsh conditions is indicative of their remarkable metabolic capacity and deserves special attention, as they can pose serious threats to public safety and health.

Bcc BACTERIA AS CONTAMINANTS OF PHARMACEUTICAL PRODUCTS

Product Recalls Associated with the Presence of Bcc Bacteria

One of the most commonly reported contaminants of nonsterile pharmaceutical products is *Burkholderia cepacia* (69), whether it was definitively identified as *B. cepacia* (the type species) or was just a member of the *Burkholderia cepacia* complex, since most of the literature available on the topic dates back to the pre-Bcc (or even the pre-*Burkholderia*) era. This is a particular concern for recently described members of the Bcc, which may have been involved in contamination episodes in the past, but their role cannot be recognized due to the deficient taxonomic knowledge at the time. Those contaminants can be transmitted through raw materials, water, and machine surfaces

A53210128
Downloaded from https://journals.asm.org/journal/cmr on 04 June 2025 by 194.9.111.110.

used in pharmaceutical manufacturing. According to United States Food and Drug Administration (FDA) recall data, from 1998 to 2006, *B. cepacia* was identified as the cause of 22% of nonsterile product recalls (22). This tendency has grown over recent years, with this species being involved in 34% of the nonsterile product recalls between 2004 and 2011 (22). *B. cepacia* was considered the most common microbial contaminant found in nonsterile products between January and July 2012, corresponding to 39% of the bacterial species isolated from contaminated samples, while other bacterial genera, including *Pseudomonas*, *Staphylococcus*, and *Enterobacter*, were less prevalent within the collected samples (69). Bcc bacteria have been isolated from diverse types of pharmaceutical and personal care products, including nasal sprays (70, 71), multiple lotions and oils (72), water-based products (73), mouthwash (74, 75), cleansing washcloths and baby wipes, preoperative skin solutions, hand sanitizers (76), and gas relief liquid drops (22, 69).

In an epidemiological survey performed by our group between 1995 and 2002, which included patients receiving treatment at the major Portuguese CF center within a central Lisbon hospital, an unusually high prevalence of *B. cepacia* and *B. contaminans* in sputum cultures was detected (57, 71). Later, a market surveillance conducted by INFARMED, the National Authority of Medicines and Health Products, in 2003 and in 2006, detected Bcc bacteria contamination in several batches of nonsterile saline solutions for nasal application, which are often administered to CF patients for inhalant therapy. Further analysis confirmed that the clinical clones and the strains isolated from contaminated saline solutions were indiscernible based on molecular typing methods (57, 77).

Looking at the FDA's list of recalls, market withdrawals, and safety alerts (78) in recent years, several warnings have been launched concerning the presence of Bcc bacteria in a wide variety of products. In October 2016, the FDA, in collaboration with the Centers for Disease Control and Prevention (CDC), detected the presence of *B. cepacia* in the water system used for oral liquid docusate sodium manufacture. This led to a national alert, and the product was voluntarily recalled from the market by its producing pharmaceutical company (79). In 2017, the FDA detected a potential *B. cepacia*-related contamination of decongestant relief syrups for the treatment of cough, cold, and allergies and advised the voluntary recall of the products from the market (80). More recently, in 2018, the FDA detected the presence of several microbial contaminants in homeopathic drug products, including *B. multivorans*, and the recall of all water-based products from the company in question was recommended (81).

Ability of Bcc Bacteria To Survive and Proliferate in Pharmaceutical Products

Sterile pharmaceutical products typically are intended for intravenous administration (e.g., injection or infusion) or to be applied directly in the eyes. Due to the high infection risk associated with administration through these routes, such products must be manufactured in an environment that is free from bacteria, viruses, and other potentially infectious microorganisms (82). Nonsterile products (e.g., docusate, mouthwash, and body wash) are usually administered orally or topically and, theoretically, have a lower potential to cause infection. For that reason, those compounds do not require sterilization before use (83). Nevertheless, microbiological control of nonsterile products is particularly important, since they are more prone to microbial contamination, which can reduce product quality and, above all, cause drug-related infections (84).

Given their ability to use numerous organic compounds as carbon and energy sources, several of them xenobiotics that are very difficult to catabolize (4, 75), Bcc bacteria can grow and proliferate in a wide variety of medicinal drugs (24). One example of such metabolic diversity is their ability to grow on nitroaromatic and aromatic compounds through the oxidation of aromatic structures and breakdown of halogenated compounds by monooxygenases and dioxygenases (76, 77). Since nitroaromatic compounds make up a vast array of pharmaceutical drugs, Bcc bacteria can lead to the degradation of active ingredients and excipients, compromising drug

A53210128
Downloaded from https://journals.asm.org/journal/cmr on 04 June 2025 by 194.9.111.110.

stability and purity, as well as their potency and effectiveness (24, 78). Apart from altering the chemical, physical, and organoleptic properties, drug degradation might also lead to the formation of toxic substances (84). This constitutes a serious risk for the consumers of such products, who typically suffer from other pathological conditions. Bcc-contaminated products constitute a vehicle for transmission of these opportunistic pathogens to susceptible individuals, favoring the development of life-threatening chronic infections.

Reasons Underlying Bcc Contamination in Pharmaceutical Settings and Preventive Measures

The persistence of Bcc bacteria in pharmaceutical products is, in part, attributed to the lack of good manufacturing practices. Pharmaceutical companies are responsible for ensuring quality control of their products as well as for monitoring the processing steps and components that are used (26). However, the lack of adequate cleaning procedures; the use of an unsuitable grade of water, associated with poor water control and design systems; the use of the same disinfectants for long periods of time; insufficient microbiological controls; and inadequate testing, specification, and validation guidelines constitute some of the causes of bacterial contamination in pharmaceutical settings (69).

According to the Parenteral Drug Association (PDA) technical report no. 67, *Exclusion of Objectionable Microorganisms from Nonsterile Pharmaceutical and Over-the-Counter (OTC) Drug Products*, *Medical Devices and Cosmetics*, an objectionable organism is defined as a microorganism that can proliferate in a certain pharmaceutical product, causing adverse effects on its chemical, physical, functional, and therapeutic properties (39). This definition also comprises microorganisms with a pathogenic character that, when present in a certain pharmaceutical product in large numbers, can cause infection after administration (22, 39, 40). The high prevalence of product recalls due to contamination with Bcc bacteria and the numerous nosocomial outbreaks verified throughout the years constitute the main reasons why members of the Bcc are considered objectionable organisms (22–24, 62). Moreover, their role as human opportunistic pathogens (affecting both CF and non-CF patients) (3, 17), as well as their resistance to antibiotics and antimicrobial preservatives, also contribute to their inclusion in that category (30, 33, 38, 77).

The U.S. Pharmacopeia (USP) provides several guidelines and methodologies to detect the presence of specific indicator organisms in nonsterile products, namely, the USP guidelines 61, *Microbial Enumeration Tests* (85), and 62, *Tests for Specified Microorganisms* (86). However, despite the fact that Bcc bacteria are widely recognized as objectionable organisms, the USP does not provide any specific test to determine their presence in nonsterile drug products (38, 69). Due to the lack of information and adequate detection methods, Bcc contamination is often disregarded, since these microorganisms are not considered a priority for pharmaceutical manufacturers, who are often unaware of their impact and the consequences that might result from releasing Bcc-contaminated products into the market (38). The concern raised by the undetected presence of Bcc in pharmaceutical products is not a new topic and has been the object of discussion by the FDA since 1981, when the regulatory agency detected irregularities in the validation and control processes of a water deionization system, which resulted in the contamination of a drug product with *B. cepacia* (38, 69). Another example dates back to 1993 and concerns the recall of a metaproterenol sulfate inhalation solution contaminated with *B. cepacia*, which, according to the USP, required no microbial testing before being released onto the market (38, 69). More recently, a chemically preserved oral fexofenadine antihistaminic suspension was found to be contaminated with *B. cepacia* 6 months after the manufacturing process (87). The objectionable organism had not been detected earlier because it was not included in the routine testing described by USP guideline 62 and was not considered a threat, even when its presence had been detected once in the manufacturing company's water system (87). The microbiological counts obtained during product stability testing were

A53210128
Downloaded from https://journals.asm.org/journal/cmr on 04 June 2025 by 194.9.111.110.

acceptable for 6 months, after which a considerable increase of CFU numbers was registered. *B. cepacia* was subsequently identified through Gram staining and biochemical assays (87). These case reports highlight the urgent need for pharmaceutical companies and regulatory agencies to work together in order to reformulate the current protocols and legislation regarding the presence of Bcc bacteria in pharmaceutical products.

Presently, the FDA continues to warn pharmaceutical companies about the contamination hazard posed by Bcc bacteria when present in sterile and nonsterile pharmaceutical products, reinforcing the fact that the number of product recalls due to Bcc contamination remains high (88). On May 2017, the regulatory agency provided new regulatory guidance for manufacturers of nonsterile water-based drug products, stating the importance of establishing guidelines to prevent contamination with such objectionable organisms, including correct process design and quality assurance of incoming materials, as well as the monitoring of storage conditions and cleaning procedures (88).

In the specific case of Bcc bacteria, the number of product recalls reported in the literature confirms that antimicrobial preservatives are not effective as a way of preventing contamination, since several strains can proliferate in preserved solutions (38). Therefore, manufacturers cannot rely on the addition of antimicrobial preservatives for contamination control and must instead apply stringent in-process control and guarantee sterile conditions during every step of the manufacturing process instead of testing only the finished products (26, 37, 38). Water is the most commonly used raw material in the pharmaceutical industry and is considered a frequent source of Bcc contamination. In fact, several Bcc outbreaks that occurred throughout the years have identified pharmaceutical-grade water as the root cause of product contamination, whereas contamination of raw materials and inadequate quality control procedures were less implicated in product recalls (37, 38). Therefore, in industrial settings, every source of water should be considered a potential reservoir (38), and every piece of equipment used for processing (tanks, pumps, and filling lines) should be properly cleaned, disinfected, and dried, especially the product contact surfaces (37).

Both the FDA and the USP have provided technical guidelines concerning the water used for pharmaceutical manufacturing. The FDA advises manufacturers inspect the source of water used for wet granulations or aqueous liquid preparations, which should be chemically and microbiologically purified USP water (89). Moreover, potable water might only be used for bulk drug manufacturing and not to prepare USP-compliant dosage-form products or laboratory reagents. Nonpotable water systems, such as cooling water for air conditioning or fire sprinklers, should be correctly identified, and cross-connections with potable water must be avoided (89). Regular collection of water samples from piping systems should be a common practice, since these constitute a major source of water contamination. Maintaining the water circulation systems at constantly high temperatures (typically 80°C) is also advised to prevent significant microbial growth (89). Additionally, during the formulation of aqueous oral and topical dosage-form products, reduced water activity (a_w) is important to prevent microbial contamination and guarantee the product's self-preservation capacity (90). Pharmaceutical products with an a_w below 0.75 are significantly less prone to contamination, while nasal inhalants, hair shampoos, and antacids, which have higher water activities (a_w of 0.99), are very susceptible to contamination by Gram-negative bacteria, namely, Bcc (90).

UNIQUE ABILITY OF Bcc TO OVERCOME BIOCIDE ACTION

Bacterial Resistance to Biocides and Outbreaks Associated with Contaminated Solutions

The term biocide is generally employed to describe a chemical agent that destroys or inhibits the growth or activity of living organisms. While antiseptics are substances with antimicrobial activity that are applied to the skin/living tissue in order to reduce the microbial flora, disinfectants are applied to nonliving objects to destroy harmful

A53210128

Downloaded from https://journals.asm.org/journal/cmr on 04 June 2025 by 194.9.111.110.

microorganisms. Preservatives are added to a wide variety of products, some of them not required to be sterile (e.g., medicines, food, and cosmetics), to prevent microbial growth (27, 32). These chemical agents are also employed at different concentrations, depending on whether the purpose is disinfection or preservation. For example, the biocide biguanide chlorhexidine is used for surface disinfection at concentrations in the range of 0.5% to 4% (vol/vol), for antisepsis at 0.02% to 4% (vol/vol), and for preservation at 0.0025% to 0.01% (vol/vol) (91).

Antiseptics and disinfectants (biocides) are widely used in hospital settings as a way of controlling infections. In general, biocides have a broader spectrum of activity and tend to act upon multiple targets, whereas antibiotics usually have specific intracellular targets (27). The most commonly used biocides include alcohol, iodine, iodophores, triclosan, chloroxylenol, chlorohexidine gluconate (CHX), and quaternary ammonium compounds, such as benzalkonium chloride (BZK) (32). One of the most worrying features of Bcc populations is that they can remain viable and/or proliferate within the currently commercialized biocide formulations, displaying low susceptibility to a variety of compounds, including CHX, cetylpyridinium chloride, triclosan, BZK, and povidone (30). Several studies also have demonstrated that the biocide concentration in many commercial products is insufficient to kill Bcc bacteria, especially when they form biofilms. This is the case for CHX, hydrogen peroxide, and BZK (92–94). For example, the typical BZK and CHX concentrations applied in commercial products range from 0.02% (200 μg/ml) to 5% (50,000 μg/ml), which might not be sufficient to eradicate resistant strains (85). Based on susceptibility assays, proper elimination of Bcc bacteria might require the use of biocide concentrations 25 times higher than those currently applied (24).

Most outbreaks have been associated with improper product utilization, namely, the use of contaminated water during manufacturing processes, overdilution of antiseptic solutions, use of outdated products, prolonged storage periods after opening, and improper storage conditions (32, 93). The use of biocides beyond the expiration date is risky, since changes in the chemical concentration or composition are likely to occur, leading to a decreased bactericidal/bacteriostatic potency (93). Contaminated solutions may appear clear and, therefore, are difficult to distinguish from truly sterile solutions (88). The ability of Bcc bacteria to survive and thrive for long periods of time in biocide-containing solutions raises an alarming concern in terms of public health, since they can be transmitted to patients through the use of contaminated products and cause subsequent problems.

The mechanisms of biocide resistance can be intrinsic or acquired through mutation events or horizontal gene transfer (27, 28). Gram-negative bacteria generally have a higher inherent resistance to biocides than Gram-positive bacteria due to the structure of their outer membrane, which acts as a barrier against the entry of several antimicrobial agents. The presence of an intact and highly charged lipopolysaccharide layer is also an intrinsic Bcc characteristic that helps prevent the diffusion of hydrophobic antimicrobials (27, 28). The presence and activation of efflux pump systems is among the major mechanisms of intrinsic biocide resistance. The most relevant family of efflux pumps comprises the resistance-nodulation-cell division (RND) transporters (95). These are usually chromosomally encoded and composed of a periplasmic membrane fusion protein and an outer membrane factor, allowing efflux of solutes across the inner and outer membranes, thereby reducing accumulation in the periplasm (95). The role of these efflux systems has been described for some Bcc species, conferring resistance to BZK and CHX in *B. cenocepacia* (33, 96) and to methylisothiazolinone-chloromethylisothiazolinone (M-CMIT) and fluoroquinolones in *B. lata* (97). Genomic expression analysis of two sequential *B. cenocepacia* isolates recovered from a CF patient undergoing antibiotic therapy revealed an increased transcription of several genes encoding efflux pumps in the highly resistant clonal isolate, namely, those encoding RND transporters, drug efflux pumps of the major facilitator superfamily (MFS), and ABC transporters (54). The same highly antibiotic-resistant isolate displayed

A53210128
Downloaded from https://journals.asm.org/journal/cmr on 04 June 2025 by 194.9.111.110.

reduced outer membrane permeability, which was associated with the downregulation of genes encoding porins that may function as channels for the entry of antibiotics (54).

Phenotypic adaptations, such as biofilm growth, also can be considered intrinsic resistance mechanisms. Biofilm formation in Bcc bacteria has been linked to an increased ability to cause persistent infections, especially in CF patients (98, 99). The composition of the biofilm matrix, rich in polymeric substances, might contribute to the development of resistant bacteria by restricting the diffusion of antimicrobial agents (98). However, some compounds, including antibiotics, still can penetrate through biofilms, depending on the nature of both the compound and the biofilm (98, 100). The antimicrobial peptide nisin was able to penetrate through the biofilm structure, causing bacterial death, even though the viability loss was more pronounced in the case of planktonic cells than in biofilm-grown bacterial populations (101). Within the biofilm, the development of a microenvironment characterized by lower nutrient/oxygen availability and reduced bacterial growth is likely to occur together with the production of enzymes that can be involved in the degradation/neutralization of chemicals (27). Overall, biocides like CHX and hydrogen peroxide fail to significantly reduce the viability of sessile cells compared to the effects on planktonic cells (92). The exposure of *B. cenocepacia* biofilms to high levels of oxidizing agents, namely, hydrogen peroxide and sodium hypochlorite, led to the upregulation of several genes, some of which are involved in oxidative stress and general stress responses, as well as others that encode proteins required for the repair of reactive oxygen species (ROS)-induced cellular damage (102). The treatment of *B. cenocepacia* biofilms with CHX also led to the transcriptional upregulation of genes encoding membrane-related and regulatory proteins as well as drug resistance determinants, including sessile-specific RND efflux pumps (96). Bacteria within the biofilms might also resist the action of antimicrobial agents by existing in a slow-growing state, typically characterized by lower antimicrobial susceptibility (98).

Acquired resistance can occur through mutations in genes involved in the biosynthesis of the cell wall, membrane lipids, porins, or outer membrane proteins (OMPs) (28). Horizontal gene transfer may contribute to the acquisition of mobile genetic elements, such as plasmids or genes encoding proteins responsible for modification/degradation of the biocide (e.g., *o*-phosphotransferases, *o*-adenyltransferases, and *n*-acetyltransferases) (28). Another mechanism by which microorganisms can gain biocide resistance is through molecular target alteration. For instance, in *Escherichia coli*, a missense mutation in the FabI protein is sufficient for altering the target site for triclosan, conferring resistance to that compound (28).

Biocides will continue to play an important role in preventing the spread of infection in the health care environment, but it is critical to reevaluate the type of products and the concentrations at which they should be added. For successful biocidal formulations and regulation policies, knowledge about the mechanisms of action and possible development of bacterial resistance is of the utmost importance.

Mechanisms of Benzalkonium and Chlorhexidine Resistance in Bcc Bacteria

BZK and CHX are two of the most common biocides used in health care settings and personal care products, being classified as low-level antiseptics with a broad spectrum of activity against Bcc bacteria (28, 32). BZK is commonly used as an antimicrobial preservative for pharmaceutical products, being the biocide of choice for the majority of multidose aqueous nasal, ophthalmic, and optic products (103). It is a quaternary ammonium compound, composed of a positively charged nitrogen covalently bonded to three alkyl group substituents and a benzyl substituent (34, 104). Bcc-contaminated BZK solutions have been pointed out as the major cause of outbreaks, unlike any other biocide available in the market (32). BZK's effects occur mainly at the level of membrane permeability, starting with its adsorption onto and penetration of the bacterial cell surface, followed by membrane destabilization/disorganization and consequent leakage of cellular constituents, culminating in cell death (27, 104, 105).

A53210128
Downloaded from https://journals.asm.org/journal/cmr on 04 June 2025 by 194.9.111.110.

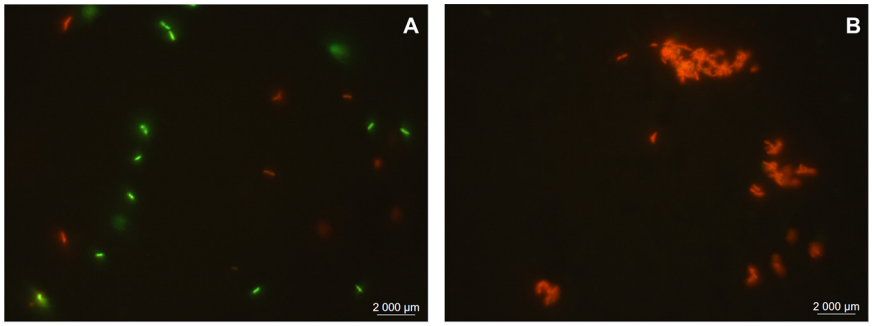

FIG 3 Microscopic observation of cells costained with SYTO9 (green) and propidium iodide (red), showing the effect that the presence of the biocide benzalkonium chloride (BZK) has on *B. cepacia* bacterial viability and aggregation into large clumps that settle on the bottom of the incubation flasks when incubated for several months under conditions mimicking pharmaceutical storage in control saline solution (0.9% [wt/vol] NaCl) (A) or saline solution with 0.05% (wt/vol) BZK (B).

CHX is typically used for hand hygiene and as a component of mouthwash solutions (27, 32, 93). It is a biguanide disinfectant that exerts its effects at the cell membrane level, compromising its structure through the breakdown of associated divalent cations and disruption of lipopolysaccharides, which results in the loss of cytoplasmic components and periplasmic enzymes (93, 96). Several Bcc-related nosocomial outbreaks also have been attributed to the use of contaminated CHX solutions, especially in recent years (106–109).

Early studies identified a *B. cepacia* strain that remained viable for 14 years under nutrient limitation in a saline solution supplemented with 0.05% (wt/vol) BZK (110). More recently, the BZK and CHX susceptibility of 36 different Bcc strains that had been incubated in distilled water for 40 days was assessed through MIC assays and compared to the values at initial inoculation (day zero) (94). Although the 40-day incubation period in distilled water, prior to the addition of the biocides, resulted in a higher susceptibility to both BZK and CHX, six *B. cenocepacia* strains still retained a high level of resistance (94). The same study also reported that clinical strains of *B. contaminans*, *B. multivorans*, *B. vietnamiensis*, and *B. ambifaria* were better recovered after 14 days in the presence of BZK rather than during the first 24 h (94). These observations suggest that BZK was inactivated by the bacteria and was even used as carbon and energy sources for bacterial growth and metabolism (94). Long-term incubation (18 months) with BZK (at 53 μg/ml and 500 μg/ml) also induced structural and organizational alterations in *B. cepacia* cell suspensions incubated in aqueous saline solutions (0.9% [wt/vol] NaCl), including the formation of cellular aggregates, which could be visualized both macro- and microscopically, as evidenced in Fig. 3 (our unpublished results). When the antimicrobial effects of sublethal concentrations of BZK (10 to 50 μg/ml) and CHX (2 to 10 μg/ml) were compared between six *B. cenocepacia* strains, all of them remained viable, exhibiting low susceptibility toward the antiseptics upon incubation at 23°C for 28 days (93). In another study, short-term exposure of a *B. lata* strain to 50 μg/ml of both CHX and BZK resulted in reduced susceptibilities to ceftazidime, ciprofloxacin, imipenem, and, to a lesser extent, meropenem (35). The upregulation of transporter and efflux pump genes, namely, of an outer membrane protein and an ABC transporter, was registered, suggesting that drug efflux plays an important role in reducing the intracellular concentration of these particular antimicrobial peptides (35). Repeated exposure of a *B. cepacia* strain to sublethal concentrations of CHX during 10 passages in the presence of the biocide was reported to induce a 7.3-fold decrease in bacterial susceptibility (111).

An extensive study on the resistance of Bcc bacteria to BZK examined the potential involvement of efflux pumps, the presence of a putative BZK degradation pathway, and the proteome changes induced in response to that biocide. All 20 of the Bcc strains tested were able to partially degrade (4.7 to 42.6% degradation) BZK in a period of

A53210128
Downloaded from https://journals.asm.org/journal/cmr on 04 June 2025 by 194.9.111.110.

7 days (33). Quantitative proteomic analysis revealed that treatment with BZK resulted in a rapid alteration in the expression patterns of several proteins at a genome-wide level. Proteins belonging to the major facilitator superfamily and to the RND family, presumably involved in multidrug efflux, were upregulated (33). This suggests an intrinsic ability of *B. cenocepacia* to resist BZK's action, which may involve extrusion of the biocide, catalyzed by efflux pumps, and synthesis of metabolic enzymes involved in its degradation. These two mechanisms appear to work synergistically, accelerating the development of resistance (33). The cleavage of the C-N bond in the early steps of the degradation pathway also resulted in reduced BZK toxicity. Finally, the ability of Bcc bacteria to generate acetyl-coenzyme A from BZK, which can be used in central carbon metabolism, allows its utilization as energy and carbon sources, besides being an effective way of degrading BZK without the accumulation of intermediates or toxic metabolites (33).

DETECTION AND IDENTIFICATION OF Bcc BACTERIA IN PHARMACEUTICAL PRODUCTS OR COMPONENTS

Complexity of the Problem

The correct detection of Bcc bacteria is of extreme importance in pharmaceutical industries, allowing the identification of contamination sources and subsequent implementation of corrective measures. The ideal detection method should be rapid and easy to perform due to the clinical relevance of Bcc organisms and the need to ensure the quality and safety of pharmaceutical products. Since Bcc bacteria are adapted to survive and proliferate in water-based environments, as well as under nutrient limitation, they may not grow as well (or at all) if transferred to nutrient-rich culture media (18, 64). In pharmaceutical industries, microorganisms are subjected to multiple stresses, associated not only with the underlying manufacturing processes but also with the lack of nutrients that characterize the raw materials, air, and water, as well as the temperatures applied for manufacturing and storage procedures, which might be below or above room temperature (26). Bcc bacteria have developed several strategies to cope with environmental stresses, among which is the induction of a viable but nonculturable (VBNC) state, a reversible process in which metabolic activity drops to very low levels and no replication occurs (112, 113). Under these conditions, cells might be viable and maintain their integrity and pathogenic potential but cannot be cultured (112, 113). In addition, bacteria adapted to stressful environments, such as nutrient limitation or the presence of antimicrobial agents, often undergo metabolic and morphologic alterations that might interfere with the processes used to eradicate/control their presence. One example is the development of bacterial subpopulations, designated small-colony variants (SCVs), which are characterized for being approximately one-tenth the size of colonies originating from wild-type bacteria and for growing at a rate nine times lower than that of their progenitor cells (114–116). These SCVs have been identified in the respiratory tract of cystic fibrosis patients after lung transplantation, including representative strains of *B. multivorans*, *B. cepacia*, *B. stabilis*, and *B. vietnamiensis* (116). When grown in petri dishes, the reduced size of the colonies may render their visualization with the naked eye difficult, and sometimes even impossible, if a standardized incubation time is used (Fig. 4) (our unpublished results). Moreover, many Gram-negative pathogens alter their characteristic rod-shaped forms to smaller coccoid-like forms after incubation for days or weeks in nutrient-poor environments (117), as observed during long-term colonization of the CF lungs with *B. cenocepacia* (118). Therefore, during membrane filtration processes, those smaller bacterial forms might be able to pass through the 0.2-μm-pore-size filters, which theoretically retain all bacterial species (26). As a result of the referenced limitations, the presence of Bcc bacteria is frequently overlooked during pharmaceutical manufacturing and in the final products, frequently leading to false-negative results (38). Difficulties in detecting the presence of Bcc bacteria within CF patients' respiratory secretions also arise due to their growth rate being lower than that of other coinfecting microorganisms, which might result in the overgrowth of other bacterial populations,

A53210128

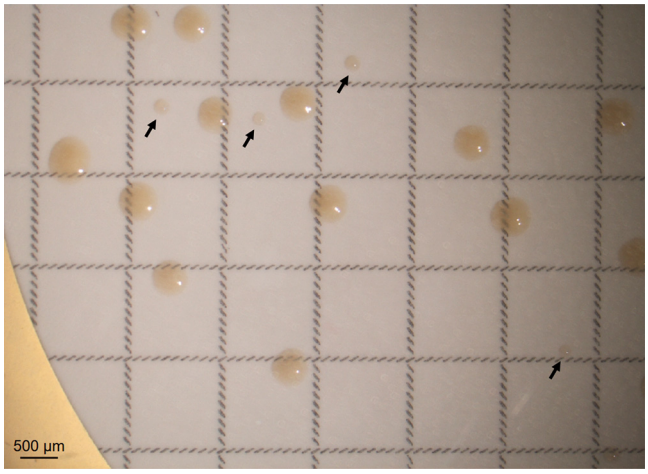

FIG 4 Section of a filter disk corresponding to a *B. cepacia* cell population incubated for several months in a saline solution (0.9% [wt/vol] NaCl) containing benzalkonium chloride (BZK) at 0.05% (wt/vol) under conditions mimicking pharmaceutical storage. The presence of small-colony variants (SCVs), indicated by black arrows, that were absent from the cell population at time zero can be observed on the filter disk following incubation in agar plates (our unpublished results).

masking the presence of Bcc (119). However, the correct detection and identification of Bcc bacteria is of paramount importance for the application of adequate infection control policies as well as to evaluate the most suitable treatment options (120, 121).

Detection and Identification by Phenotypic Methods

Reference laboratories responsible for the quality control of pharmaceutical products typically perform standard phenotypic methods for bacterial isolation and identification (122). In general, these methods rely on enrichment, cultivation, and isolation of microorganisms, requiring long incubation times and extensive manipulation (24). Additionally, traditional cultivation methods and phenotypic assays do not provide enough sensitivity and often underestimate microbial communities, given that some bacteria are not able to grow in certain substrates or do it at such low rates that the incubation periods are not sufficient to allow proper detection (24, 26, 122). Conventional biochemical methods based on catalase, gluconate, malate, phenylacetate, and leucine arylamidase activity are not useful for identification, since Bcc and non-Bcc bacteria cannot be distinguished (123). Many identification errors arise from the phenotypic similarities between *Burkholderia* and other bacterial genera, such as *Cupriavidus*, *Ralstonia*, *Achromobacter*, *Brevundimonas*, *Comamonas*, *Pandoraea*, and *Delfia*, which are frequently misidentified as Bcc species (123, 124). Automated identification systems have also been developed, such as the Vitek MS and the Bruker Biotyper, based on matrix-assisted laser desorption ionization–time of flight mass spectrometry (MALDI-TOF MS) (123). This technique consists of the spectral analysis of bacterial ribosomal proteins, which are ionized by laser irradiation of bacterial cells (123). It has a high initial investment cost but provides results in a matter of minutes, as opposed to days, when traditional methods are used (37). Despite the advances registered in this field, further developments still are required for the successful identification of Bcc members, including the development of a database of mass-charge fingerprints, which requires continuous updates to comprise more microorganisms, including Bcc species, which are currently underrepresented (37).

Apart from the correct identification of Bcc bacteria, it is also relevant to know if these contaminants are viable or not. Flow cytometry is a widely used technique that can be useful to characterize bacterial viability by assessing cell membrane integrity (125). Usually, the fluorescent probes SYBR green I (for total cell staining) and propidium iodide (for staining dead cells) are used for nucleic acid costaining. It is a cultivation-independent approach that is particularly useful to detect Bcc bacteria

A53210128
Downloaded from https://journals.asm.org/journal/cmr on 04 June 2025 by 194.9.111.110.

residing in a viable but nonculturable state (125). Fluorescence species-specific identification could be achieved by labeling with antibodies that bind specifically to Bcc bacterial cell surface molecules. The combination of flow cytometry with fluorescence species-specific detection, although time-consuming, potentially is useful in the pharmaceutical industry (113).

Detection and Identification by Genotypic Methods

Due to the challenges associated with Bcc bacterial identification using traditional phenotypic methods, the application of molecular methods, based on DNA or RNA analysis, is of great importance for quality control in pharmaceutical industries, providing higher resolution, easier analysis, and faster results (123, 126). PCR-based methods are the most widely used for DNA analysis, and their implementation in quality control laboratories has grown over the years. The first reports of the use of PCR-based assays for bacterial detection in artificially contaminated pharmaceutical products date back to 1998, when Jimenez et al. developed the BAX system, which allowed the detection of *Salmonella enterica* serovar Typhimurium within a 30-h period, instead of the 5- to 6-day period associated with traditional cultivation methods (127). Two years later, the same researchers reported a simplified method with PCR beads, which allowed the detection of bacteria in artificially contaminated pharmaceutical products in 27 h (128). The majority of the genotypic methods are based on single genes, such as *recA* (129), *fur* (130), and *hisA* (131), with *recA* being the most widely used. Bcc bacteria exhibit 94 to 95% similarity in terms of *recA* gene sequences among different species and 98 to 99% between sequences of the same species, making it a good candidate for species identification (129). Despite being commonly used for bacterial identification, the 16S rRNA gene sequence has a high similarity level (98 to 100%) among Bcc species, providing only limited resolution for differentiation at the species level (129). A method for the rapid identification of Bcc species based on differences in the *recA* gene sequence, detected by rapid-cycle PCR and through the use of specific fluorescence resonance energy transfer (FRET) probes, was proposed in 2006 that provided results within an hour (132). An expanded multilocus sequence typing (MLST) for the identification of Bcc species, with PCR primers targeting different housekeeping genes (*atpD*, *gltB*, *gyrB*, *lepA*, *phaC*, *recA*, and *trpB*), was proposed later (133). MLST analysis has proven very useful for epidemiological studies, being able to correctly identify Bcc at the genus level and presenting very good results in terms of species identification (134).

To improve the sensitivity of PCR-based methods for Bcc identification, other approaches have been developed, including seminested PCR (SN-PCR) and real-time PCR (RT-PCR). SN-PCR consists of two PCR rounds with two sets of primers, in which the second round uses one of the primers applied in the first round (135). One hundred randomly collected commercial syrup preparations were analyzed by both SN-PCR and conventional methods. The PCR assay detected the presence of *B. cepacia* in two of the samples that had not been detected by standard approaches, highlighting the advantages of using PCR-based methods (136). RT-PCR also has been used for the identification of *B. cepacia* in pharmaceutical products (137). This technical approach allowed bacterial identification in all of the artificially contaminated samples within 30 h (137). The main advantages of RT-PCR include high sensitivity and accuracy, reproducible data, low contamination risk, time efficiency, low labor intensity requirements, and a lack of the need for post-PCR analysis (138).

In recent years, metagenomic approaches, based on next-generation sequencing, have proven very useful for pathogen detection in clinical laboratories by allowing the identification of virtually all pathogens present in a clinical sample without requiring prior cultivation (139). There are at least two strategies for performing metagenomic studies, including deep amplicon sequencing, which involves PCR-based amplification of a highly conserved taxonomic marker, typically the 16S rRNA gene in the case of bacteria, or shotgun metagenomics, where total metagenomic DNA first is extracted and sequenced by a next-generation platform, followed by its assembly and annotation

A53210128
Downloaded from https://journals.asm.org/journal/cmr on 04 June 2025 by 194.9.111.110.

(139, 140). This approach does not require prior knowledge of microbial identity (139). The main advantages of metagenomics in these settings include quick pathogen identification and the ability to detect less abundant pathogens (139). The generation of complete genome assemblies also allows thorough microorganism characterization, contributing to the development of novel diagnostic methods and the prevention of future contamination outbreaks (139). To our knowledge, there are no current reports on the use of metagenomics for the detection of Bcc bacteria in pharmaceutical or clinical settings, but this approach has successfully detected the presence of bacteria from the *Burkholderia* genus in stream water samples of a polluted urbanized area in São Pedro, Brazil (141).

CONTAMINATION OUTBREAKS IN HEALTH CARE SETTINGS AND CONTROL MEASURES

Throughout the years, a growing body of evidence has confirmed the impact of Bcc bacterial outbreaks, with multiple case studies being reported in order to identify the sources of contamination and their implications in clinical settings. The majority of the cases in which Bcc bacteria have been detected in clinical samples have an environmental origin, typically from contaminated pharmaceutical/personal care products. Contamination of medical products can be classified as extrinsic, when it is introduced during product use, or intrinsic, meaning that the product was already contaminated before use. The easy cross-transmission of Bcc bacteria is particularly worrying, since it facilitates the rapid spreading of infections between different wards within the same facility or even between hospitals situated in different regions of a country (142). The types of products identified as sources of Bcc contamination are diverse, including anesthetic eye drops (143), mouthwash solution (75), fentanyl infusion (144), ultrasound gel (145), antiemetic drugs (15), chlorhexidine solutions (106, 108, 109), liquid soap (76), caffeine citrate (146), distilled water (73), dextrose solutions (147), catheters (16), liquid docusate (148, 149), filters and water oxygen humidifiers (150), washing gloves (151), ventilators (152), and saline flush syringes (153) (Table 1).

Outbreaks and sporadic failures associated with biocides also may be due to user error rather than microbial contamination itself. Common errors include the use of overdiluted solutions and outdated products, the use of tap water to prepare biocide solutions, refilling of small-volume dispensers from large-volume stock containers, and improper product selection (38). Nonsterile products, especially multidose containers, should be handled with extra care, since most of them lose physical integrity after being opened for the first time, becoming more prone to microbial contamination (87). Training of end-users and hospital personnel health care settings should be indispensable (38). Concerning infection control and prevention, there are certain measures that should be followed to minimize the risk of cross-contamination, especially among CF patients. Although associated with anxiety and psychosocial consequences, the segregation of Bcc-positive patients has contributed to a reduction of *B. cepacia* complex-related infections. Additionally, regular microbiological surveillance in clinical settings should include examination for Bcc organisms. Bcc-infected patients should attend different clinics according to the strains they are infected with to avoid superinfections (154). Good hygiene practices are mandatory, including handwashing, disinfection with alcohol rubs, and the use of disposable gloves. Extra care should be taken when handling patient samples, such as sputum specimens and throat swabs. Patients should have well-ventilated, single rooms, and any medical procedure involving respiratory function tests, nebulizations, and airway clearance should be carried out in a separate room (154).

CONCLUSIONS AND PERSPECTIVES

Pharmaceutical products contaminated with Bcc bacteria constitute a serious risk for susceptible patients, particularly those suffering from CF and CGD. Bcc infection also has been reported in immunocompromised individuals (e.g., cancer patients submitted to chemotherapy, HIV/AIDS patients, mechanically ventilated patients, and infants/the

TABLE 1 *Burkholderia cepacia* complex-related outbreaks[a]

Species	Product	Location	Time period	Patient information	No. of patients affected	Reference
Bcc bacteria	Anesthetic eye drops	Madurai, India (Aravind Eye Hospital)	December 2011–February 2012	Patients who underwent cataract surgery and developed acute postoperative endophthalmitis	13	143
B. cepacia	Intrinsically contaminated alcohol-free mouthwash solution	General medical intensive care unit, Vozandes Hospital, Quito, Ecuador	March 2011–May 2012	Ventilated; 3 developed ventilator associated-pneumonia, non-CF patients	13	75
B. contaminans	Continuous fentanyl infusion prepared by institutional compounding pharmacy	Duke University Hospital, Durham, NC	31 August–6 September 2012	1 Child, 6 adults, anemia, cirrhosis, hepatic failure, trauma, HIV, infectious endocarditis, peritonitis	7	144
B. cepacia	Ultrasonic couplant	Hospital in Zhongshan, China	May 2013	Post-C-section patients	4	155
Bcc bacteria	Antiemetic drug granisetron	Mumbai, India (daycare unit of private hospital)	End of 2009	Cancer patients with tunneled catheters	13	15
Bcc bacteria	0.5% Chlorhexidine solution	Seoul, Republic of Korea (Boramae Medical Centre)	10 October–16 December 2013	NR	40	106
B. stabilis, *B. contaminans*, and *B. ambifaria*	Intrinsically contaminated ultrasound gel	Neonatal and adult intensive care units, Argentina	April–July 2013	7 Preterm neonates with respiratory distress, 3 ICU patients who had undergone recent cardiovascular surgery, 1 general ward patient	11	145
B. stabilis	NR[b]	500-Bed tertiary-care hospital in Beijing, China, ophthalmology and otolaryngology	19 March–20 September 2013	Chronic bacterial or fungal sinusitis	53	156
B. cepacia	NR	Hemodialysis center, La Linea de la Concepción, Cadiz, Spain	November 2013–February 2014	NR	7	157
B. cepacia and *B. contaminans*	Nonsterile saline solutions for nasal application	CF care unit of a Lisbon central hospital	2003–2005	CF patients		57, 77
Bcc bacteria	Liquid soap	Near East University Hospital, Nicosia, Cyprus	November 2013	Sickle cell anemia	1	76
B. cepacia	Caffeine citrate	Neonatal intensive care unit, India	September–October 2015	Preterm infants	7	146
B. cepacia	Intravenous solutions of 5% dextrose, normal saline (opened bottles), and continuous-positive-airway-pressure humidifier water	Neonatal intensive care units of 2 hospitals, India	January–March 2014	Neonates, 10 preterm, 11 showed signs of sepsis	12	147
Bcc bacteria	Distilled water	Pediatric intensive care unit, Father Muller Medical College, India	NR	Pediatric patients, 1 with subaortic ventricular septal defect, 1 with rhabdomyosarcoma, on chemotherapy, 1 with pneumonia and pneumothorax	3	73
Bcc bacteria	Central venous catheter, pneumonia	U.S. Veterans Health Administration medical centers	1 January 1999–31 December 2015	Non-CF, advanced age, chronically ill, severe disease	248	16
Bcc bacteria	Liquid docusate	629-Bed, tertiary-care, pediatric hospital in Houston, TX	February 8–July 4, 2016	Pediatric, non-CF	24	148
Bcc bacteria	NR	Urology clinics, Jordan	NR	3 Uncomplicated infections + 1 recurrent infection	4	158
B. cepacia	Flow filter, hemodialysis water, water-oxygen humidifier	Hemodialysis unit, Regional Hospital Coronel Oviedo, Paraguay	November 2013–February 2014	NR	NR	150

TABLE 1 (Continued)

Species	Product	Location	Time period	Patient information	No. of patients affected	Reference
B. cenocepacia	Gel packaged in sachets for use within the sterile ultrasound probe cover	4 Hospitals across Australia	26 March 2017–7 April 2017	Patients with significant preexisting morbidities	11	159
B. stabilis	Commercially available washing gloves	9 Institutions in Switzerland	May 2015–August 2016	Bloodstream and non-bloodstream infections	46	151
B. cepacia	Ventilators	General 1,600-bed hospital, Beijing, China	1–14 June 2015	Ventilator-associated pneumonia	4	152
Bcc bacteria	Rubber stopper of sealed multidose amikacin injection vials	Pediatric ICU and pediatric ward of a tertiary-care hospital, India	June 2012–January 2013	Children with peripheral interavenous catheters	76	160
B. cepacia	Ultrasound probe gel	Referral hospital in Riyadh, Saudi Arabia	8 January–15 June 2016	Non-CF patients	15	161
Bcc bacteria	Oral liquid docusate sodium	Pediatric intensive care unit, The Johns Hopkins Hospital, Baltimore, MD	19 May 2017–30 July 2017	Infants with multiple chronic medical conditions	8	149
Bcc bacteria	Octenidine mouthwash solution	Cardiothoracic intensive care unit in Germany	August–September 2018	Critically ill, postcardiac surgery patients	3	74
Bcc bacteria	Saline flush syringes	59 Nursing facilities in 5 U.S. states	September 2016–January 2017	NR	162	153
B. lata	Chlorhexidine mouthwash	2 Tertiary-care hospitals in Australia	May–June 2016	Intensive care patients	8	107
Bcc bacteria	Prefilled syringe containing liquid docusate	16 Facilities in USA	February 2016	Infants, children, adults and older adults 80 mechanically ventilated and 41 with feeding tubes	108 (63 confirmed and 45 suspect cases)	162
B. cepacia	Intrinsically contaminated commercial 0.5% chlorhexidine solution	600-Bed university-affiliated teaching hospital in South Korea	November 2014–January 2015	Infants, mostly preterm, with respiratory distress syndrome	21	108
B. cepacia	4% Chlorhexidine aqueous body wash	Peritoneal Dialysis Unit, Middlemore Hospital, Auckland, New Zealand	NR	Dialysis patients with peritoneal catheters	9	109
B. cepacia	NR	Tertiary-care hospital, Turkey	2013–2018	NR	46	163
B. cepacia	NR	Neurotrauma critical care unit of a level 1 trauma care center in India	August–November 2014	Mostly patients with head and spinal trauma	48 (15 of which with central line-associated bloodstream infections)	164

[a]*Burkholderia cepacia* complex-related outbreaks that have occurred in different settings and the types of products identified as sources of Bcc contamination, as described in the literature published during the past 5 years. The majority of the contaminations are attributed, in the corresponding publications, to Bcc in general, with no information at the species level, or to the type species *Burkholderia cepacia*. However, since a significant number of reports predate the year in which each Bcc species has been described, the impact of the more recently described species in the contamination outbreaks is currently unknown. The 24 species that currently comprise the *Burkholderia cepacia* complex (and the year of each species description in the literature [41–45, 153, 154, 165–171]) are the following: *B. alpina* (2017), *B. ambifaria* (2001), *B. anthina* (2002), *B. arboris* (2008), *B. catarinensis* (2017), *B. cenocepacia* (2003), *B. cepacia* (1950), *B. contaminans* (2009), *B. diffusa* (2008), *B. dolosa* (2004), *B. lata* (2009), *B. latens* (2008), *B. metallica* (2008), *B. multivorans* (1997), *B. pseudomultivorans* (2013), *B. paludis* (2016), *B. puraquae* (2018), *B. pyrrocinia* (2002), *B. seminalis* (2008), *B. stabilis* (2000), *B. stagnalis* (2015), *B. territorii* (2015), *B. ubonensis* (2000), and *B. vietnamiensis* (1995).

elderly). Over recent years, both sterile and nonsterile pharmaceutical products have been recalled from the market due to Bcc contamination and subsequent nosocomial outbreaks. The difficulties in terms of detection and correct identification of Bcc bacteria by traditional cultivation techniques or even by genotypic methods, their capacity to grow under conditions of low nutrient availability, and an inherent resistance to chemical preservatives (that can even be used as carbon and energy sources) reinforces their potential to cause disease, hampering the application of adequate infection control policies and therapeutic approaches. Since water is the most common source of this contaminant, aqueous pharmaceutical products represent a particular risk for spreading infection. The negative impact of Bcc bacterial contamination in clinical settings and their prevalence as the number one contaminant in pharmaceutical industries has led authorities, namely, the United States Food and Drug Administration (FDA), to propose the inclusion of these bacteria in the "Objectionable Microorganisms" category. Therefore, it is essential and urgent to prevent Bcc contamination in pharmaceutical manufacturing settings, including the raw materials and finished products, and to develop efficient methods to detect and correctly identify members of this complex when their presence is suspected.

ACKNOWLEDGMENTS

Isabel Sá-Correia acknowledges all those who have, over the years, contributed to the field of *Burkholderia cepacia* complex bacterial epidemiology and functional and comparative genomics in her laboratory. Special thanks are due to those who, over the last 2 decades, collaborated with her research group at the Bacteriology Laboratory and the Cystic Fibrosis sectors of Hospital de Santa Maria, in Lisbon, as well as at INFARMED, the National Authority of Medicines and Health Products.

Funding received by the iBB–Institute for Bioengineering and Biosciences from the Portuguese Foundation for Science and Technology (FCT) (UIDB/04565/2020) is acknowledged.

Mariana Tavares received her bachelor of science degree in cellular and molecular biology at the Faculty of Sciences and Technology of the Universidade Nova de Lisboa (FCT/NOVA). She obtained an M.Sc. degree in biotechnology from the Instituto Superior Técnico (IST), Universidade de Lisboa (ULisboa), in 2019. Her one-year M.Sc. thesis work, entitled "Adaptation and survival of *Burkholderia cepacia* and *B. contaminans* in saline solutions containing benzalkonium chloride: impact on microbiological quality of pharmaceuticals," was developed under the supervision of Prof. Isabel Sá-Correia at the Biological Sciences Research Group (BSRG) of the Institute for Biotechnology and Bioengineering (IBB), Instituto Superior Técnico (IST), Lisbon, Portugal. Currently, she is working at PhD Trials, performing clinical assessments of the safety and efficacy of raw material products for cosmetics.

Mariya Kozak received a bachelor's degree in biology at the Faculty of Sciences, Universidade de Lisboa (ULisboa). She obtained her M.Sc. degree in microbiology from the Instituto Superior Técnico (IST), ULisboa, in 2018. Her one-year M.Sc. thesis work, entitled "Long-term survival and phenotypic variation of *Burkholderia cepacia* complex bacteria in saline solutions with or without benzalkonium and direct molecular detection of these bacteria," was developed under the supervision of Prof. Isabel Sá-Correia at the Biological Sciences Research Group (BSRG) of the Institute for Biotechnology and Bioengineering (IBB), Instituto Superior Técnico (IST), Lisbon, Portugal. Currently, she is working at SGS Molecular in its Food Quality Control unit.

Alexandra Balola received a bachelor's degree in biology from the Faculty of Sciences, Universidade de Lisboa (ULisboa). She obtained her M.Sc. degree in biotechnology from the Instituto Superior Técnico (IST), ULisboa, in 2018. Her one-year M.Sc. thesis work, entitled "*Burkholderia cepacia* complex bacteria as contaminants of saline solutions containing benzalkonium: phenotypic characterization of emerging clonal variants," was developed under the supervision of Prof. Isabel Sá-Correia at the Biological Sciences Research Group (BSRG) of the Institute for Biotechnology and Bioengineering (IBB), Instituto Superior Técnico (IST), Lisbon, Portugal. Currently, she holds a research fellowship at the Center for Ecology, Evolution and Environmental Changes (cE3c), Faculty of Sciences, ULisboa.

Isabel Sá-Correia, Er., Ph.D., is a Distinguished Full Professor of Biological Sciences at Instituto Superior Técnico (IST), Universidade de Lisboa, and Director of the Biological Sciences area of the Institute for Bioengineering and Biosciences (iBB) at IST, Lisbon, Portugal. A chemical engineering graduate, she earned a Ph.D. in the field of microbiology (yeast biology; at IST), and, as a Fulbright Visiting Assistant Professor, she carried out postdoctoral studies at the University of Illinois at Chicago, Medical Center, Chicago, IL, USA (molecular biology of alginate biosynthesis in *Pseudomonas aeruginosa)*. Prof. Sá-Correia was the mentor and advisor of 15 postdocs and more than 30 Ph.D. theses. She is the current President of the Portuguese Society of Microbiology. Her research activities are in the fields of molecular and cellular microbiology (yeasts and Gram-negative bacteria) and of functional and comparative genomics, with a focus on microbial responses and resistance to stress. In the field of bacterial pathogenomics, her laboratory contributed to the elucidation of adaptive mechanisms employed by *Burkholderia cepacia* complex (Bcc) bacteria to persist in the lung of cystic fibrosis (CF) patients. Over the last 2 decades, her group carried out the systematic surveillance of Bcc-mediated respiratory infections at the major Portuguese CF Center, in Lisbon, having published the first studies describing the epidemiology of Bcc infections in Portugal. Prof. Sá-Correia (researcher ID H-4054-2011) has published over 250 articles in the Web of Science (5,000 citations since 2014).

Introduction: The extent to which sinks are contaminated by carbapenem-resistant *Acinetobacter baumannii* (CRAB) in intensive care units (ICUs) and the association between these contaminated sinks and hospital-acquired CRAB infections during the non-cluster period remains largely unknown. Here, we performed a prospective multicenter study in 16 ICUs at 11 tertiary hospitals in Chengdu, China.

Methods: We sampled sinks, collected CRAB clinical isolates, and conducted whole-genome sequencing and analysis.

Results: A total of 789 swabs were collected from 158 sinks, and 16 CRAB isolates were recovered from 16 sinks, resulting in a contamination rate of 10.16%. Twenty-seven clinical isolates were collected during the study period. The majority (97.67%, 42/43) of the CRAB isolates belonged to ST2, and 36 (83.72%) of them had both bla_{OXA-23} and bla_{OXA-66}. The 43 strains belonged to 12 clones. One certain clone caused multiple contaminations of seven sinks in one GICU. Two clones of ST2 bla_{OXA-23} and bla_{OXA-66}-carrying sink strains were likely the sources of the two clusters in the two GICUs, respectively. Five ST2 bla_{OXA-23}-carrying isolates were found to be common clones but were recovered from two hospitals.

Conclusion: The contamination rate of CRAB in handwashing sinks is high in some local ICUs, and the contaminated sinks can serve as environmental reservoirs for CRAB clusters.

KEYWORDS

carbapenem-resistant *Acinetobacter baumannii*, intensive care units, handwashing sinks, environmental reservoir, outbreak source

1 Introduction

Carbapenem-resistant *Acinetobacter baumannii* (CRAB) is a common healthcare-associated infection (HAI) pathogen and has been classified as a critical priority by the World Health Organization due to the urgent need for new antibiotics to combat it (1). A systematic review conducted by Antimicrobial Resistance Collaborators showed that the CRAB contributed to 57,700 deaths globally in 2019 (2). In the intensive care unit (ICU), CRAB is particularly common and is mainly responsible for HAIs and hospital outbreaks (3–5), causing a wide range of infections, including ventilator-associated pneumonia and bloodstream infections (6–8).

The most common mechanism by which CRAB strains exert carbapenem antibiotic resistance is the production of oxacillinase (OXA)-type carbapenem-hydrolyzing class D β-lactamases, which are encoded by intrinsic $bla_{\text{OXA-51-like}}$ genes (e.g., $bla_{\text{OXA-51}}$, $bla_{\text{OXA-64}}$, $bla_{\text{OXA-65}}$, $bla_{\text{OXA-66}}$, and $bla_{\text{OXA-98}}$,) and/or acquired genes, such as $bla_{\text{OXA-23-like}}$ (e.g., $bla_{\text{OXA-23}}$, $bla_{\text{OXA-27}}$, $bla_{\text{OXA-49}}$, and $bla_{\text{OXA-225}}$), $bla_{\text{OXA-24/40-like}}$ (e.g., $bla_{\text{OXA-24}}$, $bla_{\text{OXA-25}}$, $bla_{\text{OXA-26}}$, $bla_{\text{OXA-40}}$, and $bla_{\text{OXA-72}}$), $bla_{\text{OXA-58-like}}$ (e.g., $bla_{\text{OXA-58}}$ and $bla_{\text{OXA-164}}$), $bla_{\text{OXA-235-like}}$ (e.g., $bla_{\text{OXA-235}}$ and $bla_{\text{OXA-237}}$), and $bla_{\text{OXA-143-like}}$ genes (9–12). The most prevalent acquired carbapenemase gene reported is $bla_{\text{OXA-23}}$, followed by $bla_{\text{OXA-24/40}}$ (12–16). In addition, class B metal β-lactamase genes (e.g., bla_{NDM}, bla_{VIM}, and bla_{IMP}) have also been reported to exist in a very small number of CRAB strains (9, 10).

Handwashing sinks play an important role in infection prevention and control systems and are common in all hospitals, including in the ICU. In China, a multicenter investigation conducted in 14 provinces showed that the total installation rate of handwashing sinks increased from 69.30% in 2010 to 77.20% in 2016 in 200 hospitals (17). However, handwashing sinks can be contaminated by multi-drug-resistant organisms and cause outbreaks in hospitals (18). Previous studies have identified that certain parts of handwashing sinks, such as sink traps and sink splashing (19, 20), sink bowls and drains (21, 22), faucet aerators (23), and water taps (24), can be contaminated by CRAB during the outbreak period.

However, few studies have focused on the level of handwashing sink contamination by CRAB in different ICUs during the non-outbreak period, and the degree to which contaminated handwashing sinks are associated with hospital-acquired infections in CRAB remains largely unknown. In this study, we conducted a prospective multicenter investigation across 11 hospitals in Chengdu, with the following three objectives: (1) to evaluate the prevalence of CRAB contamination in the sinks of local ICUs during a non-outbreak period; (2) to characterize the carbapenem-resistant genes and molecular epidemiological features of CRAB strains isolated from infected patients and from handwashing sinks in these ICUs; and (3) to assess the potential role of CRAB-contaminated sinks in contributing to patient infections during the non-outbreak investigation period.

2 Materials and methods

2.1 Study setting and design

This multicenter prospective investigation was performed in 16 ICUs at 11 hospitals in Chengdu, Sichuan Province, China. The 16 ICUs included 9 general ICUs (GICUs, with a total of 279 beds and 103 handwashing sinks) and 7 neonatal ICUs (NICUs, with a total of 282 beds and 55 handwashing sinks) (Table 1). From March 2019 to August 2019, all handwashing sinks in the included ICUs were sampled once to screen for CRAB. The clinical CRAB isolates recovered from patients were collected between 2 weeks before and 3 months after the date of sampling in ICUs. If one or more sinks were positive for CRAB, the clinical isolates from this ICU or from other participating ICUs at the same hospital were recovered and transferred to West China Hospital for identification again using the Vitek II automated system (bioMérieux, Marcy l'Etoile, France). All the isolates were subjected to whole-genome sequencing (WGS) to detect homology.

The study was approved by the Ethical Committee of the West China Hospital, and the need to obtain informed consent was waived.

2.2 Sample sites and sampling methods

The sample points included the surfaces, faucets, bowls, drains, overflows, and drain holes of the handwashing sinks. A total of 100 cm^2 of the sink surface and the bowl were sampled using sterile rayon swabs (Copan, Brescia, Italy) moistened with tryptic soy broth (TSB, Hopebio, Qingdao, China). A 5 × 5 cm caliper was used to confirm the sampling area. The sample points for the faucet included a surface area of 5 cm from the outer wall of the water outlet and 3–5 cm from the inner wall. For the bubbled faucets, the bubbler was removed, and the samples were sampled using sterile rayon swabs. The drain holes were sampled 3–5 cm below the drain by the swabs. All the swabs were immediately placed into 15 mL sterile tubes containing 6 mL of TSB.

2.3 Microbiological methods

All the tubes were incubated at 37°C overnight and centrifuged as described in our previous study (25). The supernatant was subsequently discarded, and the precipitants were resuspended in 1 mL of TSB. A 50 µL suspension was inoculated onto *Acinetobacter* selected agar plates (CHROMagar™, Paris, France) containing 4 µg/mL meropenem to screen for CRAB. Isolates that were pink, round, smooth, raised, and moist on the selected agar plates were suspected and identified using a matrix-assisted laser desorption/ionization–time of flight mass spectrometry (Bruker, Billerica, Massachusetts). The minimum inhibitory concentrations (MICs) of meropenem were determined using the broth microdilution method of the Clinical and Laboratory Standards Institute (CLSI) (26).

WGS was performed for all identified isolates using the Illumina HiSeq X10 platform (Illumina, San Diego, California). Subsequent reads were assembled into contigs using SPAdes version 3.14.0 (27). Precise species identification was established based on average nucleotide identity between the strains and type strains of *Acinetobacter* species using JSpeciesWS (28). The sequence of the STs was determined using the genome sequence to query the multilocus sequence typing database.[1] Antimicrobial-resistant genes were identified using ResFinder.[2] The draft genomes of the strains have been deposited in GenBank under BioProject number PRJNA977829. Single-nucleotide polymorphisms (SNPs)

among the same ST strains were analyzed using Snippy version 4.6.0.[3] Recombination regions were predicted using Gubbins version 2.4.1 (29) under the GTRGAMMA model with a maximum of 50 iterations. A cutoff of equal to or less than 11 high-quality SNPs was used to define clones within the same ST strains, as described in a previous study (30).

3 Results

3.1 The contamination of sinks by CRAB

In total, 789 swabs were collected from 158 handwashing sinks in 16 ICUs at 11 hospitals, and 16 CRAB isolates were recovered from 16 handwashing sinks in 5 ICUs at 5 hospitals (Table 1). The total contamination rate of CRAB in the handwashing sink was 10.16% (16/158, 95% CI 5.40–14.83%). The contamination rate in different ICUs ranged from 0 to 63.6%, and the sink contamination rate in the GICU was 15.29% (95% CI 7.75–21.38%), while it was 3.57% (95% CI 0.0–5.35%) in the NICU. Of the 16 sink CRAB isolates, 15 were recovered from the GICUs and belonged to ST2 (12 isolates carrying both $bla_{\text{OXA-23}}$ and $bla_{\text{OXA-66}}$ carbapenemase genes, 1 isolate harboring both $bla_{\text{NDM-1}}$ and $bla_{\text{OXA-98,}}$ and 2 isolates carrying only $bla_{\text{OXA-23}}$). The remaining CRAB isolate was recovered from a NICU and belonged to ST203, and this isolate harbored both $bla_{\text{OXA-23}}$ and $bla_{\text{OXA-66}}$ (Table 2). The 16 sink isolates could be assigned to 6 clones.

3.2 Characteristics of clinical isolates

A total of 27 CRAB clinical isolates were recovered from 4 of the 5 ICUs with CRAB-contaminated sinks. The vast majority of the 27 CRAB clinical isolates were recovered from sputum ($n = 21$, 77.8%), whereas the remaining were from bronchoalveolar lavage fluid (BALF, $n = 5$, 18.5%) and cerebrospinal fluid ($n = 1$, 3.7%). All of the clinical isolates belonged to ST2. Twenty-four of them harbored both $bla_{\text{OXA-23}}$ and $bla_{\text{OXA-66}}$ carbapenemase genes, while the other three carried only $bla_{\text{OXA-23}}$ (Table 2). The 27 clinical isolates could be assigned to 12 clones.

3.3 Diverse clonal backgrounds of CRAB isolates and sink as a source of transmission in a GICU

A total of 18 ST2 CRAB isolates were recovered from ICU 1G, including 2 isolates from two sinks, 15 isolates from sputum, and 1 isolate from BALF. The 18 isolates could be assigned to 6 clones. Seven clinical isolates recovered from sputum, along with one sink isolate (090698), harbored both $bla_{\text{OXA-23}}$ and $bla_{\text{OXA-6}}$. These strains shared 1–7 SNPs, and therefore belonged to a common clone (clone 2b) (Figure 1), indicating an outbreak. Four (090713, 090714, 090715, and 090736) of these seven clinical isolates were recovered before the sink sampling date, and the other three clinical isolates (090739, 090740, and 090745) were recovered after the sink sampling date. These three isolates shared smaller SNPs (2, 4, and 2, respectively) with the clinical isolate (090713) than with the sink

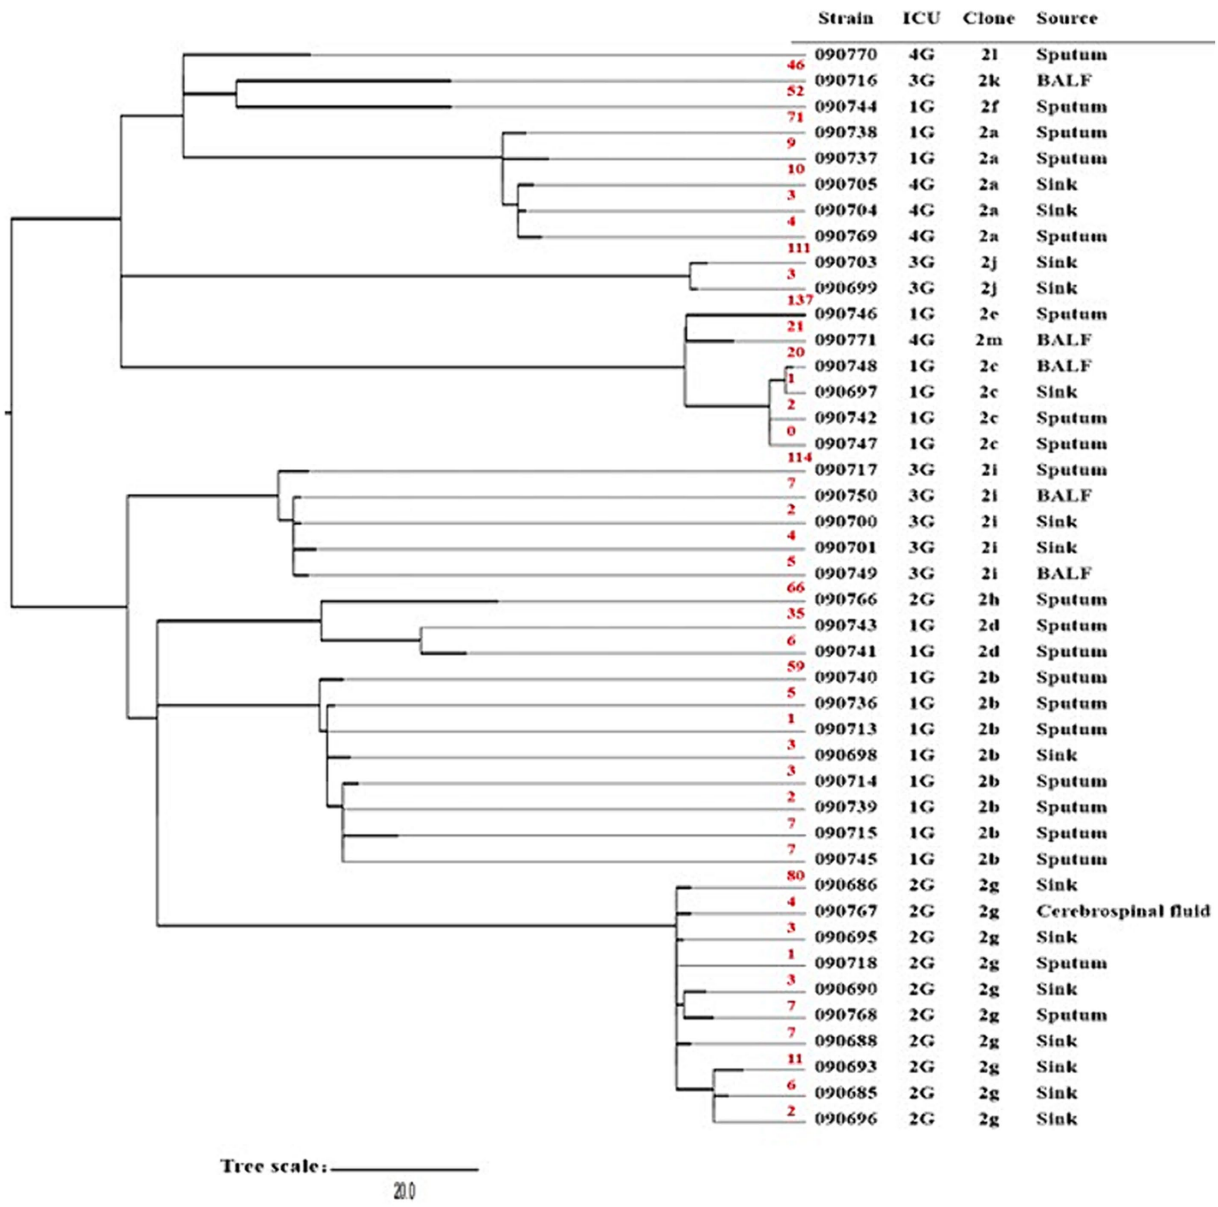

FIGURE 1
Phylogenetic trees of sequence type (ST) 2 carbapenem-resistant *Acinetobacter baumannii* strains. Shown are the strain name, the ICU where the strain was recovered (see Table 1), and the clone to which the strain belonged (see Table 2). The number of single-nucleotide polymorphisms between the adjacent two strains is indicated in red. Abbreviations: BALF, bronchoalveolar lavage fluid; ICU, intensive care unit.

isolate (5, 7, and 5, respectively); therefore, the sink isolate (090698) was likely to be contaminated but not the exact route of transmission.

Another isolate (090697) from another sink shared 0–2 SNPs with three clinical isolates (two isolates were recovered from sputum, and one was recovered from BALF) and therefore belonged to a common clone (clone 2c) (Figure 1), also indicating an outbreak in the ICU 1G. All three clinical isolates were recovered at a later date than the sink sampling date; therefore, the sink was likely to be the route of infection transmission. However, the two sink isolates in this ICU shared 117 SNPs, indicating that they were assigned to two strains. The remaining six clinical isolates belonged to four clones but were not the same as the two sink isolates from ICU 1G.

3.4 A clone of ST2 bla_{OXA-23} carrying CRAB transmission in two GICUs

There were five isolates (two clinical isolates from ICU 1G, one clinical isolate, and two sink isolates from ICU 4G) that only carried the bla_{OXA-23} gene and shared 3–10 SNPs (clone 2a) (Figure 1), suggesting interhospital transmission. These two sink isolates (090704 and 090705) were recovered approximately 3 months prior to the clinical isolate (090769); therefore, the sinks were likely to constitute the route of patient transmission. Although the two clinical isolates (090704 and 090705) from ICU 1G were recovered approximately 1 month prior to the two sink isolates from ICU 4G, the exact route of interhospital transmission remains unclear.

3.5 A high contamination rate of CRAB in the NICU and GICU at a hospital

There were 8 (7 from ICU 2G and 1 from ICU 2N) of the 15 sinks recovered CRAB isolates with a CRAB contamination rate as high as 53.3% in hospital 2. One sink isolate (090694) recovered from ICU 2N belonged to ST203, but no clinical isolate was obtained during the period of the study in this ICU. Therefore, ST203 CRAB was not a common cause of infection among patients. Seven sink isolates (six harboring both bla_{OXA-23} and bla_{OXA-66} and one isolate harboring both bla_{NDM-1} and bla_{OXA-98}) and three clinical isolates (two recovered from sputum and one recovered from cerebrospinal fluid) recovered from ICU 2G belonged to ST2, sharing 1–11 SNPs and belonging to a common clone (clone 2g) (Figure 1). Only one of the three clinical isolates (090718) was recovered earlier date than the sink sampling date and shared 2–5 SNPs with the other two clinical isolates (090767 and 090768). Compared to the seven sink isolates, the two isolates (090767 and 090768) shared 3–7 SNPs and 6–14 SNPs, respectively. Therefore, the sink was likely to be contaminated but not the exact route of the transmission. The remaining clinical isolate (090766) from ICU 2G belonged to a distinct clone (2h) and shared 35–142 SNPs with other isolates.

3.6 A cluster of ST2 bla_{OXA-23} and bla_{OXA-66}-carrying CRAB in a GICU

In ICU 3G, four sinks were contaminated by CRAB, which belonged to the ST2 type and carried both bla_{OXA-23} and bla_{OXA-66} genes. Two of the four sink isolates (090700 and 090701) shared 2–7 SNPs with three clinical isolates (090717, 090749, and 090750), indicating the presence of a common clone (clone 2i). Although one (090717) of the three clinical isolates was recovered at an earlier date than the sink sampling date, the other two (090749 and 090750) clinical isolates shared fewer SNPs (3–5 and 2–4) with the two sink isolates than with the clinical isolate (8, 7). Therefore, these two contaminated sinks were likely to be the route of the transmission. The other two sink isolates (090699 and 090703) shared three SNPs and belonged to another common clone (2j) (Figure 1). The remaining clinical isolate (090716) in this ICU belonged to clone (2k) alone, sharing 46–122 SNPs with other isolates.

4 Discussion

To our knowledge, this study was the first multicenter investigation on handwashing sink contamination by the CRAB in China. Unlike most studies in which the handwashing sink was sampled during an outbreak period, this study was conducted during a non-outbreak period in the included ICUs. The results showed that the contamination rate of handwashing sinks ranged from 0 to 63.6% in different ICUs, while other investigations did not find CRAB contamination in handwashing sinks during non-outbreak scenarios (31, 32). It has been well documented in the literature that the contamination level of handwashing sinks is related to the improper use, the size and depth of the sink, and the frequency of environmental cleaning (33). This study further revealed that the contamination rate of CRAB in handwashing sinks was significantly higher than that of carbapenem-resistant *klebsiella pneumoniae* (CRKP) or carbapenem-resistant *klebsiella oxytoca* (CRKO), with a rate of 10.1, 3.8, and 3.8%, respectively, during the same period, as we previously reported (25). This disparity may be attributed to the biofilm-forming capability of *Acinetobacter baumannii*, which enables it to survive on various surfaces more effectively than CRKP (34). In addition, the higher prevalence of CRAB compared to CRKP in local settings likely contributed to this difference (15).

All 27 clinical strains of CRAB obtained in our study were sourced from GICU, and this may be attributed to several factors: Patients in the GICU suffer from more severe illnesses, have longer hospital stays, experience higher rates of CRAB colonization, and are subjected to increased antibiotic usage (35, 36). Furthermore, a lack of awareness regarding the prevention and control of HAIs and insufficient cleaning and disinfection practices in GICU environments, including handwashing sinks, may contribute to CRAB infections among GICU patients (22, 37). In China, hospitals have already possessed relatively good resources for neonatal care and treatment (38), which likely results in fewer infections occurring in the NICU. It has been reported that CRAB strains carrying class B metallo-β-lactamase genes (e.g., bla_{NDM}, bla_{VIM}, and bla_{IMP}) are prevalent in pediatric populations (16, 39). However, our findings indicate that the dominant strains identified in the GICU sinks carried class D β-lactamase genes, specifically bla_{OXA-23}, with only one strain carrying bla_{NDM-1} isolated from a GICU sink.

In this study, we found that sink contamination by CRAB was not the major source of CRAB clinical infections in most ICUs in this study. However, at least three clones (clone 2c in ICU 1G, clone 2a in ICU 4G, and clone 2i in ICU 3G) of ST2 CRAB sink isolates were demonstrated to be the sources of patient infections or outbreaks. The results indicated that these three ICUs should take some proven measures to reduce the microbial contamination rate of sinks, including disinfection, use of drain covers, or even rebuilding the handwashing sink (21, 40, 41). In addition, we identified a transmission of clone 2a between two hospitals, along with two sink strains that were detected prior to a clinical strain in one of the hospitals. This finding underscores the need to pay close attention to hospital sewage contaminated with antibiotic-resistant bacteria (ARB) and antibiotic-resistant genes (ARGs) (42). Hospital sewage may serve as a potential reservoir for CRAB, highlighting the importance of strengthening disinfection, management, and monitoring protocols for hospital sewage in local settings (43).

ST2 is the most dominant type of CRAB in the world as well as in China (42). The main mechanism of carbapenem resistance in *Acinetobacter baumannii* is the acquisition of carbapenem-hydrolyzing oxacillinase-encoding genes, and bla_{OXA23} is by far the most widespread in most countries (44). In this study, all of the clinical isolates and all but one of the sink isolates belonged to ST2. The bla_{OXA-23} gene was also the most common (42/43, 97.7%) oxacillinase-encoding gene. In addition, we found that most CRAB isolates (37/43, 86.0%) carried both bla_{OXA-23} and bla_{OXA-66}, similar to the findings of other studies (45–48). One ST2 CRAB strain isolated from a sink, carrying both bla_{NDM-1} and $bla_{OXA-51-like}$ gene bla_{OXA-98}, was not reported previously, which was alarming.

A strain of ST203 CRAB was recovered from a sink in a NICU. Although ST203 *Acinetobacter baumannii* has been found in cats in France and Japan (49, 50), this is the first report of ST203 CRAB recovered from a hospital environment and harboring both bla_{OXA-23} and bla_{OXA-66}. Although there were no patients infected with this strain in our study, rigorous monitoring is needed to prevent the spread of ST203 CRAB from the sink to humans, especially neonates.

This study also has several limitations. First, the P traps of handwashing sinks were not sampled in our study, which means potential colonization by CRAB in these areas could have been missed. However, we sampled the drainage pipe 3–5 cm below the drainage tube,

A53210128

and the results can reflect the contamination degree of the drainage pipe to a certain extent. Second, the clinical strains were collected only within 2 weeks before and 3 months after sink sampling. There might have been additional cases of CRAB associated with sinks, which could have been missed. Third, sinks were only sampled once, and other environmental surfaces were not sampled; additional isolates from the sinks may have been missed. Despite these limitations, this study revealed the level of handwashing sink contamination by CRAB in different ICUs and the association of contaminated CRAB with hospital-acquired infections.

5 Conclusion

This study revealed that the contamination rate of CRAB in handwashing sinks was high in some local ICUs, and the contaminated sinks could serve as environmental reservoirs for CRAB clusters.

Data availability statement

The data presented in the study are deposited in the GenBank under BioProject repository, accession number PRJNA977829, available at https://www.ncbi.nlm.nih.gov/bioproject/?term=PRJNA977829.

Ethics statement

The studies involving humans were approved by the Ethical Committee of the West China Hospital. The studies were conducted in accordance with the local legislation and institutional requirements. The ethics committee/institutional review board waived the requirement of written informed consent for participation from the participants or the participants' legal guardians/next of kin because The study only used clinical strains and did not require sample collection for patients.

Key Words:
Drug-resistant *Acinetobacter baumannii* ST219
Hand hygiene sink
Intensive care unit
Oral care
Outbreak
Tap water

An outbreak of amikacin- and ciprofloxacin-resistant *Acinetobacter baumannii* ST219 in Tokai University hospital's emergency intensive care unit was caused by its colonization in water systems and subsequent spread through oral care using tap water. The outbreak was successfully controlled after replacement of the water system and implementation as of daily cleaning of water taps and oral care with a dry method. It is important to strictly manage the water system in critical care areas.

Acinetobacter baumannii has the capability of long-term survival in both dry and wet hospital environments.[1] This pathogen produces a biofilm in water and has been isolated from water systems in medical facilities.[2] We experienced an outbreak of amikacin- and ciprofloxacin-resistant (hereinafter designated drug-resistant [DR]) *A baumannii* in the emergency intensive care unit (EICU) at Tokai University Hospital. The drinking tap water had been contaminated as a reservoir, and thus oral care with this tap water was a route of transmission. Here we describe the study of this outbreak of DR *A baumannii* in the EICU and measures implemented to control infection.

MATERIALS AND METHODS

The advanced emergency and critical care center at Tokai University Hospital accepts approximately 7,000 ambulances and 2,600 admissions per year. The center has a total of 58 beds, including a 19-beds EICU, a 36-beds high care unit in the emergency ward, and a 3-beds burn unit.

In the bacteriological investigation of the transmission route, samples from environmental surfaces of critical and noncritical areas were collected by wiping with a sterile swab moistened with sterile normal saline and then inoculated on a 5% sheep's blood agar plate (Kyokuto Pharmaceutical Industrial Co, Ltd, Tokyo, Japan). Bacterial identification and antimicrobial sensitivity tests were performed with the MicroScan WalkAway 96 Plus System (Siemens, Erlangen, Germany). To confirm the identification of *A baumannii*, OXA-51−like genes were examined by polymerase chain reaction (PCR).

The DR *A baumannii* isolates were screened for gene homology according to repetitive-sequence-based (rep) PCR as described previously.[3] The genealogical tree was determined using DendroUPGMA (http://genomes.urv.cat/UPGMA/). Multilocus sequence typing (MLST) was performed as described previously.[4] The amplification products were purified with a Qiagen DNA Purification Kit (Qiagen, Venlo, The Netherlands). DNA sequencing was performed using an ABI PRISM 3730 DNA analyzer (Life Technologies, Carlsbad, CA). The MLST sequences were uploaded to the *A baumannii* MLST sequence type database (http://pubmlst.org/abaumannii/) to determine the alleles and sequence types. Clonal

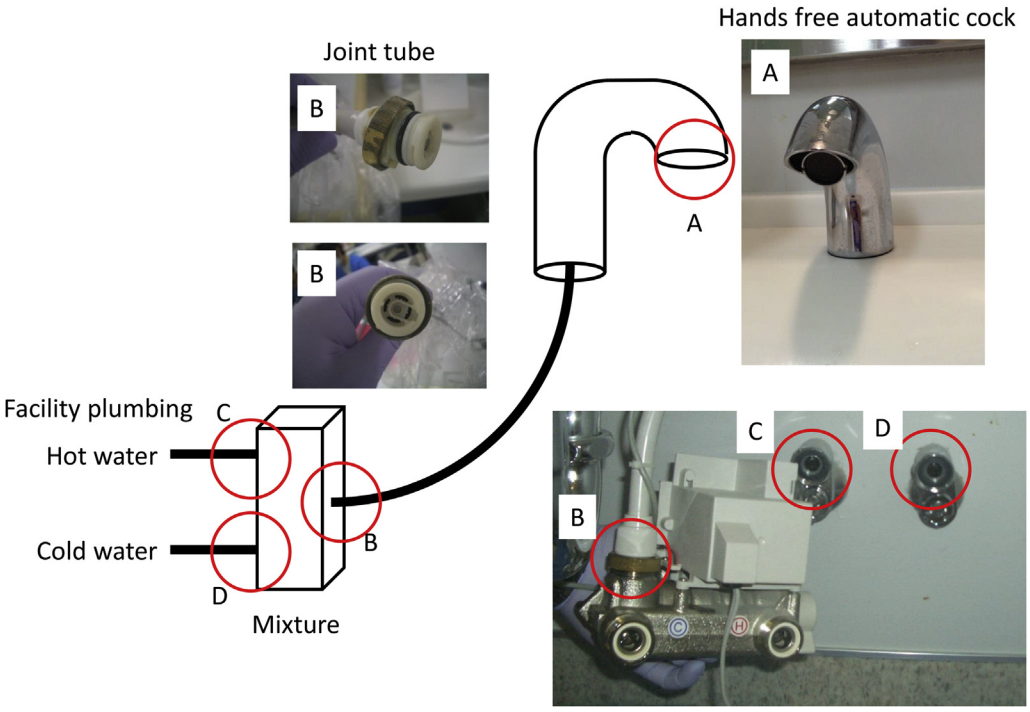

Fig 1. Bacterial investigations of parts of a hand hygiene sink in the EICU. DR *A baumannii* ST219 was isolated from a hands-free automatic tap (A) and water mixture side of the joint tube (B), but not the plumbing for either hot water (C) or cold water (D).

complexes were defined as single-locus variants or double-locus variants.

RESULTS

An outbreak of DR *A baumannii* was initially recognized in September 2013 from the aspirated sputum of tracheal intubation in a series of 3 patients under mechanical ventilation. An epidemiologic study revealed nothing shared by the 3 patients, including the patient flow, bed, respirator (closed airway suctioning system), medical staff, or care areas. Moreover, bacterial investigation of 29 medical staff hands was negative for the detection of DR *A baumannii* ST219. On environmental screening, DR *A baumannii* was detected on hands-free automatic taps of hand hygiene water sinks in critical areas of the EICU. Each component of the water sinks was subjected to a bacteriological investigation (Fig 1). DR *A baumannii* was isolated from the hands-free automatic tap (Fig 1A) and the joint tube on the mixture side (Fig 1B), but not from the plumbing for either hot water or cold water (Fig 1C and D). In addition to hand hygiene sinks, DR *A baumannii* was detected from other critical areas in the EICU environment, including the bronchoscope cabinet, the expectoration supporting device (CoughAssist), and plate sampling test.

On day 23 of the outbreak, use of all 10 hand hygiene water sinks was prohibited. The sinks, automatic taps, tubes, and hot and cold water mixture unit were replaced. Cleaning of the water tap was added to the daily sink cleaning routine. On day 26, the method of oral care was changed to a waterless technique, performed by wiping the teeth and gingiva with a swab after moistening the tissue with sterile water (dry oral care) under the guidance of a dental hygienist. Up to that time, conventional oral care had been performed by nurses using a toothbrush, toothpaste, and tap water while suctioning (wet oral care).

Finally, DR *A baumannii* was detected in sputum from 15 patients under tracheal intubation without pneumonia, all of whom had been receiving wet oral care. After the outbreak was controlled, DR *A baumannii* was not detected in the EICU in routine active surveillance cultures of any patients over the next 6 months.

DR *A baumannii* was detected in OXA-51–like genes by rep-PCR. The rep-PCR analysis revealed a high level of similarity in the patterns of all patient isolates and the hand hygiene sink samples (hands-free automatic tap and joint tube) (Fig 2A and B). The MLST analysis of all isolates of DR *A baumannii* obtained from the patients and the water system revealed the ST219 strain (Fig 2B). The clinical isolates of drug-sensitive *A baumannii* demonstrated the ST679 strain.

DISCUSSION

In this outbreak of DR *A baumannii*, oral care using contaminated tap water was identified as a transmission route. A waterless mouth care method proved useful in preventing further transmission. Oral hygiene is recommended as means of reducing the incidence of ventilator-associated pneumonia.[5] We had been adopting routine oral care using tap water, which was considered safe in Japan even without daily cleaning of taps. On the other hand, water sources in our hospital had recognized reservoirs for water-transmissible pathogens such as *A baumannii*.[6] Design and daily cleaning of sink and tap are important for prevention of latent colonization of *Acinetobacter* in the hand hygiene sink. To prevent such infections, wide and deep hand hygiene sinks with hands-free automatic water taps should be installed.[7]

MLST typing of DR *A baumannii* identified the outbreak of the ST219 strain. A few cases of infection with *A baumannii* ST219 have been reported as well.[8] *A baumannii* ST208 was implicated in an outbreak in the EICU and burn unit of Tokai University Hospital in 2010, where the air fluidity bed was identified as a reservoir.[9] It is likely that the EICU environment is readily contaminated with *A baumannii*, leading to a risk of contamination in the tap water in the hand hygiene sink via the hands of health care workers. To prevent future outbreaks, it is important to minimize the risk in the wet environmental reservoir, including sanitary strict management of water systems, particularly in critical care areas.

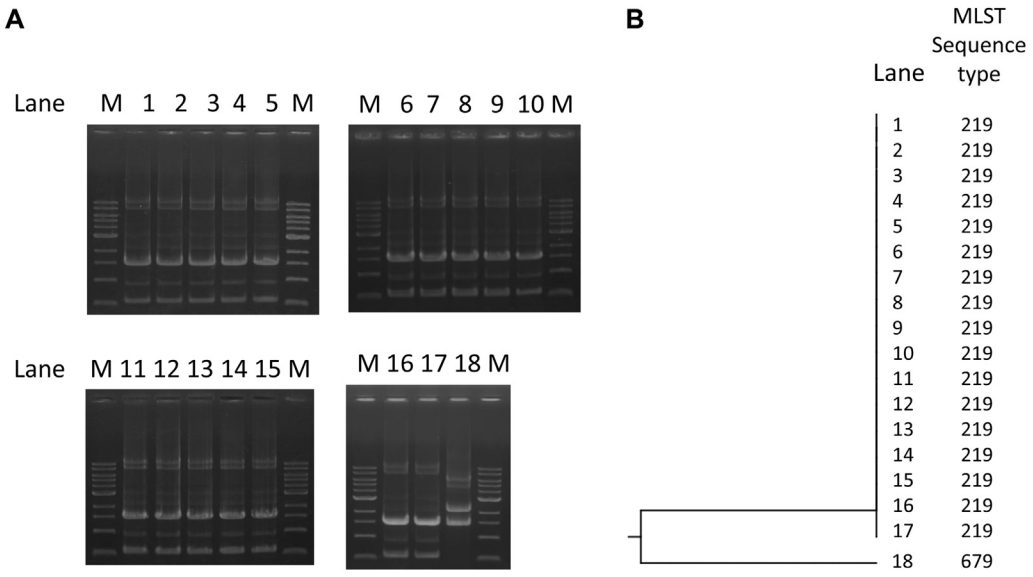

Fig 2. Molecular typing of the clinical isolates of DR *A baumannii* using rep-PCR and MLST. All of the isolates of DR *A baumannii* were subjected to molecular typing using rep-PCR, as shown in the electrophoretic analysis (A), as well as a genealogical tree and molecular typing using MLST (B). Lanes 1-15 indicate DR *A baumannii* isolated from the patients. Lanes 16 and 17 indicate DR *A baumannii* isolated from hands-free automatic tap and water mixture side of the joint tube, respectively. Lane 18 indicates a clinical isolate of drug-sensitive *A baumannii*. Lane M is a Marker.

Acknowledgment

We thank the staff of Support Center for Medical Research and Education of Tokai University for their technical assistance and the infection control nurses on the Tokai University Hospital emergency ward for their support in daily practice. Received 30 September 2016; returned 12 December 2016; revised 19 December 2016; accepted 6 January 2017

Objectives: OXA-48-like carbapenemases have spread worldwide since 2001. We analysed patient and microbiological data for UK isolates with these enzymes as confirmed by the national reference laboratory from November 2007 to December 2014.

Methods: MICs were determined using BSAC agar dilution. Isolates with reduced susceptibility or resistance to at least one carbapenem and high-level resistance to both piperacillin/tazobactam (MICs ≥64 mg/L) and temocillin (MICs ≥128 mg/L) were screened by PCR for $bla_{\text{OXA-48-like}}$ genes. The genomes of about half of the isolates were sequenced, with MLST types, resistance genes and plasmid replicon types inferred. Patient data provided by sending laboratories were reviewed.

Results: Isolates ($n = 741$) with OXA-48-like carbapenemases were submitted from 111 UK laboratories, representing 536 patients. Almost all (99%; 736 of 741) were Enterobacteriaceae, predominantly *Klebsiella pneumoniae* (55%; 408), and most (80%; 595) were from inpatients. WGS of 351 non-duplicate isolates identified $bla_{\text{OXA-48}}$ as the most common variant, found in two-thirds (235 of 351) of isolates, followed by $bla_{\text{OXA-181}}$ (68), $bla_{\text{OXA-232}}$ (32), $bla_{\text{OXA-244}}$ (10), $bla_{\text{OXA-484}}$ (5) and $bla_{\text{OXA-245}}$ (1). Among *K. pneumoniae* (163 of 351), *Escherichia coli* (114 of 351) and *Enterobacter cloacae* (42 of 351), 119 STs were identified. Mapping analyses revealed that 63% (222 of 351) of isolates harboured plasmids that shared >99% identity to one of four known plasmids [pOXA-48a (44%; 154 of 351), pOXA-232 (10%; 34 of 351), pOXA181 (9%; 30 of 351) and pKP3-A (1%; 4 of 351)]; the remaining 37% of isolates harboured $bla_{\text{OXA-48-like}}$ in unknown environments.

Conclusions: OXA-48-like carbapenemases are an increasing problem in the UK. This study highlights both the role of successful plasmids and the polyclonal nature of their dissemination.

Introduction

OXA-48-type carbapenemases were first identified in 2001 in a carbapenem-resistant *Klebsiella pneumoniae* isolate from the urine of a patient hospitalized in Istanbul, Turkey.[1] Since then, reports of infections caused by OXA-48-producing Enterobacteriaceae have escalated—particularly in Europe, Asia and Africa, and less so in the Americas.[2–5] There are six carbapenem-hydrolysing class D β-lactamase (CHDL) subgroups that are clinically significant: OXA-23, OXA-24/40, OXA-48, OXA-51, OXA-58 and OXA-143.[6] All except the OXA-48 group are predominantly found in *Acinetobacter* spp. isolates,[6] whereas OXA-48 enzymes are usually found in Enterobacteriaceae.[5] To date, 14 OXA-48-like variants have been described (OXA-48, -162, -163, -181, -199, -204, -232, -244, -245, -247, -370, -405, -436 and -484) of which 11 are CHDLs. These vary in sequence by one to five amino acids from the 'classical' OXA-48 variant and hydrolyse penicillins and carbapenems, but not extended-spectrum cephalosporins (e.g. cefepime and ceftazidime).[1] In contrast to their CHDL counterparts, OXA-163, -247 and -405 also differ from OXA-48 by one or two amino acids, but additionally have a four amino acid deletion in the active site region; as a result they lack significant carbapenemase activity, but do exhibit increased activity toward extended-spectrum cephalosporins.[7–9]

$bla_{\text{OXA-48}}$ has only been found in Enterobacteriaceae and has been associated with outbreaks in Turkey, the Middle East and North Africa.[5,10] Other variants have different geographical associations: in particular $bla_{\text{OXA-181}}$ and $bla_{\text{OXA-232}}$ have been epidemiologically linked to the Indian subcontinent and are often co-harboured with NDM enzymes.[11,12]

The proliferation of OXA-48-like enzymes has been attributed both to successful clones and to plasmid spread. In 2011, OXA-48-positive *K. pneumoniae* ST395 was identified in patients in Morocco,

the Netherlands and France, suggesting the country-to-country transfer of this clone,[13] with patient-linked transfer of OXA-48-producing *Enterobacter cloacae* from Morocco to France also documented.[14] On the other hand, pOXA-48a, a 61.9 kb self-conjugative IncL/M plasmid, was shown to be the primary vehicle for dissemination of bla_{OXA-48} in several outbreaks.[5,15] This broad host range plasmid harbours bla_{OXA-48} within Tn*1999* and occurs across several enterobacterial species.[5,15]

This study describes the epidemiology of OXA-48-like carbapenemase producers submitted to PHE's Antimicrobial Resistance and Healthcare Associated Infections (AMRHAI) Reference Unit between 2007 and 2014.

Materials and methods

Bacterial isolates, identification and susceptibility testing

Isolates were submitted to PHE's AMRHAI Reference Unit from clinical laboratories across the UK between November 2007 and December 2014 for investigation of unusual resistance, including to carbapenems.

Bacterial identification was carried out using chromogenic agars [CHROMagar™ Orientation (CHROMagar, Paris, France) and Brilliance UTI (Oxoid, Basingstoke, UK)] together with API-20E tests (bioMérieux SA, Marcy-l'Étoile, France) or, since August 2012, by MALDI-TOF MS (Bruker Microflex LT; Bruker Daltonik GmbH, Bremen, Germany).

Antibiotic susceptibilities (MICs) were determined by BSAC agar dilution[16] using AMRHAI's standard Gram-negative antibiotic panel, which includes ertapenem, meropenem and imipenem (the latter with/without 320 mg/L EDTA to detect metallo-carbapenemases), and interpreted using EUCAST breakpoints.[17]

Screening for carbapenemase genes

Isolates displaying high-level resistance to piperacillin/tazobactam (MICs ≥64 mg/L) and temocillin (MICs ≥128 mg/L), as well as reduced susceptibility or resistance to any carbapenem, were tested for $bla_{OXA-48-like}$ genes by in-house PCR[1] and/or with a commercial microarray (Check-MDR CT102; Check-Points, Wageningen, The Netherlands).[18] In instances where imipenem potentiation by EDTA was observed, isolates were also tested by PCR for the presence of metallo-carbapenemases (bla_{NDM}, bla_{VIM}, bla_{IMP}, bla_{GIM}, bla_{SIM} and bla_{SPM}) by in-house PCRs.[19]

WGS and analyses

Three hundred and seventy isolates, temporally and geographically distributed throughout the study, were selected for WGS. Genomes were sequenced using the Nextera sample preparation method with the standard 2× 100 base sequencing protocols on a HiSeq instrument (Illumina, San Diego, CA, USA). Data were analysed using an in-house bioinformatics pipeline as previously described.[20] STs were inferred from WGS data where MLST schemes exist.

For plasmid analysis, sequencing reads were mapped against known OXA-48 plasmids, namely pOXA-48a (NC_019154), pOXA-232 (JX423831), pKP3-A (NC_019160) and pOXA181 (KP400525).

Analysis of patient demographic information

Patient data were obtained from the request forms sent with submissions from referring laboratories. A patient was categorized as 'new' if they were found to have OXA-48-like-positive isolates detected by AMRHAI for the first time and 'known' if any OXA-48-like-positive isolate, irrespective of species, had previously been identified from the patient by AMRHAI.

Results

Demographics of affected patients and distribution

During the study period, AMRHAI confirmed 741 OXA-48-like positive isolates from 111 laboratories throughout the UK and obtained from 536 patients. Figure 1 illustrates the temporal distribution of these isolates among 'new' and 'known' patients, and among submitting laboratories. The first OXA-48-like positive isolate was a *K. pneumoniae*, submitted to AMRHAI in November 2007 and obtained from the urine of a patient previously hospitalized in Turkey.[10]

Isolates with OXA-48-like carbapenemases were submitted from laboratories across all UK regions. The national distribution of affected patients was as follows: England ($n = 514$), Scotland ($n = 13$), Northern Ireland ($n = 6$) and Wales ($n = 3$). The greatest number of affected patients was in the London region ($n = 203$), followed by the North West ($n = 143$).

Most source patients were hospitalized (79%; 421 of 536), but a few were outpatients (7%; 38 of 536), in primary care (8%; 41 of 536) or in unknown settings (7%; 36 of 536). The mean patient age was 59.5 years and 54% (289 of 536) were male.

A travel history was reported for 130 of 536 (24%) patients. Of these, 55 patients had documented foreign travel to the following destinations: India (12), Turkey (9), Pakistan (5), Egypt (4), Libya (4), Spain (4), Kuwait (3), Malta (3), Sri Lanka (2), Tunisia (2) and single patients had travelled to Cyprus, Kenya, Morocco, Russia, Saudi Arabia, Singapore and Syria. Twenty patients were known to have been hospitalized while abroad in Egypt (4), Libya (4), Turkey (4), India (3), Pakistan (2), Cyprus (1), Spain (1) and Sri Lanka (1).

Single OXA-48-like-positive isolates were referred from 408 of 536 (76%) patients and multiple isolates from the remaining 128 (24%). Among the patients with multiple OXA-48-like-positive isolates, 43 of 128 (34%) yielded isolates of different species or genera and 63 of 128 (49%) had isolates referred from different anatomical sites. The OXA-48-like-positive isolates were referred over a period of <14 days in 65 of 128 (51%) instances, for 17 of 128 over a period of 14–28 days, 38 of 128 over a period of 1–6 months and over a period >6 months from 8 patients. Seventeen percent (127 of 741) of isolates were submitted from a single laboratory (laboratory 1), which serves three hospitals (to be subsequently known as hospitals A, B and C), over a 2 year period. Further details of the isolates from this laboratory are given below.

Microbiology

Most (99%; 736 of 741) submitted isolates were Enterobacteriaceae, comprising: *K. pneumoniae* (55%; 408 of 741), *Escherichia coli* (29%; 218 of 741), *Enterobacter* spp. (9%; 68 of 741), *Klebsiella oxytoca* (3%; 24 of 741), *Citrobacter* spp. (2%; 14 of 741), *Serratia marcescens* (>1%; 3 of 741) and one *Raoutella ornithinolytica*. There were also five non-Enterobacteriaceae isolates comprising *Pseudomonas aeruginosa* ($n = 3$; all from one patient)[21] and *Shewanella* spp. ($n = 2$; OXA-48-like enzymes are intrinsic in this genus).

If samples rather than patients were considered as the denominator, most were taken in hospitals (89%; 656 of 741), but some were general practice urines (6%; 45 of 741) and a few from unknown settings (5%; 40 of 741). The most frequently reported specimen type was urine (29%; 215 of 741), followed by faeces or

Downloaded from https://academic.oup.com/jac/article/72/5/1340/2990247 by guest on 04 June 2025

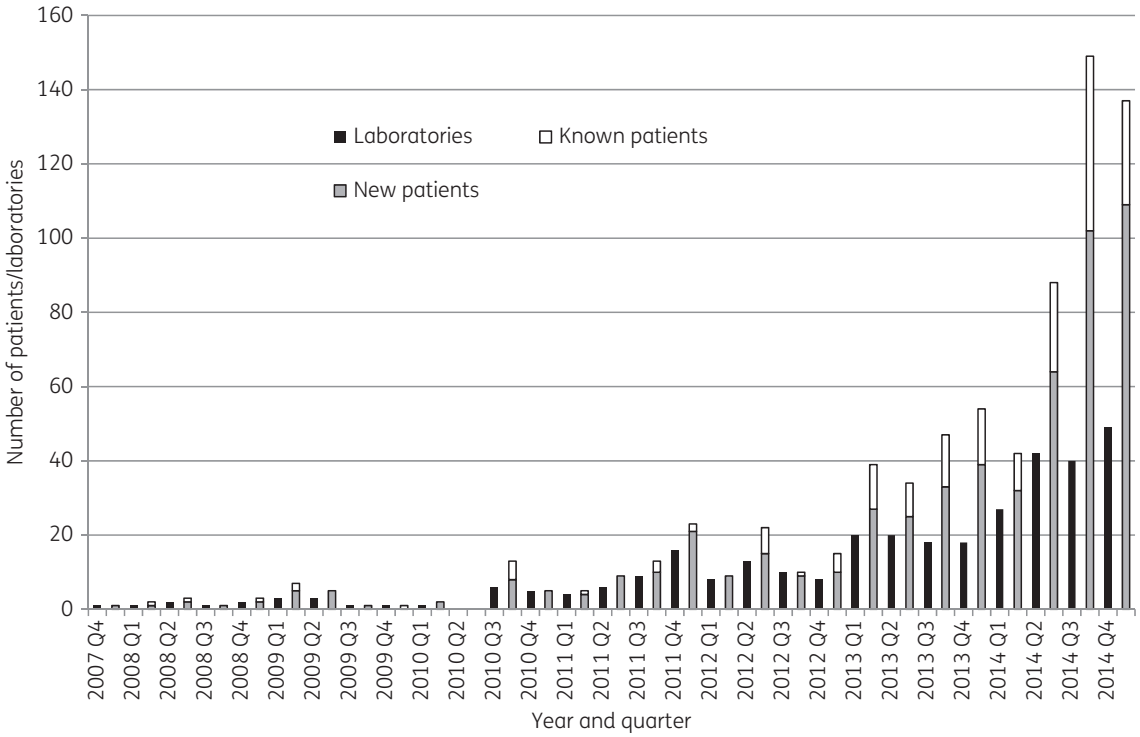

Figure 1. Numbers of new and known affected patients and laboratories sending OXA-48-positive isolates per quarter during the study period.

rectal swabs (27%; 202 of 741). Fifteen percent (110 of 741) of isolates were obtained from tissue and fluid samples, 11% (83 of 741) from blood cultures and line tips, 9% (68 of 741) from screening swabs, 5% (40 of 741) from respiratory samples and 3% (23 of 741) were unknown specimen types (Table 1).

Carbapenemase alleles and typing of the isolates

WGS was undertaken for 351 non-duplicate isolates from single patients and their STs (where MLST schemes exist) and carbapenemase alleles were defined. These comprised: *K. pneumoniae* ($n = 163$), *E. coli* ($n = 114$), *E. cloacae* ($n = 42$), *K. oxytoca* ($n = 13$), *Citrobacter* spp. ($n = 11$), other *Enterobacter* spp. ($n = 5$), *S. marcescens* ($n = 2$) and *P. aeruginosa* ($n = 1$). Their carbapenemase genes comprised: $bla_{\text{OXA-48}}$ (66%; 230 of 351), $bla_{\text{OXA-181}}$ (18%; 62 of 351), $bla_{\text{OXA-232}}$ (7%; 24 of 351), $bla_{\text{OXA-244}}$ (3%; 10 of 351), $bla_{\text{OXA-245}}$ (<1%; 1 of 351), $bla_{\text{OXA-484}}$ (1%; 5 of 351), $bla_{\text{OXA-48}} + bla_{\text{NDM-1}}$ (1%; 5 of 351), $bla_{\text{OXA-181}} + bla_{\text{NDM-1}}$ (2%; 6 of 351) and $bla_{\text{OXA-232}} + bla_{\text{NDM-1}}$ (2%; 8 of 351). The carbapenemase variants and allele combinations OXA-48, OXA-181, OXA-48 + NDM-1 and OXA-181 + NDM-1 were found in multiple species. OXA-232, OXA-245, OXA-484 and OXA-232 + NDM-1 were found only in *K. pneumoniae* isolates, while OXA-244 was found only in *E. coli* isolates. Numerous other genes encoding resistance to several other classes of antibiotics were also detected throughout all species (Table 2). Overall, 19 of 351 (5%) isolates had OXA-48-like enzymes together with another carbapenemase, 266 of 351 (76%) also harboured a predicted ESBL or plasmid-encoded AmpC and 85 of 351 (24%) had OXA-48-like enzymes without any of these additional β-lactamase types.

K. pneumoniae

One hundred and sixty-three non-duplicate *K. pneumoniae* isolates, from 56 laboratories across 10 UK regions, were sequenced. Individual laboratories submitted between 1 and 15 isolates. Forty-nine STs were identified, the most frequent being ST14 (27 isolates from 17 centres over 16 months), followed by ST231 (18 from 14 centres over 15 months), ST147 (17 from 13 centres over 7 years), ST101 (13 from 10 centres over 4 years), ST11 (10 from 7 centres over 16 months) and ST16 (6 from 5 centres over 3 months). The remaining 43 STs were each represented by five isolates or fewer. Five OXA-48-like variants were identified [$bla_{\text{OXA-48}}$ ($n = 86$), $bla_{\text{OXA-181}}$ ($n = 31$), $bla_{\text{OXA-232}}$ ($n = 24$), $bla_{\text{OXA-484}}$ ($n = 5$) and $bla_{\text{OXA-245}}$ ($n = 1$)] and 16 isolates produced more than one carbapenemase [$bla_{\text{OXA-48}} + bla_{\text{NDM-1}}$ ($n = 3$), $bla_{\text{OXA-181}} + bla_{\text{NDM-1}}$ ($n = 5$) and $bla_{\text{OXA-232}} + bla_{\text{NDM-1}}$ ($n = 8$)].

Multiple plasmid replicon types were identified including IncL/M, IncA/C, several IncF variants, IncHI2, IncX3 and ColE-like replicons. Plasmid mapping revealed that 70 of 86 (81%) isolates with OXA-48 enzymes and 1 with OXA-245 had plasmids exhibiting >99% sequence identity to pOXA-48a, whereas among the 31 with OXA-181 enzymes 8 (26%) and 5 (16%) had plasmids with >99% sequence identity to pOXA181 and pKP3-A, respectively. All 32 isolates with OXA-232 enzymes had plasmids exhibiting >99% sequence identity to pOXA-232. pOXA-48a sequences were found in 37 STs, most frequently ST11 ($n = 8$) and ST101 ($n = 9$), whereas pOXA181 sequences were found in five STs (ST11, ST61, ST25, ST307 and ST709), each with one to three representatives; pKP3-A sequences were found in two STs, with one representative (ST395) and four representatives (ST147), respectively. pOXA-232 sequences were found in seven STs (ST14, ST15, ST16,

ST147, ST231, ST307 and ST395), most often ST14 (15 isolates from 13 centres), ST231 (11 from 8 centres) and ST147 (3 from 2 centres).

The earliest UK isolate with an OXA-48-like enzyme dated from 2007 and was from a patient who had previously been hospitalized in Turkey.[10] It was shown here to belong to ST147 and to harbour a pOXA-48a-like plasmid.

The most frequent submitter, laboratory 1, sent 15 isolates that were subjected to WGS over 22 months—13 of which were obtained from hospital A. These 15 represented 11 STs and all harboured plasmids with >99% sequence identity to pOXA-48a.

E. coli

One hundred and fourteen non-duplicate *E. coli* isolates, from 49 laboratories across seven UK regions, were sequenced. Laboratories submitted between 1 and 16 isolates and 37 STs were identified. The most frequent of these were ST38 (53 isolates from 34 laboratories over 42 months) and ST410 (12 from 9 laboratories over 20 months). The remaining 35 STs were each represented by four isolates or fewer. Three OXA-48-like variants were identified [$bla_{\text{OXA-48}}$ ($n = 74$), $bla_{\text{OXA-181}}$ ($n = 30$) and $bla_{\text{OXA-244}}$ ($n = 10$)].

Multiple plasmid replicon types were identified including IncL/M, several IncF replicons, IncB/O, IncHI2, IncK and IncX3. Plasmid analyses revealed that 22 of 74 (30%) *E. coli* with OXA-48 enzymes had plasmids exhibiting >99% sequence identity to pOXA-48a, and 22 of 30 (73%) of those with OXA-181 had plasmids that exhibited >99% sequence identity to pOXA181. pOXA-48a sequences were found in 17 STs, each with one to four representatives. pOXA181 sequences were found in 10 STs, predominantly ST410 ($n = 11$), which were submitted from eight laboratories across five regions. No plasmid could be identified in 70 isolates. Of these, 50 belonged to ST38, 41 of them harbouring $bla_{\text{OXA-48}}$ and 9 harbouring $bla_{\text{OXA-244}}$. The most frequent submitter, laboratory 1, sent 16 isolates that were subject to WGS over a 21 month period (14 of which were obtained from hospital A); these represented 14 STs, all had OXA-48 and 12 of 16 (75%) harboured pOXA-48a sequences.

Enterobacter spp.

Forty-seven non-duplicate *Enterobacter* spp. isolates, sent from 15 laboratories across seven UK regions, were sequenced. These comprised: *E. cloacae* ($n = 42$), *Enterobacter aerogenes* ($n = 4$) and *Enterobacter hormaechei* ($n = 1$). Individual laboratories submitted between 1 and 27 isolates. Forty-five isolates harboured $bla_{\text{OXA-48}}$ and the remaining two isolates harboured $bla_{\text{OXA-48}} + bla_{\text{NDM-1}}$. Thirteen STs were identified among the *E. cloacae* isolates, each with between 1 and 17 representatives. The most frequently

obtained ST was ST108 (17 isolates from two centres over 15 months); the remaining 12 STs were represented by ≤5 isolates. Multiple plasmid replicon types were identified including IncL/M, IncN, IncHI1 and several IncF replicons. Plasmid mapping revealed that 42 of 47 (89%) isolates had DNA exhibiting >99% sequence identity to pOXA-48a. These comprised 40 *E. cloacae* and single isolates of *E. aerogenes* and *E. hormaechei*. Thirteen STs were identified among the 40 *E. cloacae* isolates, but predominantly ST108 with 17 representatives. Most were submitted (16 of 17) from laboratory 1 and 14 of 16 were obtained from hospital A, over a 3 month period. Fifteen of these 16 (94%) harboured pOXA-48a sequences. In total, over half (27 of 48) of the *Enterobacter* spp. isolates with OXA-48-like enzymes were submitted by laboratory 1 over a 15 month period—26 of which were obtained from hospital A, with these comprising 25 *E. cloacae* and 1 *E. hormaechei*. All 26 isolates produced OXA-48 and the 25 *E. cloacae* isolates represented 5 STs.

K. oxytoca

Thirteen non-duplicate *K. oxytoca* isolates, sent from seven laboratories across four UK regions, were sequenced, with individual laboratories submitting between one and four isolates. All harboured the classical bla_{OXA-48} variant. Five STs were identified, namely ST176 (six isolates from five centres in four regions), ST27 (four isolates from one centre in 1 month) and single representatives of ST36, ST95 and ST168. Multiple plasmid replicons were identified including IncL/M, IncHI2 and several IncF replicons. Plasmid mapping analyses revealed that all isolates shared >99% sequence identity to plasmid pOXA-48a.

Other species

The remaining 14 isolates that were sent for WGS comprised: *Citrobacter freundii* ($n = 9$), *Citrobacter koseri* ($n = 2$), *S. marcescens* ($n = 2$) and *P. aeruginosa* ($n = 1$). All harboured classical bla_{OXA-48} except for one *C. freundii* isolate, which harboured $bla_{OXA-181} + bla_{NDM-1}$, and the *P. aeruginosa* isolate that had $bla_{OXA-181}$. The *P. aeruginosa* isolate was previously found to belong to ST773 with $bla_{OXA-181}$ encoded within Tn*2013*.[21] Plasmid replicon types included IncL/M, several IncF replicons and IncA/C. Within the nine *C. freundii* isolates eight STs were identified. Five of these were obtained from inpatients in hospital A, three of which harboured pOXA-48a sequences. In the remaining isolates, two *C. koseri* isolates that produced OXA-48 shared >99% identity to plasmid pOXA-48a and one OXA-181-producing *C. freundii* isolate shared >99% identity to pKP3-A.

Antibiotic susceptibility

MIC distributions for OXA-48-like-positive isolates are shown in Table 3. Ninety-nine percent (724 of 728) of isolates with available susceptibility data were resistant or non-susceptible to ertapenem; however, 42% (312 of 735) and 54% (400 of 735) remained susceptible to imipenem and meropenem, respectively, based on EUCAST breakpoints. In all but eight cases, MICs of meropenem were above the EUCAST screening cut-off concentration of 0.125 mg/L.[22] For the remaining eight cases the imipenem MICs were also below the EUCAST screening cut-off of 1 mg/L, but were above the ertapenem MIC cut-off of 0.125 mg/L. All eight isolates were *E. coli* and the analysis of seven of these by WGS indicated that six different STs and two OXA-48-like variants [bla_{OXA-48} (five) and bla_{OXA181} (two)] were represented. Piperacillin/tazobactam resistance (MIC >16 mg/L) was observed in 732 of 734 of tested isolates (data not shown). All the isolates that co-produced either NDM or VIM enzymes were non-susceptible to all three carbapenems. Non-susceptibility to ceftazidime and cefotaxime was observed in 69% and 89% of isolates. Non-susceptibility to the aminoglycosides amikacin, gentamicin and tobramycin was observed in 26%, 55% and 61% of isolates, respectively. Almost all (28 of 34) isolates that co-produced another carbapenemase were non-susceptible to all three aminoglycosides and all were resistant to ciprofloxacin. Most (91%; 659 of 722) isolates were susceptible to colistin.

Colistin resistance was observed in 63 isolates, submitted from 32 laboratories over 6 years, the majority (54 of 63) of which were *K. pneumoniae* and had MICs in the range of 4 to >32 mg/L. Sequencing of 22 of 54 colistin-resistant *K. pneumoniae* isolates identified 10 STs, 6 of which were represented by a single isolate and the 4 remaining STs were as follows: ST14 (6), ST101 (4), ST147 (2) and ST231 (4). These 22 were submitted from 14 laboratories across five regions. For 10 isolates colistin MICs were >32 mg/L; these comprised 7 *K. pneumoniae* and 1 *E. coli* along with 2 *S. marcescens* with inherent resistance. These were referred from 10 laboratories across four regions. Non-susceptibility to ciprofloxacin and tigecycline was observed in 63% and 32% of isolates, respectively.

Discussion

This report reviews all isolates producing an OXA-48-like carbapenemase and referred to PHE's AMRHAI Reference Unit from laboratories across the UK between November 2007 and December 2014. Over this study period, 741 OXA-48-like-positive isolates were obtained from 536 patients across all UK regions.

The majority of isolates were from clinical specimens, predominantly urines. All isolates were resistant to at least two classes of antibiotics and most were non-susceptible at EUCAST breakpoints to at least one of the three carbapenems tested. A high rate of susceptibility was maintained only to colistin (91%), with amikacin (74%) and tigecycline (68%) next in rank order. High levels of resistance to the third-generation cephalosporins, ceftazidime and cefotaxime, could be attributed to the co-carriage of ESBL/AmpC enzymes in 76% of sequenced isolates. There was huge variation in susceptibility to other antibiotics tested in this study, attributable to the presence of a plethora of other resistance genes, as identified in the WGS analyses (Table 2), sometimes including other carbapenemase genes—5% (34 of 741) of isolates with OXA-48-like enzymes also harbouring either a bla_{NDM} (33 of 741) or bla_{VIM} (1 of 741) allele. It follows that there can be no 'standard' antibiotic regimen for the treatment of infections caused by OXA-48-like producers without additional susceptibility testing and/or resistance gene data, although ceftazidime/avibactam shows promise based on *in vitro* data.[23] Although colistin, tigecycline and amikacin retained the highest levels of susceptibility their individual indications may make them unsuitable for the treatment of some infections. For example, tigecycline cannot be used for the treatment of urinary tract infections[24] and colistin use has been associated with both neurotoxicity and nephrotoxicity.[25]

[a]MIC greater than or equal to indicated value.
[b]MIC less than or equal to indicated value.
[c]Other spp. comprise *P. aeruginosa* and *Shewanella* spp.

At the time of writing, there are 14 known OXA-48-like variants, 11 of them CHDLs, and WGS analysis of 351 non-duplicate UK isolates identified 5 of the CHDL types. OXA-48 was by far the most common variant, found in two-thirds (235 of 351) of isolates. The earliest OXA-48-positive isolate identified in the UK was obtained in 2007 from a patient who had recently been hospitalized in Turkey; this isolate was shown here to be an ST147 *K. pneumoniae* carrying a plasmid with >99% identity to pOXA-48a. pOXA-48a has been implicated in early OXA-48 dissemination in Turkey.[15,26]

A travel history was available for only 24% of patients, of whom 42% had documented travel to 17 different countries, several of which have previously reported outbreaks involving bacteria with OXA-48-like enzymes.[2,4,5,27] All five patients with reported travel to Turkey and six of seven with travel to other Middle Eastern or North African countries whose isolates were analysed by WGS were found to carry organisms with bla_{OXA-48}, as repeatedly found in Turkey.[26,27] By contrast, both OXA-181 and OXA-232 have been associated with the Indian subcontinent,[12,28] and were found in 12 of 13 sequenced isolates from patients reporting travel to India, Pakistan or Sri Lanka. These data further underscore the role that international travel may play in carbapenemase dissemination. Notably four *K. pneumoniae* with OXA-48-like enzymes were from patients transferred to the UK for intensive care treatment of injuries received during the Libyan 'Emergency' of 2011.

Forty-four percent (154 of 351) of sequenced isolates and 153 of 235 of those with classical bla_{OXA-48} possessed DNA with >99% sequence identity to pOXA-48a, an IncL/M plasmid of ~62 kb first associated with bla_{OXA-48}, in Turkey and North Africa and now with multiple polyclonal and cross-species outbreaks.[15] pOXA-48a-like sequences were found here in multiple species and STs. Except for one isolate with $bla_{OXA-245}$ these all carried bla_{OXA-48}. The demonstration of both the broad range and success of this plasmid supports an earlier and much smaller analysis where we found IncL/M OXA-48 plasmids among several enterobacterial species and STs.[10] Of the remaining 197 isolates sequenced, 68 carried DNA with >99% identity to one of three plasmids: pOXA-232 (32 of 68), pOXA181 (30 of 68) or pKP3-A (6 of 68). pOXA-232 and pKP3-A are ColE-like plasmids, of ~6 and 7.6 kb, respectively, originally discovered in *E. coli* and *K. pneumoniae* isolates obtained from patients following hospitalization in India.[28,29] All of the 32 sequenced isolates harbouring $bla_{OXA-232}$ and 6 of 69 isolates with $bla_{OXA-181}$ contained sequences with >99% sequence identity to pOXA-232 and pKP3-A, respectively. Thirty further isolates with OXA-181 enzymes were shown to carry DNA with >99% sequence identity to pOXA181, an IncX3 plasmid of ~51.5 kb that was first found in an *E. coli* ST410 isolate obtained from the blood sample of a patient in China who had no history of travel to the Indian subcontinent.[30]

We found $bla_{OXA-48-like}$ genes in multiple species and STs and that some clones were particularly successful as a vehicle for $bla_{OXA-48-like}$ dissemination. In *K. pneumoniae* some STs (such as ST14 and ST147) were associated with multiple OXA-48-like plasmids, indicating the success of the ST, but not indicating expansion of a specific clone/plasmid pairing. Although *K. pneumoniae* ST395 has been associated with outbreaks in Europe and Morocco,[13] we found only two representatives among those sequenced and these harboured different OXA-48-like variants, bla_{OXA-48} and $bla_{OXA-181}$, in different genetic environments; one in a pKP3-A sequence and the other in an unidentified environment.

Downloaded from https://academic.oup.com/jac/article/72/5/1340/2990247 by guest on 04 June 2025

Rather alarmingly, 16% of isolates were submitted from a single hospital, hospital A, representing at least six species and 33 STs. Within the 61 isolates from hospital A that were sequenced, most (54 of 61) harboured pOXA-48a sequences. This suggests the local spread of pOXA-48a among different genera, species and STs within this hospital and is indicative of the success of pOXA-48a in dissemination.

In contrast to the ST diversity among *K. pneumoniae* isolates with OXA-48-like enzymes ST38 accounted for almost half of all the sequenced *E. coli* isolates with OXA-48-like enzymes (53 of 114). ST38 has previously been associated with bla_{CTX-M} carriage in multiple countries.[31] Plasmid mapping could not establish a location for bla_{OXA-48} in most (50 of 53) of these isolates. In a previous study[10] the authors failed to obtain any plasmid transformants from ST38 isolates and, more recently, it was reported that bla_{OXA-48} and $bla_{OXA-244}$ can be chromosomally encoded in ST38 isolates.[32] This may apply here, but establishing this would require utilization of longer read sequencing techniques (e.g. PacBio and MinION).

In conclusion, this study has shown an increase in OXA-48-like enzymes in the UK over a 7 year period. We suggest that the accumulation of OXA-48-like carbapenemases within the UK is due to repeated import, coupled with both the dissemination of successful plasmids, notably pOXA-48a, and the spread of successful clones (e.g. *E. coli* ST38); the linkage to plasmid spread was particularly strong.

Acknowledgements

We are grateful to colleagues in UK hospitals for sending these isolates to us. We also thank colleagues in AMRHAI and the Genomic Services and Development Unit for genomic DNA preparation and carrying out Illumina sequencing on isolates.

Funding

This work was funded internally.

Contaminated Handwashing Sinks as the Source of a Clonal Outbreak of KPC-2-Producing *Klebsiella oxytoca* on a Hematology Ward

We investigated sinks as possible sources of a prolonged *Klebsiella pneumonia* carbapenemase (KPC)-producing *Klebsiella oxytoca* outbreak. Seven carbapenem-resistant *K. oxytoca* isolates were identified in sink drains in 4 patient rooms and in the medication room. Investigations for resistance genes and genetic relatedness of patient and environmental isolates revealed that all the isolates harbored the bla_{KPC-2} and bla_{TEM-1} genes and were genetically indistinguishable. We describe here a clonal outbreak caused by KPC-2-producing *K. oxytoca*, and handwashing sinks were a possible reservoir.

The prevalence of carbapenem-resistant *Enterobacteriaceae* has increased over the past 10 years (1). The production of *Klebsiella pneumonia* carbapenemases (KPCs) is one way of conferring resistance to carbapenems belonging to Ambler class A (2). Nosocomial infections due to KPC-producing *Enterobacteriaceae* are of increasing concern, especially in long-term care facilities and intensive care units (ICUs) (2). In 2011, a nosocomial outbreak of KPC-producing *Klebsiella oxytoca* occurred in a medical ICU at the Medical University of Graz in Graz, Austria. Five patients, all of whom survived, were affected (3).

From October 2011 to October 2013, KPC-producing *K. oxytoca* isolates with resistance patterns identical to that of the outbreak strain were identified from 10 more patients in the Division of Hematology ward. As *K. oxytoca* isolates were detected over a 2-year period, a reservoir in the environment was suspected. Nosocomial outbreaks with *K. oxytoca* have been reported previously (4–10). In two publications, handwashing sinks, especially sink drains, were identified as the source of the outbreaks (9, 10).

The aim of this study was to investigate sink drains as possible sources of the KPC-producing *K. oxytoca* isolates, the genetic relatedness of patient and environmental isolates, and the underlying mechanism of carbapenem resistance.

The outbreak occurred at the Division of Hematology at the Medical University of Graz, a tertiary care facility. This 28-bed ward has approximately 1,200 admissions annually, almost exclusively of patients with hematological malignancies. The index patient involved in the outbreak of KPC-producing *K. oxytoca* was in the medical ICU in December 2010 (3). The patient was considered colonized but not infected according to CDC criteria (11). The patient was then transferred to the hematology ward, where contact precautions were continued.

KPC-producing *K. oxytoca* isolates with resistance patterns identical to those of the outbreak strain were identified from 10 more patients in the Division of Hematology. Three patients were identified in late 2011 and 2012, and seven were detected from January to July 2013. Six patients developed an infection (Table 1). All the patients were admitted more than once during the outbreak period either for chemotherapy or because of side effects during chemotherapy.

Screening swabs from dry surfaces are taken and tested routinely 4 times per year by our infection control team and have never yielded *K. oxytoca*. In addition, in two publications dealing with nosocomial outbreaks of *K. oxytoca*, swabs from dry surfaces in the environment surrounding the patients did not yield any *K. oxytoca* isolates. In contrast, *K. oxytoca* was identified in sinks and drains (9, 10). Therefore, we chose to focus our investigation on sinks. Fifty-eight swabs were taken from handwashing sink drains, 23 from handwashing sink overflows (not all sinks had overflows), and 19 from shower drains in the Division of Hematology. Swabs from sink surfaces were taken from contaminated sinks in a second round of testing.

Swabs were seeded onto MacConkey agar and chromID Carba (both from bioMérieux, Marcy l'Étoile, France) and analyzed according to microbiological standards (12). The isolates were screened for the presence of resistance genes with the DNA microarray-based Check-MDR 103 kit (Check-Points, Wageningen, Netherlands) according to the manufacturer's protocol (http://www.check-points.com/support/manuals/). Sequencing of the detected carbapenemases and other beta-lactamase gene families was performed as previously described (13, 14). Repetitive sequence-based PCR (rep-PCR) was carried out with the DiversiLab system (bioMérieux, Nürtingen, Germany). In addition, all the isolates were tested using multilocus sequence typing (MLST), as described previously (15).

Eleven *K. oxytoca* isolates were found in the sink drains. Seven

isolates showed multidrug resistance, including resistance to carbapenems, one was an extended-spectrum beta-lactamase (ESBL)-producing *K. oxytoca* isolate, and three isolates showed wild-type resistance. The 7 KPC-producing *K. oxytoca* isolates were found in rooms 23, 25, and 29 (double rooms housing 2 patients each with two sinks), room 37 (a single room), and 32A (a room in which medication is prepared by the nursing staff). Five KPC-producing *K. oxytoca* isolates were detected in sink drains (in rooms 23, 25, 29, 37, and 32A). One isolate was found in the sink overflow (room 37), and one was found in the shower drain (room 25). Swabs taken from sink surfaces in a second round did not yield any additional KPC-producing *K. oxytoca* isolates.

All the isolates from the patients and the seven isolates derived from sinks were multidrug resistant, exhibited susceptibility to amikacin, colistin, and fosfomycin only, and were found to be KPC producers. When microarray technology was used, bla_{KPC} and bla_{TEM} were detected in all the isolates and were identified as bla_{KPC-2} and bla_{TEM-1} by sequencing. rep-PCR revealed that all strains tested were indistinguishable with a similarity index of >97.5%. MLST yielded only one sequence type, ST4, for all the KPC-2-producing *K. oxytoca* isolates.

The starting point for this outbreak was a colonized patient from the ICU who later was transferred to the hematology ward. We hypothesize that in the case of this patient, KPC-2-producing *K. oxytoca* got into the sink most likely during personal hygiene activities or by the disposal of contaminated body fluids where it persisted. In the Division of Hematology, the water from the sink faucets directly hits the mesh that covers the sink drain. We hypothesize that some patients were colonized by contaminated aerosols when using the sinks for personal hygiene; 6 of 10 affected patients stayed in rooms with contaminated sinks, and 2 patients shared a room with a patient who later proved to be infected or colonized. We speculate that cross-contamination took place either by direct contact between the patients or through the hands of health care workers. The potential involvement of the health care workers is indicated by the fact that KPC-2-producing *K. oxytoca* was found in the sink of the room where medication is prepared by the health care staff.

As a consequence of the prolonged outbreak, the existing infection control measures (isolating colonized patients, enforcing hand hygiene measures, and cleaning the ward, particularly the sinks and equipment) were reinforced. An exchange of all the colonized sinks is under way. Since October 2013, no more KPC-producing *K. oxytoca* isolates have been identified.

In conclusion, a clonal relationship between environmental isolates and patient strains was determined and pointed to handwashing sinks as a possible reservoir for the prolonged nosocomial outbreak of KPC-2-producing *K. oxytoca*.

TABLE 1 Clinical data and epidemiological information

Patient no.	Patient age (yr) and gender[a]	Comorbidity	Date of first detection (day/mo/yr)	Site(s) of detection	Infection or colonization	Outcome	Patient stayed in a room with *K. oxytoca* in sink (room no.)
1	39, m	AML[b]	25/10/2011	Anal swab	Colonization	Alive	No
2	65, m	AML	28/12/2011	BAL[c]	Infection	Death due to KO[d] pneumonia	No
3	50, f	AML	13/11/2012	Blood, skin, stool, urine, abscess	Infection	Death due to KO abdominal wall abscess	Yes (23, 25)
4	51, f	AML	8/1/2013	Stool, BAL	Infection	Death due to AML relapse	No, but shared room with patient 5
5	60, f	AML	15/1/2013	Stool	Colonization	Alive	Yes (25)
6	61, m	B-cell non-Hodgkin lymphoma	9/4/2013	Anal swab, throat, BAL	Infection	Death due to KO pneumonia	Yes (25)
7	72, m	Myelodysplastic syndrome, secondary AML	14/05/2013	Stool	Colonization	Alive	Yes (23)
8	54, m	AML	17/5/2013	BAL, throat, anal swab	Infection	Death due to KO pneumonia	Yes (25)
9	89, m	B-cell non-Hodgkin lymphoma	31/7/2013	Catheter urine, throat	Colonization	Alive	No, but shared room with patient 8
10	56, m	AML	31/10/2013	Blood, throat, anal swab, skin, stool	Infection	Alive	Yes (25)

RESEARCH

Outbreak of Extended-Spectrum β-Lactamase–producing *Klebsiella oxytoca* Infections Associated with Contaminated Handwashing Sinks[1]

Christopher Lowe, Barbara Willey, Anna O'Shaughnessy, Wayne Lee, Ming Lum, Karen Pike, Cindy Larocque, Helen Dedier, Lorraine Dales, Christine Moore, Allison McGeer, and the Mount Sinai Hospital Infection Control Team

Klebsiella oxytoca is primarily a health care–associated pathogen acquired from environmental sources. During October 2006–March 2011, a total of 66 patients in a hospital in Toronto, Ontario, Canada, acquired class A extended-spectrum β-lactamase–producing *K. oxytoca* with 1 of 2 related pulsed-field gel electrophoresis patterns. New cases continued to occur despite reinforcement of infection control practices, prevalence screening, and contact precautions for colonized/infected patients. Cultures from handwashing sinks in the intensive care unit yielded *K. oxytoca* with identical pulsed-field gel electrophoresis patterns to cultures from the clinical cases. No infections occurred after implementation of sink cleaning 3×/day, sink drain modifications, and an antimicrobial stewardship program. In contrast, a cluster of 4 patients infected with *K. oxytoca* in a geographically distant medical ward without contaminated sinks was contained with implementation of active screening and contact precautions. Sinks should be considered potential reservoirs for clusters of infection caused by *K. oxytoca*.

Klebsiella oxytoca is an opportunistic pathogen that causes primarily hospital-acquired infections, most often involving immunocompromised patients or those requiring intensive care. Reported outbreaks have most frequently involved environmental sources (*1*–*4*). *K. oxytoca*, like other *Enterobacteriaceae*, may acquire extended-spectrum β-lactamases (ESBL) and carbapenemases (*1*,*5*); outbreaks of multidrug-resistant *K. oxytoca* infection pose an increasing risk to hospitalized patients.

We report an outbreak of infections caused by ESBL-producing *K. oxytoca* in the intensive care unit (ICU), step-down unit, and medical care unit at a hospital in Toronto, Ontario, Canada, during a 4-year period. Contributing to the ongoing difficulties in the containment of this outbreak has been the contamination of handwashing sinks in the ICU. We describe a retrospective review of all *K. oxytoca* isolates intermediate or resistant to third-generation cephalosporins identified from inpatients from April 1997 through December 2011, the investigation of the source of the *K. oxytoca* outbreak, and the interventions implemented to contain the outbreak.

Methods

The outbreak occurred at an acute tertiary-care facility in Toronto with 472 beds, including a 16 single-bed medical-surgical ICU, a 6-bed cardiac care unit , and two 4-bed step-down units. Outbreak cases of *K. oxytoca* were defined as hospital-acquired isolates with pulsed-field gel electrophoresis (PFGE) patterns belonging to 2 related clonal groups; all such isolates produced an Ambler class A ESBL. Isolates were considered hospital acquired if the first specimen (clinical culture or rectal swab) yielding resistant *K. oxytoca* was obtained ≥3 days after the admission date or if the specimen was obtained <3 days after admis-

A53210128

sion in a patient who had been hospitalized at the outbreak hospital within the previous 3 months. Patients were characterized as infected or colonized on the basis of National Healthcare Safety Network definitions (*6*).

Hospital infection-control guidelines provide that each patient colonized or infected with class A ESBL-producing *Enterobacteriaceae* be moved to a separate, single room with contact precautions in place. Risk factor–based admission rectal swab screening for ESBL-producing *Enterobacteriaceae* was initiated in 2004. High-risk populations are all patients admitted to an ICU and general medicine or surgical patients being transferred from an acute or long-term care facility or having a history of recent hospitalization or colonization/infection with a multidrug-resistant organism. Periodic prevalence screening is undertaken on medical and surgical wards, and potential clusters of clinical ESBL-producing isolates are investigated. ESBL colonized or infected patients are flagged in an electronic clinical system. Additional precautions are continued until weekly rectal swab specimens are negative over 4 weeks, at which point patients are placed in private rooms with ongoing periodic screening for 6 months.

Clinical specimens were processed by using conventional microbiological techniques. The VITEK 2 system (bioMérieux, Marcy l'Etoile, France) was used for identification and antimicrobial drug susceptibility testing of *K. oxytoca* isolates. Rectal screening swabs were plated on MacConkey agar with cefpodoxime (2 μg/mL). Tap water was cultured by vigorously swabbing the inside of each faucet with a cotton swab, turning the tap on and collecting 50 mL of water, vortexing the tube containing the water and the swab, centrifuging the sample twice at 3,500 × *g* for 15 minutes, and resuspending the resulting pellet of precipitated material in 3 mL of brain–heart infusion broth. Other environmental samples were obtained by inoculating premoistened cotton swabs (for dry surfaces) or by adding ≈0.25 mL of gel/liquid to 3 mL of brain–heart infusion broth. For sink cultures, cotton swabs were used to sample ≈10 cm^2 areas of the surface of the sink rim or basin. Drains were sampled by rotating swabs inserted 5–7 cm through the sink drain. Inoculated brain–heart infusion broth was incubated overnight at 37°C and then plated onto MacConkey agar with cefpodoxime. Clinical isolates intermediate or resistant to cefpodoxime (MIC ≥4 μg/mL) and colonies growing on the MacConkey agar with cefpodoxime underwent disk diffusion phenotypic confirmation (ceftriaxone, ceftazidime and aztreonam plus/minus clavulanic acid and cefoxitin) on Mueller-Hinton agar (*7*). PFGE was performed by using the restriction enzyme *Xba*I, with a run time of 20 h and switch times of 5 to 35 s at 12°C and 6 V/cm (CHEF-DR II System; Bio-Rad, Hercules, CA, USA); profiles were analyzed by using BioNumerics (Applied Maths, Sint-Martens-Latem, Belgium).

Results

Outbreak Description

Isolation of ESBL-producing *K. oxytoca* was uncommon in the 9 years before the outbreak; from January 1, 1997, through September 30, 2006, 10 clinical isolates (no bacteremias) and 6 colonized patients were identified. All but 1 colonized patient acquired the organism in the hospital, and 16/19 (84.2%) patients were previously or currently admitted to the ICU at the time of culture. PFGE of these isolates revealed that 5 (26.3%) isolates belonged to pattern A, 3 (15.8%) isolates belonged to pattern B, 3 isolates were closely related to each other but unrelated to isolates of pattern A or B, and 3 isolates had unique patterns. Two isolates were unavailable for typing. Only 1 case (April 2004) was identified between April 2003 and September 2006.

From October 2006 through March 2011, ESBL-producing *K. oxytoca* was isolated from 87 patients (Figure 1); 21 were not part of the outbreak. Eight of these nonoutbreak patients had isolates from clinical cultures or screening specimens obtained within 72 hours of first admission to the hospital, and each isolate had a unique pattern by PFGE. The remaining 13 had isolates first identified ≥3 days after admission (n = 11) or had been previously admitted to this hospital (n = 2), but each isolate had a unique PFGE pattern, with no temporal or geographic clustering. The remaining 66 patients were classified as outbreak case-patients.

All 66 outbreak case-patient isolates carried Ambler class A β-lactamases. Clinical *K. oxytoca* isolates were identified from 27 patients; among these, 24 patients had 25 hospital-acquired infections (9 urinary tract infections, 4 of them bacteremic; 8 asymptomatic bacteriurias; 4 soft tissue infections, 1 of them bacteremic; 3 primary bacteremias; and 1 pneumonia with bacteremia). Of the 9 bacteremias,

8 were PFGE pattern A. On the basis of study definitions, 3 patients had clinical specimens (2 sputum samples and 1 bronchoalveolar lavage culture) that were not associated with infection. In 11 cases, clinical cultures were preceded by identified rectal colonization; median time to first identification of a clinical isolate after recognition of colonization was 10 days (mean 12.5 days, range 1–31 days). Of the remaining 16 cases with clinical isolates of *K. oxytoca*, 13 patients had a prior negative result from an ESBL rectal screening. Thirty-nine patients were identified as colonized by rectal swab screening but no subsequent clinical isolate was identified. Patients remained colonized for variable periods of time, with the proportion colonized still positive on repeat screening as follows: 7 days (30/49, 61.2%), 14 days (20/41, 48.7%), 21 days (15/38, 39.4%), 28 days (14/33, 42.4%), 2 months (6/22, 27.3%), and 3 months (4/17, 23.5%).

Figure 2 summarizes the occurrence of outbreak-related ESBL-producing *K. oxytoca* clinical isolates over time in the ICU, where most cases occurred (49/66, 74%). Cases with clinical isolates were identified regularly from October 2006 through December 2009; however, no clinical isolates have been recovered from patients in or exposed to the ICU since that time. The 6 outbreak cases in 2010 and 4 in 2011 were identified only by rectal swab screening. The number of newly identified cases on point-prevalence screens was 13/1,049 in 2008 (1.2%), 7/1,744 (0.4%) in 2009, 6/921 (0.7%) in 2010, and 1/754 (0.1%) in 2011 ($p = 0.01$). Because prevalence screens were performed more frequently when new cases were occurring, the total number of prevalence screens decreased in 2010 and 2011 compared with 2008 and 2009.

Seventeen case-patients who had not been admitted to the ICU were identified as colonized or infected with outbreak strains. Eleven of these were part of 3 clusters. In August 2010, a total of 4 patients (3 colonized, 1 infected) from whom isolates were identified that were indistinguishable by PFGE (pattern A) acquired the strain on a single medical ward. In the medical step-down unit, 3 patients were identified as becoming colonized during June–September 2010; an additional 4 patients became colonized in February and March of 2011 (all pattern A). The remaining cases were sporadically identified on the surgical step-down unit (n = 4) and in general surgery/gastroenterology units (n = 2).

Outbreak-specific Infection-control Interventions

At the onset of the outbreak (October 2006), the investigation encompassed a search for potential environmental sources. Samples for culture were obtained from potential reservoirs (e.g., shared equipment such as electrocardiogram and ultrasound machines, bronchoscopes and solutions used in endoscopy areas, glucometers, hand creams, lubricating gels, disinfectant swabs, blood gas machines, water baths, ice machines, mouthwashes, oral medications, and soaps), and prevalence screening was conducted to detect patient colonization in the ICU. No environmental sources were identified, no multidose vials or bags of parenteral fluids or oral medications were in use in the unit, and no procedures or exposures were identified that linked affected patients but not other patients. Two of 16 sinks had aerators, neither of which yielded *K. oxytoca* on culture. Tap water and sinks were not cultured at this time. All patients newly identified as colonized or infected had contact

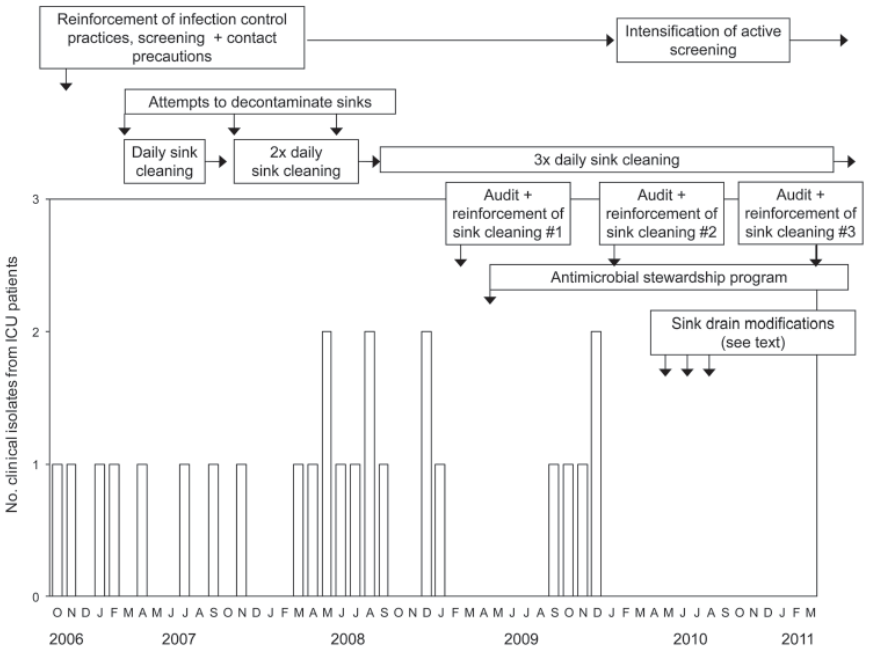

Figure 2. Nosocomial extended-spectrum β-lactamase–producing *Klebsiella oxytoca* clinical isolates from patients in the intensive care unit of a hospital in Toronto, Ontario, Canada, and the associated interventions implemented to contain the spread of the outbreak, October 2006–March 2011. ICU, intensive care unit.

A53210128

precautions applied. Hand hygiene practices, adherence to contact precautions, and appropriate management of water/liquid/gels were reinforced. These interventions had no apparent effect on the rate of new clinical infections; new patients acquired the organism after weeks without identified colonized patients in the ICU.

In April 2007, results of repeat screening of potential environmental sources were negative, as were samples of tap water; however, multiple handwashing sinks were found to be contaminated with the outbreak strains. Sinks in the ICU are foot pedal–operated, free-standing, porcelain hand hygiene sinks located just inside the door to each ICU room. Although intended only for hand hygiene, they were also used for disposal of fluids, including body fluids. When sinks were identified as a potential reservoir, use of the sinks for hand hygiene only was reinforced. Attempts were made to reduce or eradicate *K. oxytoca* contamination by cleaning sinks and leaving them unused for 48 hours with disinfectant standing in traps. When this process failed, routine daily sink disinfection was initiated; sink surfaces, including taps, rims of sinks, and basins, were cleaned with a 1:16 dilution of Virox (Virox Technologies Inc., Oakville, CA, USA), and ≈250 mL of the diluted solution was poured down the drain. Neither this daily cleaning, nor month-long trials of cleaning with bleach and with a foaming hydrogen peroxide product, resulted in reduced sink colonization rates. Sink cleaning was increased to 2×/day in late 2007 and 3×/day in August 2008. Adherence to cleaning standards, particularly frequency of cleaning, was variable. Regular reminders to cleaning staff were required, and the identification of new hospital-acquired cases usually resulted in recognition that adherence had decreased.

Figure 3 shows the overall rates of recovery for patients with outbreak-related ESBL-producing *K. oxytoca* infection associated with handwashing sinks in the ICU. ICU sink culture screens were performed on 29 separate occasions, yielding a total of 910 cultures. The average rate of sink contamination during the outbreak period was 16.4% (149/910). After implementation of 3×/day cleaning/disinfection of sinks (October–December 2008), the sink colonization rate decreased to 3.9% (3/77) during the quarter; the rate increased to 16.7% (71/424) the following quarter (January–March, 2009), when adherence to routine sink cleaning was noted to have decreased.

Many of the ICU sinks had old patented opening drains (a pipe connecting the sink basin to the sink trap), a design that allowed drainage from the overflow hole to mix with the regular drainage water, potentially impairing adequate drainage. During February–June 2010, all drains were changed, eliminating the connection with the overflow drain; the overflow holes were decommissioned; the strainers in the sink basin were replaced by strainers containing a larger number of smaller holes to reduce backsplash; and sink traps were replaced.

Investigation of the medical unit on which 4 patients acquired outbreak strains during summer 2010 failed to identify an environmental source; all sink cultures were negative. After initiation of standard contact precautions for the colonized patients, no additional colonized or infected patients were identified in that unit. In contrast, the outbreak strain of ESBL-producing *K. oxytoca* was recovered from sinks, but not other environmental sources, in the medical step-down unit during August 2010. The implementation of regular sink cleaning and contact precautions for colonized patients resulted in no cases being identified during September 2010–February 2011. When new cases were identified in 2011, the previously described sink modifications were implemented in the step-down unit.

Concomitant Infection-control Interventions

As part of an ongoing program to improve adherence to hand hygiene, routine observational hand hygiene audits started throughout the hospital in fall 2008. Compliance rates improved gradually over the course of the outbreak, from 59.4% in 2008 to 69.8% in 2011.

An antimicrobial stewardship program was initiated in only the ICU in February 2009. An audit and feedback program was instituted and run by an infectious diseases physician and a pharmacist. During the first year of the program, the mean antibacterial defined daily dose per 100 patient-days decreased 9.2% compared with the same time period in the previous year (*8*).

Discussion

Outbreaks of health care–associated infection caused by *K. oxytoca* have most often been associated with contamination of environmental reservoirs such as disinfectants (*9*), multidose vials or parenteral fluid bags (*10*,*11*), humidifiers (*2*), and ventilators (*3*). This outbreak suggests that handwashing sinks in high-intensity hospital care areas may be a reservoir for *K. oxytoca* and that person-to-person transmission may also occur.

Patients in this medical-surgical ICU continued to acquire the outbreak organism despite review of routine practices, hand hygiene education and auditing, screening to identify colonized patients, and implementation of contact precautions for colonized and infected patients. In contrast, this approach seemed to control transmission in the medical ward, where contamination in sinks was not found, and has been reported to be successful in the control of other outbreaks of ESBL-producing *Enterobacteriaceae* (*12*). In this hospital, transmission of the outbreak strains of *K. oxytoca* seemed to occur both from sinks and from colonized/infected patients. As the emergence of carbapenemase-producing organisms focuses attention on health care–associated infections due to *Enterobacteriaceae,* other reservoirs may also be recognized. Recently, a clone of *K. pneumoniae* possessing SHV-1 and CTX-M-15 ESBLs was implicated in a hospital-wide foodborne outbreak in Spain, in which the hospital kitchen and colonized food handlers were the presumed reservoirs (*13*).

During the outbreak reported here, patients who acquired ESBL-producing *K. oxytoca* colonization were followed up with routine rectal swab screening; 23.5% remained colonized after 3 months. Colonization with ESBL-producing *Enterobacteriaceae* can persist for months to years (*14*,*15*); data are insufficient to determine whether duration of carriage is different for different species or clones of *Enterobacteriaceae*. In 1 study, only 6.8% of colonized patients cleared carriage over 3 years of follow-up (*14*). In addition, colonized patients may have intermittently positive rectal screening results, which suggests carriage at concentrations below the limit of detection for rectal swab specimens (*16*).

At the hospital in this study, patients to whom contact precautions are applied remain under these guidelines for 1 month and in private rooms for 6 months. However, for resistant gram-negative bacteria of epidemiologic importance (e.g., carbapenemase-producing organisms), extending the duration of contact precautions until discharge may be warranted. Because of the long duration of colonization, hospitalization is also likely to be a risk factor for community-onset infection with multidrug-resistant *K. oxytoca*, as has recently been described in Athens, Greece (*17*). The existence of asymptomatic colonized patients compounds the difficulty of containing the spread of these organisms; containing outbreaks without active surveillance may not be possible (*18*).

The outbreak-associated clones of *K. oxytoca* found in this study were ubiquitous in sinks in the ICU, cultured from 15/16 patient rooms as well as from other sinks (e.g., staff washrooms). Increased sink cleaning and auditing was associated with a decline in clinical isolates, but these measures proved difficult to sustain. Achieving persistent reductions in the degree of contamination in ICU sinks is difficult but has been a necessary intervention in outbreaks of *Pseudomonas aeruginosa* (*19*,*20*). In these outbreaks, structural changes, including renovation to sinks and plumbing or alteration of water temperature, reduced but did not eliminate the outbreak organism from sink drains. As in our experience, although the organisms could still be recovered after alterations to improve drainage and reduce splashing, these modifications were temporally associated with persistent declines in the rate of clinical infections. Persistence of *Pseudomonas* spp. in ICU sinks has been attributed to biofilm formation, which allows stable attachment to environmental surfaces and protection from disinfection (*20*,*21*). Biofilm formation has also been described for *K. oxytoca* on filtration membranes (*22*) and is probably a factor in the persistence of *K. oxytoca* in sinks in this outbreak.

This outbreak also emphasizes the challenges associated with limited space and sinks in older hospitals. Presumptively, these handwashing sinks became contaminated because they were used for the disposal of body fluids from colonized patients. While this is clearly unacceptable, nurses in the ICU are required to walk past several rooms (and out of isolation rooms) to reach the dirty utility room for disposal of body fluids, an activity that is also associated with risk. As we increasingly recognize the risks associated with hospital water and sinks, the design of ICUs becomes critical for protecting patients from these risks.

In conclusion, we describe an outbreak in which colonized sinks were a contributing reservoir for ESBL-producing class A *K. oxytoca.* A multifaceted approach including reinforcement of infection control policies (hand hygiene,

A53210128

contact precautions, isolation and admission/routine rectal screening, clear delineation between handwashing sinks and sinks for other purposes), intensified cleaning of sinks, structural changes to the sinks, and antimicrobial stewardship has reduced but not eliminated transmission of the outbreak strain. Although *K. oxytoca* is in the family *Enterobacteriaceae*, its epidemiology is not clearly defined, and it may be more likely than other *Enterobacteriaceae* to be associated with environmental reservoirs in hospitals. Sinks should be considered potential reservoirs when clusters of infection caused by *K. oxytoca* are investigated.

Dr Lowe is a resident in medical microbiology at the University of Toronto. His current research interests are focused on identifying optimal methods for infection control of multidrug-resistant gram-negative organisms.

Abstract

Escherichia coli and *Klebsiella* spp. are important human pathogens that cause a wide spectrum of clinical disease. In healthcare settings, sinks and other wastewater sites have been shown to be reservoirs of antimicrobial-resistant *E. coli* and *Klebsiella* spp., particularly in the context of outbreaks of resistant strains amongst patients. Without focusing exclusively on resistance markers or a clinical outbreak, we demonstrate that many hospital sink drains are abundantly and persistently colonized with diverse populations of *E. coli*, *Klebsiella pneumoniae* and *Klebsiella oxytoca*, including both antimicrobial-resistant and susceptible strains. Using whole-genome sequencing of 439 isolates, we show that environmental bacterial populations are largely structured by ward and sink, with only a handful of lineages, such as *E. coli* ST635, being widely distributed, suggesting different prevailing ecologies, which may vary as a result of different inputs and selection pressures. Whole-genome sequencing of 46 contemporaneous patient isolates identified one (2%; 95% CI 0.05–11%) *E. coli* urine infection-associated isolate with high similarity to a prior sink isolate, suggesting that sinks may contribute to up to 10% of infections caused by these organisms in patients on the ward over the same timeframe. Using metagenomics from 20 sink-timepoints, we show that sinks also harbour many clinically relevant antimicrobial resistance genes including $bla_{\text{CTX-M}}$, bla_{SHV} and *mcr*, and may act as niches for the exchange and amplification of these genes. Our study reinforces the potential role of sinks in contributing to Enterobacterales infection and antimicrobial resistance in hospital patients, something that could be amenable to intervention. This article contains data hosted by Microreact.

DATA SUMMARY

Raw sequencing data are available under NCBI SRA accessions PRJNA604910 and PRJNA604975 (cultured isolates), and ENA project PRJEB36775 (metagenomes). A supporting data repository containing metadata, phylogenies, Jupyter notebooks and Pavian reports is archived at Figshare (doi:10.6084/m9.figshare.12337283). Microreact projects are available for *E. coli*, *K. oxytoca* and *K. pneumoniae* cultures. The authors confirm all supporting data, code and protocols have been provided within the article or the supporting data repository.

INTRODUCTION

Infections caused by Enterobacterales, including *Escherichia coli* and *Klebsiella* spp., are major causes of global morbidity, and particular antimicrobial-resistant strains (namely extended-spectrum beta-lactamase [ESBL] and carbapenemase producers) have been listed as critical priority pathogens for mitigation by the World Health Organization. In the UK, year-on-year increases have been observed in the number of *E. coli* and *Klebsiella* spp. bloodstream infections [1] for reasons that remain unclear. As well as causing invasive disease, these organisms are capable of colonizing a wide range of animal and environmental niches, and are frequently carried in the human gastrointestinal tract [2]. As such, they are also commonly found in human wastewater, and in wastewater-associated sites such as sewers and water-treatment infrastructure [3].

A significant proportion of Enterobacterales infections are healthcare-associated, prompting the UK government to introduce a target in 2016 to halve the number of healthcare-associated Gram-negative bloodstream infections by 2021 [4]. Wastewater sites in hospitals have been highlighted as reservoirs of drug-resistant Enterobacterales, with several studies reporting that ongoing transmission and outbreaks of human disease are associated with the contamination of, for example, sinks, by these organisms [5, 6]. More recently, several studies have shown reductions in colonization and/or invasive infection with Enterobacterales and other Gram-negative bacilli following the introduction of strategies to remove sinks and mitigate possible contamination from wastewater sources in patient rooms [7, 8]. Most of these studies however focus on the sampling and control of antimicrobial-resistant strains, often representing a more immediate clinical problem in an outbreak setting, rather than on the possibility that these sites may represent part of the wider endemic transmission network of both susceptible and resistant strains causing infection in patients.

Whole-genome sequencing of bacterial isolates is increasingly used as the most robust, high-resolution approach to characterizing relatedness between strains, and hence determining likely transmission [9]. However, the diversity of complex, polymicrobial environmental reservoirs is incompletely captured by sequencing small numbers of isolates, and this breadth of diversity can be more fully captured by using a metagenomic approach, which characterizes the genetic complement of a whole sample [10]. Combining both approaches has been shown to improve our understanding of species and antimicrobial resistance (AMR) gene diversity within environmental, wastewater and river samples [11, 12] and of transmission in a sink-associated outbreak of *Sphingomonas koreensis* (also a Gram-negative bacillus) in the NIH Clinical Centre in the USA [13].

In order to investigate the prevalence of contamination of healthcare sinks by strains of *E. coli* and *Klebsiella* spp., including those resistant to third-generation cephalosporins and carbapenems, we sampled all sink sites using p-trap (U-bend) aspirates across several wards and timepoints in a single UK hospital in 2017. We used a combination of whole-genome sequencing of cultured isolates from all sink samples and metagenomic sequencing of a subset of sink samples to facilitate a high-resolution assessment of the genetic diversity present in these niches. To determine whether sinks were a reservoir of Enterobacterales strains causing infection in patients over similar timeframes, we simultaneously retrieved relevant isolates from culture-positive specimens taken from patients admitted to the same ward locations, and used genomics to identify the degree of genetic relatedness.

Impact Statement

Escherichia coli and *Klebsiella* spp. cause a wide range of bacterial infections, including bloodstream, urine and lung infections. Previous studies have shown that sink drains in hospitals may be part of transmission chains in outbreaks of antimicrobial-resistant *E. coli* and *Klebsiella* spp., leading to colonization and clinical disease in patients. We show that even in non-outbreak settings, contamination of sink drains by these bacteria is common across hospital wards, and that many antimicrobial resistance genes can be found and potentially exchanged in these sink drain sites. Our findings demonstrate that the colonization of handwashing sink drains by these bacteria in hospitals is likely contributing to some infections in patients, and that additional work is needed to further quantify this risk, and to consider appropriate mitigating interventions.

METHODS

Ward-based sink sampling

We sampled three units (acute admissions [AA], adult critical care [ACC], adult general medicine [female only] [GM]) within a single hospital (John Radcliffe Hospital, Oxford, UK) four times on rotation every 3 weeks over 3 months, March–May 2017. Units were chosen to capture different patient populations, admission turnaround times and wastewater plumbing infrastructure. The haematology ward (on a separate hospital site) was also sampled on a single day (12 May 2017) subsequent to a small cluster of patient cases of $bla_{\text{OXA-48}}$ carbapenemase-associated Enterobacterales bloodstream infections described previously [14]. Ward and sink/wastewater layouts were obtained from estates, and each sink/drain site was assigned a unique site identifier (Table S1).

On each day of sampling, autoclaved tubing cut to 10 inches was used to aspirate from sink p-traps via a sterile 50 ml syringe. Up to 50 ml of fluid was aspirated where possible. Then, 100 µl of tenfold dilutions (10^{-2}, 10^{-3}, 10^{-4}) of each sink p-trap aspirate were plated onto CHROMagar Orientation media (Becton Dickinson, Franklin Lakes, NJ, USA), with no disc, cefpodoxime (10 µg), ertapenem (10 µg) (Thermo Scientific Oxoid, Basingstoke, UK) applied in a triangular fashion to each plate. Cultures were incubated at 37 °C for

~18 h. Growth of Enterobacterales (presence/absence) and density (sparse/dense/confluent) in all zones was recorded (i.e. no antibiotic, in the presence of cefpodoxime, and in the presence of ertapenem). Up to four distinct colonies of each of presumptive *E. coli* and *Klebsiella* spp. were sub-cultured on CHROMagar Orientation to confirm purity and species identification. Species identification of sub-cultured colonies was confirmed by MALDI-ToF (MALDI Biotyper, Bruker, Billerica, MA, USA). Stocks of sub-cultured isolates were stored at −80 °C in 400 µl of nutrient broth +10% glycerol prior to DNA extraction for sequencing. Aspirates from sink p-traps were then centrifuged at 4000 r.p.m. for 10 min at 4 °C, and supernatants removed; pellets were stored at −80 °C.

Patient isolate sampling

For AA, ACC and GM wards, a pseudo-anonymized, prospective feed was set-up to try and enable real-time capture of isolates from all samples culture-positive for *E. coli*, *K. pneumoniae* and *K. oxytoca* from patients admitted to any of these wards during the study time period, and were processed routinely through the clinical microbiology laboratory in the John Radcliffe Hospital in accordance with local standard operating procedures for clinical sample types, and compliant with national standards for microbiology investigations [15]. These typically involve selective culture steps and species identification using MALDI-ToF (MALDI BioTyper, Bruker, Billerica, MA, USA).

Pseudo-anonymized extracts of all patient culture results and admission/discharge data covering the study period were obtained after the study was finished through the Infections in Oxfordshire Research Database to enable an evaluation of (i) baseline sampling denominators, (ii) the extent of relevant clinical isolate capture and (iii) the temporal and spatial overlap of any genetically related sequenced isolates from patients and sequenced isolates/metagenomes from sinks.

Isolate sequencing and p-trap aspirate metagenomics

All isolates confirmed as *E. coli*, *K. pneumoniae* and *K. oxytoca* from patients and p-trap aspirates were extracted for sequencing using the QuickGene DNA extraction kit (Autogen, MA, USA) following manufacturer instructions, plus an additional mechanical lysis step prior to chemical lysis (FastPrep, MP Biomedicals, CA, USA; 6 m/s for two 40 s cycles).

For metagenomics, DNA was extracted from a subset of stored pellets (n=20) using the MoBio PowerSoil DNA isolation kit (Qiagen, Hilden, Germany) as per the manufacturer's instructions, and including a mechanical lysis step of two 40 s cycles at 6 m/s in lysing matrix E and final elution in buffer CDT-1 (Autogen, MA, USA). In total, 45 ng of *Thermus thermophilus* DNA (reference strain HB27, ATCC BAA-163 [DSMZ, Germany]) was added to each sample in the PowerBead tube at the start of the experiment, prior to the addition of solution C1 as an internal control and normalization marker [11]. Sink aspirates were selected for metagenomic sequencing to enable evaluation of (i) microbiome differences within and between wards, (ii) longitudinal change in microbiota composition, and (iii) whether culture-negative sinks harboured the bacterial species being studied, i.e. indicating limited sensitivity of culture-based approaches.

Short-read sequencing (single isolate and metagenomics) was performed on the Illumina HiSeq 4000, pooling 192 isolate extracts and six metagenomes per lane, and generating 150 bp paired-end reads. Median metagenomic sequencing throughput was 547 Mb (IQR 499Mb to 942Mb) per sample.

Computational methods

Cultured isolate informatics. Of the isolates sent for sequencing, 439/446 (98%) sink and 46/46 (100%) patient isolates were successfully sequenced and classified with Kraken/MiniKraken [16] as Enterobacterales, and used for subsequent analysis. Isolate consensus sequences were constructed by read mapping and consensus inference with respective *E. coli*, *K. oxytoca* and *K. pneumoniae* reference genomes AE014075.1, NC_018106.1 and CP000647.1 using Snippy 4.4.0 [17]. Isolate genomes were assembled using Shovill 1.0.4 [18]. Recombination-adjusted phylogenetic reconstruction was performed using runListCompare 0.3.8 [19] wrapping IQ-TREE 1.6.11 [20] and ClonalFrameML 1.12 [21]. Final core-genome alignments included 218/219 *E. coli* isolates, 165/167 *K. oxytoca* isolates and 98/99 *K. pneumoniae* isolates, all of which satisfied the runListCompare filtering criteria of perACGT_cutoff >=70%, varsite_keep >=0.8 and seq_keep >=0.7. Overall, 100 SNP core-genome clusters were defined by single linkage clustering of runListCompare pairwise distance matrices. Trees were midpoint rooted prior to visualization. See supporting data repository for runListCompare configuration. Read-based MASH trees were constructed using MASH 2.2.2 [22] and RapidNJ 2.3.2 using 21 mers, a sketch size of 10 000 and a minimum abundance threshold of 10 *k*-mers. Nearest neighbours between sink and clinical isolates were identified in both Core SNP and MASH space. Assembly-based core and accessory genome partitioning was performed using PopPUNK 1.1.7 [23]. Resistance genotyping and phenotype prediction in cultured isolates was performed using ResPipe [11] and ARIBA 2.14.4 [24] with the CARD 3.0.3 database [25]. Tree comparisons (tanglegrams) were generated using the R package Dendextend 1.5.0 [26].

Metagenome informatics. Metagenomic sequences were analysed for taxonomic and antimicrobial resistance gene presence using ResPipe [11] and Kraken2 [27] with CARD database version 3.0.3. Large resistance gene families were clustered to facilitate visualization of resistance profiles (methodology documented in supporting data repository). A metagenomic assembly of the *mcr-4* gene was generated with MEGAHIT 1.2.9 [28], to which reads were aligned with Minimap2 2.17-r941 [29] and consensus inferred using Kindel [30]. Metagenomic summary statistics were generated using Pavian [31].

Data analysis was performed with the SciPy ecosystem [32] and JupyterLab [33]. Matplotlib [34], Bokeh and Microreact [35] were used for visualization.

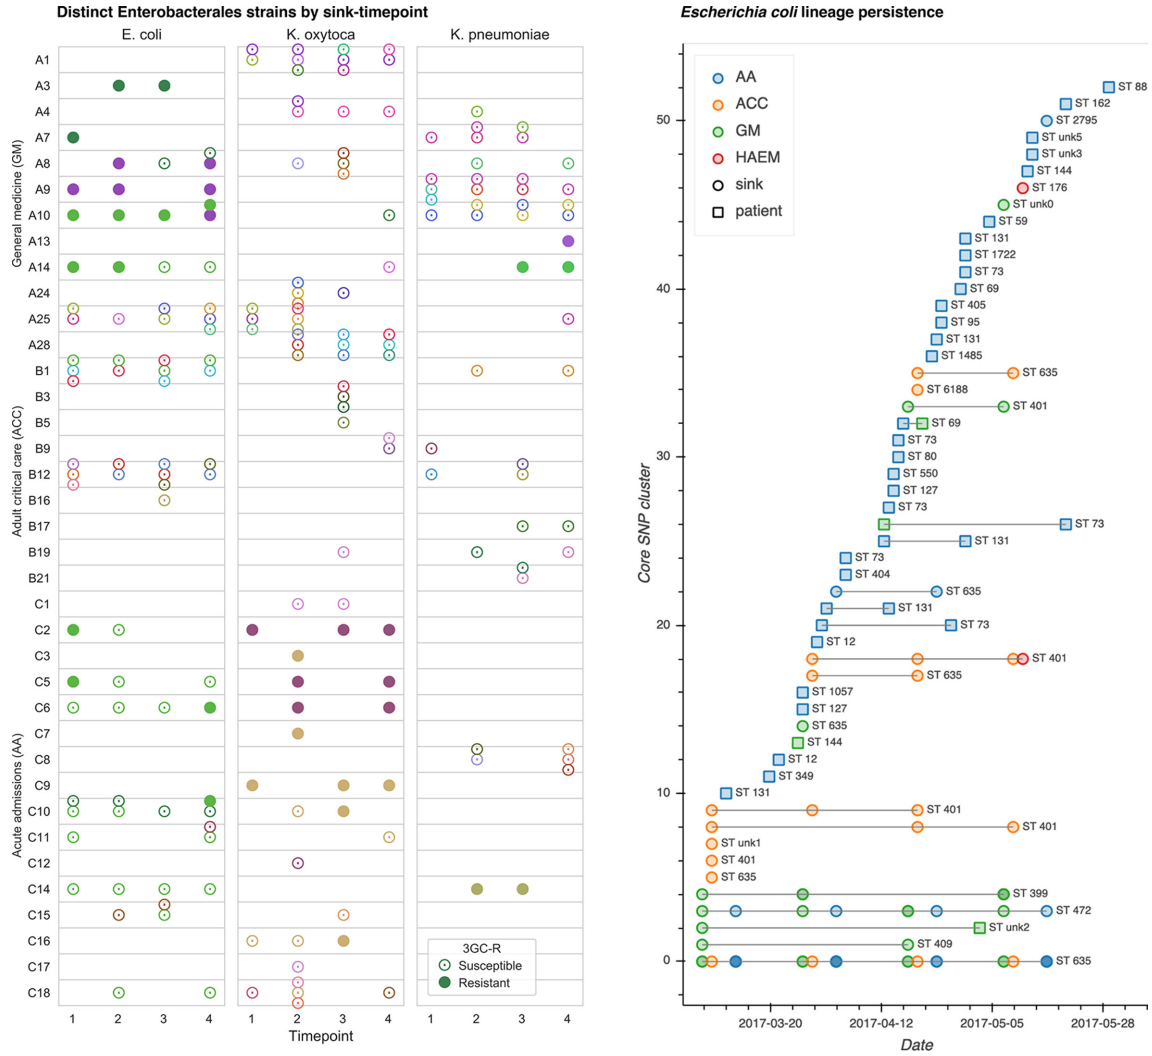

Fig. 1. Cluster distribution and persistence. Left: strain-distinct cultured isolates of *E. coli*, *K. oxytoca* and *K. pneumoniae* from sink drain aspirates sampled over 12 weeks across three hospital wards. Different colours indicate distinct strains (defined by 100 SNP clusters), and cefpodoxime-resistant and/or selected ESBL-positive isolates are indicated by filled markers. Right: persistence of sink and contemporaneous patient *E. coli* strains throughout the sampling period.

RESULTS

Diverse, often antimicrobial-resistant Enterobacterales lineages are frequent—and often persistent—colonizers of hospital sink drains

In total, 439 Enterobacterales isolates comprising *E. coli* (*n*=180), *K. oxytoca* (*n*=166) and *K. pneumoniae* (*n*=93) were cultured and successfully sequenced at one or more timepoints from 12/20 (60%), 9/23 (43%) and 16/23 (70%) sinks sampled four times over 12 weeks (March–May 2017) in general medicine (GM), adult critical care (ACC) and acute admissions (AA) wards, respectively (97/264 [37%] sink-timepoints culture-positive overall; Fig. 1). A further 30 isolates of *E. coli* (*n*=13), *K. oxytoca* (*n*=13) and *K. pneumoniae* (*n*=4) were cultured from 11/59 (19%) sinks in a haematology ward, sampled at a single timepoint only during this period (Fig. S1, available in the online version of this article). See Table S1 for surveyed sink descriptions. Species distributions (by culture) were relatively even across the general medicine ward, while the adult critical care unit was enriched for *E. coli*, and the acute admissions ward was depleted in *K. pneumoniae* (Table S2).

Analysis of whole-genome sequences from cultured Enterobacterales revealed widespread and sustained colonization of sinks by multiple sequence types (STs) of these species (Figs 1 and S1) In total, eight known and four novel *E. coli* STs were represented, of which STs 635 (*n*=109, 61%), 401 (*n*=25, 14%) and 472 (*n*=18, 10%) accounted for 84% of sequenced isolates (152/180). *Klebsiella* spp. STs were more varied: 15 known and six novel *K. oxytoca* STs were represented, of which the most frequent was ST177 (33/166, 20%), while there were 18 known and one novel *K. pneumoniae* STs, the most frequent being ST872 (24/93, 26%).

Table 1. Spatiotemporal distribution of 100 core SNP lineages of cultured *E. coli* (*n*=53), *K. oxytoca* (*n*=51) and *K. pneumoniae* (*n*=30) (a) overall, and (b) occurring in >1 isolate in sinks on wards that were repeatedly sampled

(a)		*E. coli*	*K. oxytoca*	*K. pneumoniae*	Total
Lineages with >1 isolate					
	Patient	28	1	3	32
	Sink	3	37	12	52
Lineages with >1 isolate					
Single timepoint	Same sink	5	6	3	14
	Different sinks; same ward	0	1	0	1
Multiple timepoints	Same sink	7	1	7	15
	Different sinks; same ward	1	4	4	9
	Different wards	3	1	0	4
Patients	Patient and sink (single timepoint)	1*	0	0	1
	Same patient	1	0	1	2
	Different patients	4	0	0	4
Total		53	51	30	134
(b)		***E. coli***	***K. oxytoca***	***K. pneumoniae***	**Total**
Sink lineages with >1 isolate (excludes haematology ward)					
Single timepoint	Same sink	5	4	3	12
	Different sinks; same ward	0	0	0	0
Multiple timepoints	Same sink	8	1	7	16
	Different sinks; same ward	1	4	4	9
	Different wards	2	1	0	3
Total		16	10	14	40

*Lineage has three isolates; all taken from the same ward; two from the same sink at the same timepointand one from a patient 2 months later.

Across all locations and sink-timepoints, sequenced isolates comprised 20, 50 and 26 distinct lineages (defined as differing by <=100 recombination-adjusted core SNPs; see Methods) of *E. coli*, *K. oxytoca* and *K. pneumoniae,* respectively (Fig. 1, Table 1). Numerous sinks were colonized with multiple lineages (Figs 1, S1 and S2), reflecting significant diversity within species in sink niches. Of the 37 longitudinally sampled culture-positive sinks from which sequences were obtained, 31 (84%) grew isolates of the same lineage across multiple timepoints, highlighting persistent background colonization illustrated for *E. coli* and *Klebsiella* spp. in respective Figs 1 and S3. Isolates resistant to third-generation cephalosporins were cultured at 16 sink-timepoints across 12 distinct sinks, with resistant and susceptible cultures of the same lineage co-occurring in 11/16 (69%) sink-timepoints, suggestive of gain and/or loss of genes conferring cephalosporin resistance in this setting. No carbapenem-resistant isolates were cultured.

Enterobacterales can be highly abundant in sink drains, representing dominant populations in some wards

Deep metagenomic Illumina sequencing was performed for 20 sink-timepoints on p-trap aspirates from seven sinks on the three wards at two timepoints, and all four timepoints for a single sink unit in the adult critical care ward (median throughput 547 Mb per sample; IQR 499Mb to 942Mb). The three most abundant bacterial genera were *Klebsiella*, *Escherichia* and *Citrobacter*, all common healthcare-associated pathogens (Fig. 2). Sink drains in the general medicine ward were the most abundantly colonized by Enterobacterales (Fig. 2), to which more than 50% of reads were assigned, and were markedly less diverse than those in adult critical care and acute admissions wards, which had a dominance of *Klebsiella* spp., mirroring the culture results. 90% of species-level classifications in the sink-timepoints from the general medicine ward came from a median of

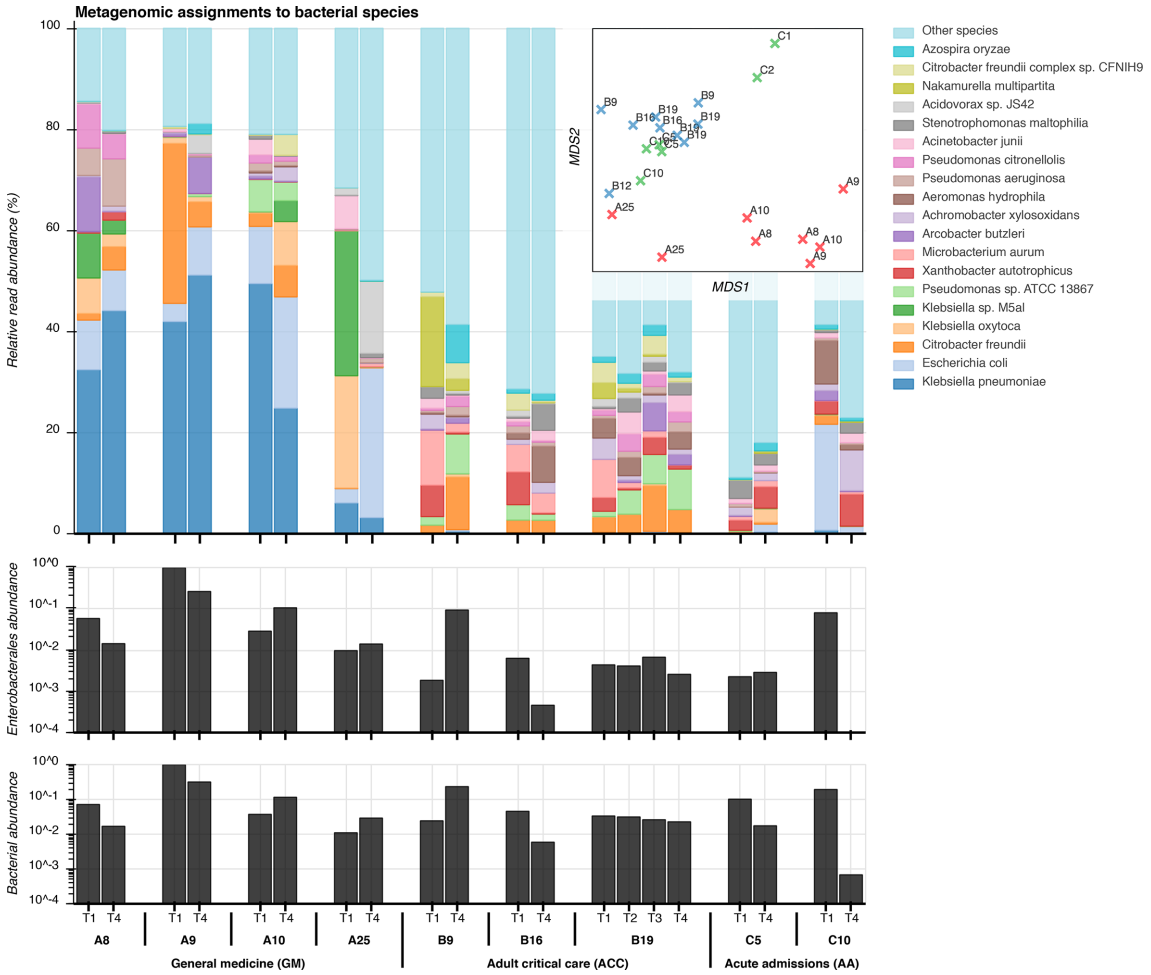

Fig. 2. Taxonomic composition of sink microbiota from metagenomic sequencing. Top: relative abundance of the 20 most abundant bacterial species among sink drain aspirates (Kraken), inset with a corresponding multidimensional scaling (MDS) projection of pairwise distances between samples. Centre: spike-normalized relative abundance of species classifications at or below the order Enterobacterales among sink-timepoints. Bottom: spike-normalized relative abundance of Kraken classifications at or below the superkingdom bacteria.

just 21 bacterial species, compared with medians of 310 and 450 species in the adult critical care and acute admissions wards, respectively. Microbial composition varied markedly between sampling timepoints for individual sinks, but sinks within wards exhibited more similar taxonomic profiles than those between wards (Fig. 2), suggesting distinct ward-based wastewater ecologies. Total metagenomic sequence content was hierarchically structured by ward and by sink (Fig. S4). Staff room sink A25 exhibited distinctive taxonomic and *k*-mer profiles from patient room sinks in the general medicine ward (Figs 2 and S4).

Sinks with high metagenomic abundance of the three Enterobacterales species reliably yielded corresponding cultures. The area beneath the receiver operating characteristic (ROC) curve for culture-based detection of these species was 0.93 (Fig. S5). When the relative metagenomic abundance of a species was above 0.1, 1 and 10%, one or more cultures of the same organism were obtained in 58% (18/31), 76% (16/21) and 89% (8/9) of sinks, respectively. Conversely, culture detection therefore failed in 42% (13/31), 24% (5/21) and 11% (1/9) of cases where an Enterobacterales species was present at or above respective thresholds of 0.1, 1 and 10% metagenomic abundance. A single sink-timepoint (first sample from A8; general medicine) failed to culture any Enterobacterales, but yielded 4, 5 and 16% relative metagenomic abundances for the three study species. Thus metagenomic sequencing suggests that persistence may be even more widespread than indicated by culture alone.

Most environmental Enterobacterales appear to cluster within specific sinks and wards, except for *E. coli* ST635, which is widely distributed

The 96 distinct 100 core SNP lineages found in sinks exhibited structure at the ward and sink level. Three were found in multiple wards (*E. coli* STs 472 and 635; *K. oxytoca* ST 146). Overall, 93 (97%) lineages were only ever found in a single ward, and of the 39 lineages cultured twice or more, only 11

(28%) were cultured from different sinks (Table 1). Further, of the 35 lineages cultured twice or more on wards which were repeatedly sampled (i.e. where it was theoretically possible for a lineage to be observed at different timepoints), 12 (34%) were only seen at the same sink-timepoint, 13 (37%) were seen in the same sink at different timepoints, and 10 (29%) in different sinks at different timepoints. This structure was reflected in the recombination-adjusted core-genome species phylogenies (Fig. 3). The main exception to ward and sink-based clustering was *E. coli* ST635, which comprised more than half of isolates sequenced from sinks, and was found in 13/20 (65%) *E. coli*-positive sinks.

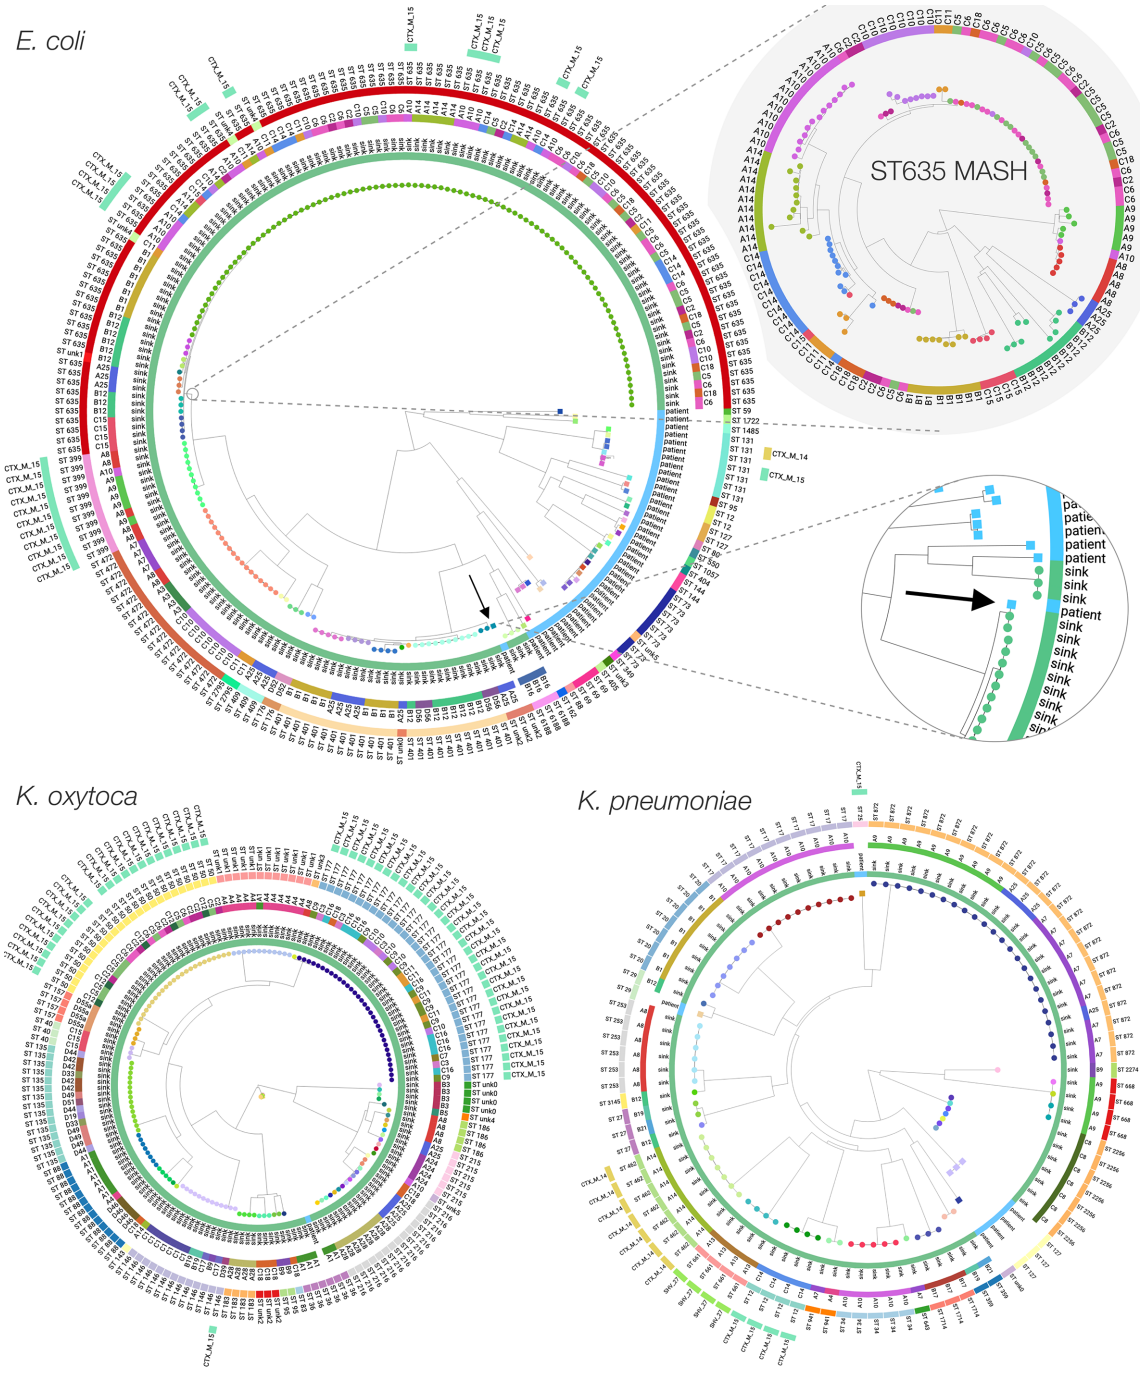

Fig. 3. Maximum-likelihood phylogenies of *E. coli*, *K. oxytoca* and *K. pneumoniae* cultured from sink drain aspirates sampled over 12 weeks across three wards, with two enlargements corresponding to an *E. coli* ST635 neighbour-joining MASH subtree whose tips are coloured by sink, and genetic overlap between a sink culture and a urine culture from a patient with ward contact during the study. Tip colours indicate strains, with rings inside-to-out denoting: patient/sink, sink designation, sequence type, and ESBL genotype.

However, there was sink-level clustering even within *E. coli* ST635, more clearly shown in neighbour-joining trees constructed from pairwise read-based MASH distances, representing both core and accessory genomic content (e.g. *E. coli* ST635 enlargement in Fig. 3; colours indicate distinct sinks). Although pairwise correlations between core and accessory genomic distances were high (Table S3), incorporating accessory content yielded additional resolution beyond core SNP distances (Fig. S6). Permutational analysis of variance (PERMANOVA) using pairwise core SNP and read-based MASH distances supported significant grouping of isolates from all three species by ward and by sink ($P<0.001$), most conclusively for *K. pneumoniae* (Table S4).

Overall diversity among patient *E. coli* isolates was greater than among sink isolates, and included known high-risk clinical lineages

From March to May 2017, 1384 relevant clinical samples from 719 patients were submitted to the microbiology laboratory for processing (AA *n*=779, ACC *n*=365, GM *n*=240), of which 397/1384 (29%) were positive for micro-organisms, and 115 were culture-positive for one of the study organisms (*E. coli* [*n*=104], *K. oxytoca* [*n*=2], *K. pneumoniae* [*n*=9]). In total, 46/115 (40%) of these isolates were retrieved for sequencing, including 21/24 isolates from bloodstream infections, 3/6 from respiratory samples and 22/79 from urine samples; no isolates were retrieved for sequencing in six cases where study organisms were cultured from other clinical specimens (fluid, tissue, joint aspirates).

Among 39 sequenced *E. coli* patient isolates, 21 STs were represented, including known high-risk lineages (23/39 [59%] isolates) not seen in sinks: namely ST73 (*n*=8), ST131 (*n*=7), ST69 (*n*=3), ST12 (*n*=2), ST127 (*n*=2) and ST95 (*n*=1). The single sequenced *K. oxytoca* isolate was ST36, and the six *K. pneumoniae* isolates came from four STs, including two high-risk lineages, ST25 and ST29. Across the three species, there were 34, 1 and 4 distinct lineages, respectively (Table 1).

Genetic similarity of sequenced patient and environmental isolates

As well as being diverse, the 39 clinical *E. coli* isolates were phylogenetically distinct from most sink isolates, which largely came from just four sequence types (ST635, ST401, ST472 and ST399). The exception was an *E. coli* isolated from urine taken on the general medicine ward, which was 17 and 19 core SNPs from two nearest neighbour isolates from sink A25 in the same ward, sampled 58 days prior to the clinical sample (Fig. 1; right; cluster 4). A read-based MASH distance of 7×10^{-6} between this pair of isolates indicated very high total genomic (chromosome+accessory) similarity. A records search for admissions of this patient prior to commencing sink sampling revealed four inpatient admissions (of 0 [day case], 1, 2 and 5 nights' duration), of which three included time on the acute admissions ward. There were no prior admissions onto the general medicine ward (in which their positive urine specimen was taken), and their 11-night spell on the general medicine ward commenced with a 7 h episode in acute admissions. The positive clinical specimen was taken 10 days after the patient's admission onto the general medicine ward, indicating a large duration of exposure to a ward environment shown to be harbouring a very similar strain of *E. coli* to the patient's urine culture. The next most closely related *E. coli* clinical isolate was 3688 core SNPs from its nearest sink neighbour (read-based MASH distance 0.009), reflecting the otherwise large evolutionary distances separating the cultured clinical and environmental *E. coli* (Fig. 3).

Unlike *E. coli*, the small numbers of *Klebsiella* spp. patient isolates were not phylogenetically segregated from environmental isolates, but the closest patient and sink isolates differed by 2558 core SNPs, indicating a lack of observed overlap over these timeframes.

Analysis of protein coding gene function using the Clusters of Orthologous Groups of proteins (COG) ontology highlighted functional differences between sink and patient isolates (Fig. S7). Accounting for the majority of clinical isolates, differences were most apparent among *E. coli*, in which sink and patient isolates were almost linearly separable in the first principle component (PC1; Fig. S7; right). Variable loadings for PC1 indicated COGs explaining the variation between sink and patient groups. The COG with highest loading was insertion sequence IS1R, highly abundant in sink *E. coli* isolates and possibly associated with the acquisition and expression of adaptive genes. Other highly explanatory COGs included genes involved in mobility, adhesion and iron metabolism, predicting functional adaptations of *E. coli* to the built environment of the sink (see supporting data repository).

Antimicrobial resistance genes are prevalent and spatially structured with respect to sink location

The presence of 571 clustered CARD antimicrobial resistance genes in cultured isolates was supported by >=75% exactly matching read coverage reported by ResPipe (Fig. 4). Among these were known transmissible genes of clinical concern including beta lactamases (e.g. bla_{TEM}, $bla_{\text{CTX-M}}$, bla_{SHV}), aminoglycoside resistance genes (*aac(3)*, *aac(6)* families) and quinolone resistance genes (*qnr* family). Some of these, including *cmlA* and *qacH*, were widely seen in sink metagenomes but less frequently in cultured isolates, consistent with a background resistance reservoir that may pose a risk in different populations to those cultured (of either same or different species). Spatial structure with respect to sink location was evident among both cultured isolates and metagenomes, although resistance repertoires of isolates frequently clustered across ward boundaries, in keeping with findings of our prior core-genome analysis. Resistance genes detected in cultured sink isolates were also abundant within sink metagenomes at one or more timepoints. Sink drain metagenomes yielded 673 CARD genes exceeding 75% coverage, and after clustering large gene families represented by many similar sequences (see Methods for detailed description), only five genes abundant in one or more cultured isolates were not detected in at least one metagenome. Notably, these five genes (*gadW*, *len-26*, *tet(B)*, *mgrA* and *sat-2*) were all seen in isolates

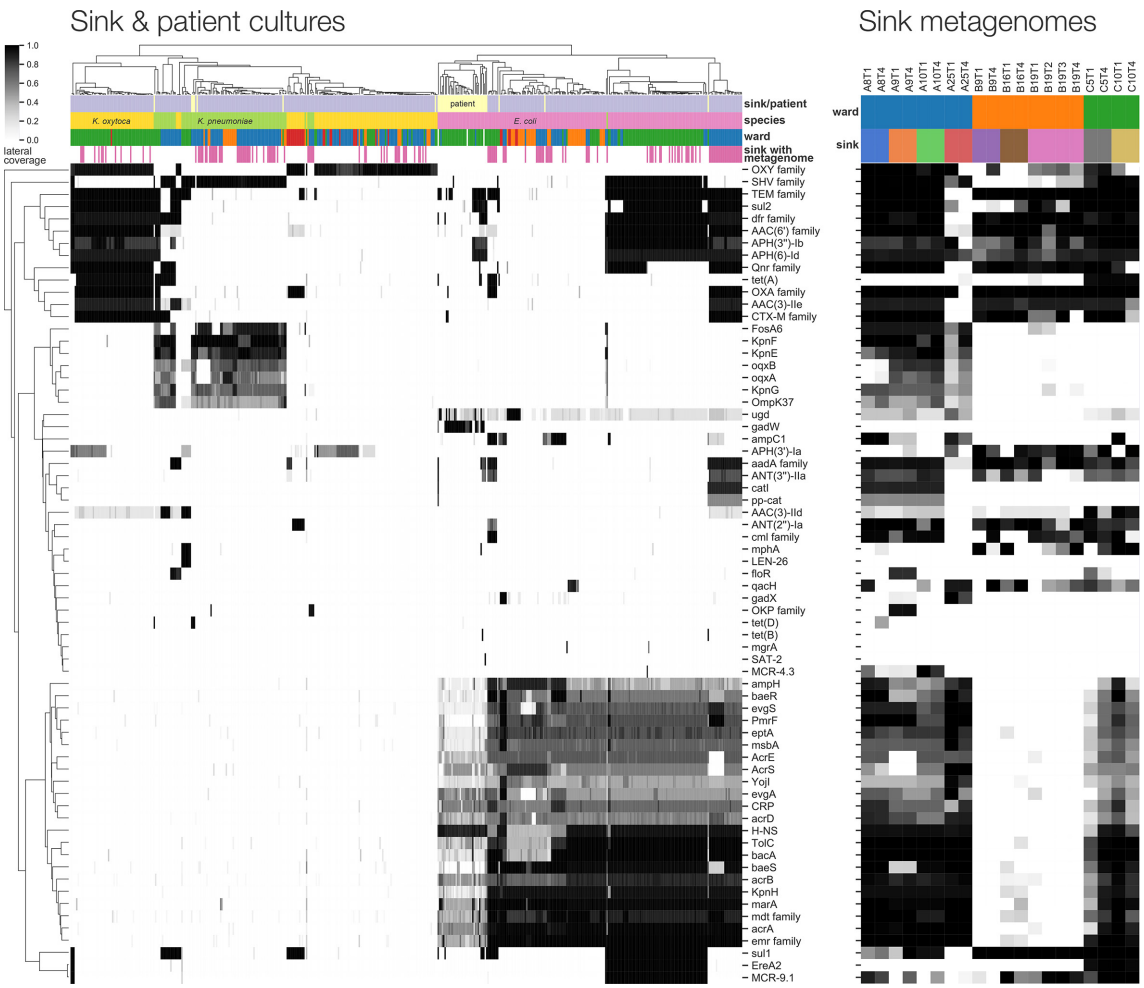

Fig. 4. Antimicrobial resistance gene content of cultured isolates and sink drain metagenomes. Left: lateral coverage of ResPipe/CARD genes within sink drain and clinical isolates. Displayed genes attained >=75% lateral coverage in one or more isolates. Right: corresponding lateral coverage of the same genes in sink drain aspirate metagenomes.

from sinks not subject to metagenomic sequencing, showing that resistance genes cultured from sink drains were highly contained in corresponding metagenomes.

Third-generation cephalosporin-resistant phenotypes in Enterobacterales sink isolates could be explained by the presence of major ESBL genes $bla_{\text{SHV-27}}$, $bla_{\text{CTX-M-14}}$ and $bla_{\text{CTX-M-15}}$, detected by ARIBA/CARD in 4, 8 and 87 isolates, respectively. $bla_{\text{CTX-M-15}}$ was identified in two distinct lineages of *E. coli* ST635 and ST399, restricted to three bay sinks (A8, A9, A10) in three adjacent rooms of the general medicine ward. $bla_{\text{CTX-M-15}}$-positive *K. oxytoca* ST50 and ST177 were identified in 10 sinks (C2-3, C5-6, C7, C9-12, C16) on the acute admissions ward. $bla_{\text{SHV-27}}$, $bla_{\text{CTX-M-14}}$ and $bla_{\text{CTX-M-15}}$ were observed in *K. pneumoniae* from sinks A13, A14 (general medicine) and C14 (acute admissions), respectively; one *K. pneumoniae* patient isolate was also $bla_{\text{CTX-M-15}}$-positive. These findings suggest sink-associated isolates, such as *E. coli*, may represent reservoirs of clinically relevant resistance genes.

Surprisingly, the colistin resistance gene *mcr-4* was detected in the metagenomes—yet not cultured genomes—of three sinks in adjacent bays of the general medicine ward (A8-10). Assembly of the sink A10 metagenome generated a 5.4 kbp plasmid sequence containing an *mcr-4 gene* with 98.8% overall identity at 94% query coverage to an 8.7 kbp pMCR-4.2 plasmid previously reported in pigs from Italy, Spain and Belgium [36]. This *mcr* variant has been previously reported in European *Acinetobacter*, *Enterobacter*, *Salmonella* and *Escherichia* spp. but not to our knowledge in the UK. Screening all metagenomes for assembled *mcr-4* produced alignments in two sinks on the ward (A8, A9) across a total of six sink-timepoints, with coverage and abundance suggesting low and declining prevalence of this gene over time (Table S5). An *mcr*-positive *E. coli* (reported as *mcr4.3*) was cultured from sink C5 (acute admissions; second timepoint) according to both ARIBA/CARD and ResPipe/CARD. Metagenomic sequencing was performed for the first and the fourth but not the second timepoint aspirate for this particular sink.

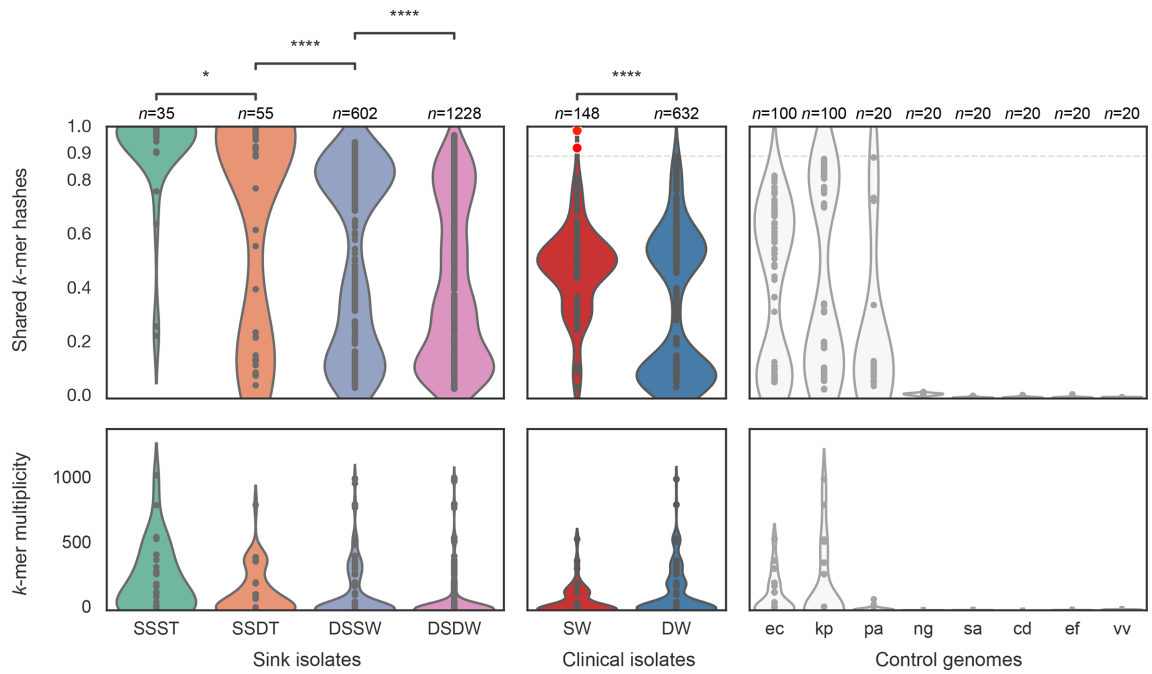

Fig. 5. Metagenomic containment of sink (left) and patient (centre) cultured lineage-representative genome assemblies, and control genomes (right). Shared *k*-mer hashes and median *k*-mer multiplicity values are as reported by MASH Screen. SSST=same sink and same timepoint; SSDT=same sink at different timepoints (shared hashes Mann–Whitney P=0.013 vs. SSST); DSSW=different sinks of the same ward (P<0.0001 vs. SSDT); DSDW=sinks on a different ward (P<0.0001 vs. DSSW). SW=lineage-representative assemblies of clinical isolates in the same ward; DW=lineage-representative assemblies of clinical isolates from a different ward (P<0.0001 vs. SW). Control genomes comprised *E. coli*, *K. pneumoniae*, *P. aeruginosa*, *N. gonorrhoeae*, *S. aureus*, *C. difficile*, *E. faecalis* and *V. vulnificus*, shown abbreviated with binomial initials. A case of within-ward sink-patient overlap is highlighted with red markers, corresponding to high strain containment in the metagenomes of sink A25 timepoints 1 and 4.

Another *mcr* gene, *mcr-9* was more widespread, and detected with complete coverage in 77 cultured isolates across 11 distinct sinks, predominantly but not exclusively in *E. coli* (73/77 occurrences). Plasmid replicon typing highlighted differences in plasmid presence between sink and clinical isolates, revealing 29 and 11 mutually exclusive replicon types to sink and patient isolates, respectively, and 15 types that were detected independently in both sink and patient isolates (Fig. S8, Table S6).

Metagenomic screening suggests that clinical isolates may be more widely present in the environmental reservoir than observed from culture-based comparisons

Sink metagenomes were individually screened for *k*-mer containment of (i) lineage-representative sink isolate genome assemblies, (ii) lineage-representative patient isolate genome assemblies and (iii) core genomes of selected control organisms, including five clinical core genomes each from pathogenic strains of *E. coli* and *Klebsiella* spp. [37], together with NCBI canonical reference sequences for several pathogen species expected to be absent from sink drain microbiota (Fig. 5; left). This demonstrated similar sink, ward and temporal structure to that of culture, particularly underlying similarities in the microbiota of nearby sinks, as well as flux between sampling timepoints. Lineage-representative sink culture assemblies from the same sink and timepoint as the screened sink metagenome were the best contained, sharing the most *k*-mer hashes. Assembled isolates originating from the same sink at a different timepoint to the screened metagenome shared significantly fewer *k*-mer hashes than same sink/same timepoint comparisons (median [IQR]: 93% [22.6%–100.0%] vs. 99.6% [97.7–100.0%], Mann–Whitney P=0.013). The containment of lineage-representative assemblies from different sinks in the same ward as the metagenome was significantly lower still (49.2% [13.8%–84.8%] vs. 93.3%[22.6%–100.0%], P<0.0001), and so in turn were the remaining comparisons of cultures grown from different sinks in different wards to the screened metagenome (33.5% [12.6%–71.1%] vs. 49.2% [13.8%–84.8%], P<0.0001).

Among control genomes, *k*-mer hashes shared between sink metagenomes and the core genomes of *Neisseria gonorrhoeae*, *Staphylococcus aureus*, *Clostridioides difficile*, *Enterococcus faecalis* and *Vibrio vulnificus* did not exceed 3%. Reference genomes of *E. coli*, *K. pneumoniae* and *Pseudomonas aeruginosa* were abundant and highly contained by many metagenomes, but none exceeded 90% shared *k*-mer hashes (Fig. 5; right).

A53210128

In contrast, screening for lineage-representative patient assemblies in sink metagenomes revealed significantly greater containment in terms of shared *k*-mer hashes (median [IQR]: 49% [37%–55%] vs. 32% [8%–56%], Mann–Whitney $P<0.0001$) between patient and environmental Enterobacterales collected from the same ward than from different wards (Fig. 5; centre), showing genetic similarity between clinical isolates from patients and uncultured isolates in sink niches in a given ward setting. Indeed, the only lineage-representative patient isolate with greater than 90% sink metagenome *k*-mer containment was the *E. coli* urine culture described in the aforementioned case of sink-patient overlap, of which 99.5 and 93.0% of *k*-mers were contained within the respective A25T1 (first timepoint) and A25T4 (fourth timepoint) sink metagenomes (Fig. 5; centre; red markers). Interestingly, this particular lineage was cultured at timepoint 1 but not timepoint 4 in sink A25, suggesting that culture may have failed to detect persistence of this lineage detected by metagenomics.

DISCUSSION

In this study, we have demonstrated that hospital sink drains are widely—and in many cases abundantly—contaminated with key Enterobacterales species causing healthcare-associated infections, and are potential reservoirs of multiple resistance genes encoding resistance to important clinical antimicrobials. Populations of antimicrobial-resistant and susceptible *E. coli* and *Klebsiella* spp. may be persistent colonizers of sinks, and different wards may have markedly different sink ecosystems, perhaps reflecting different and potentially modifiable infrastructures, selection pressures and contributing sources. Ward and sink-level genetic structure was especially evident within the accessory genome, and reflected in the observed repertoires of resistance genes. Nevertheless, a handful of key Enterobacterales lineages persisted across multiple wards throughout the duration of the sampling period, and sinks across ward settings were common reservoirs of important clinical resistance genes, including those encoding resistance to beta-lactams, sulphonamides, aminoglycosides and quinolones. Characterizing these highly diverse reservoirs is difficult, and we have shown that combination approaches utilizing metagenomics and sequencing of cultured isolates are complementary in understanding the diversity of species, lineages and the resistance genes present within these niches. For example, metagenomics highlighted several cases of abundant *mcr*-4 in sink drain aspirates from which cultured Enterobacterales isolates did not carry the gene. Furthermore, in the case of an *E. coli* lineage overlapping between sink and patient, metagenomics supported a hypothesis of persistent colonization throughout the sampling period, whereas culture detected this lineage only once.

Colonization patterns of sink niches differed markedly between the two genera investigated. *E. coli* strains have evolved to colonise and adapt to multiple niches, including some which have adopted pathogenic lifestyles, and appear to have different distributions in humans, domesticated and wild animals and the environment. There is however no absolute correlation between phylogenetic lineage and any given niche, and overlaps are observed. Interestingly, in our study, more than half of the *E. coli* sink isolates cultured were ST635, which has been recently described as a highly adapted, resistance- and virulence gene-enriched wastewater-associated strain thought to be globally distributed, but is also found in humans, animals and other environments [38]. Of note, it has been observed in association with several clinically relevant transmissible resistance genes, including ESBLs, carbapenemases and rRNA methylases, and was one of only two *E. coli* STs in our study that harboured an ESBL ($bla_{\text{CTX-M-15}}$). We observed presence/absence of $bla_{\text{CTX-M-15}}$ across closely related ST635 isolates, suggesting that this gene may be frequently lost/gained in sinks. Also notable in the context of ST635 was the ability of read-based *k*-mer composition to resolve fine-grained structure between the populations of different sinks, beyond that observed in the core-only SNP phylogeny. Other common *E. coli* sink lineages were ST399 and ST472, which to date have predominantly been seen in humans/animals, rather than the environment.

The phylogenetic distribution of sink isolates of *K. pneumoniae* appeared to mirror that seen in a global collection of isolates [39], providing little evidence that a particular lineage was predominating in, or particularly adapted to, the wastewater environment. Studies of the population structure of unselected *K. oxytoca* are limited, but again we observed a diverse population amongst sink isolates, with a deep branch separating two distinct groups as previously described. Interestingly, two *K. oxytoca* lineages associated with $bla_{\text{CTX-M-15}}$ were widely distributed amongst sinks in the acute admissions ward; outbreaks of ESBL- and carbapenem-associated *K. oxytoca* in association with contaminated handwashing sinks have been described in other settings [40].

Genomic overlap with sink isolates was identified in 1/46 (2%; 95% CI: 0.05–11%) of all sequenced isolates causing clinical infections over the same timeframe, with a temporal association consistent with acquisition from a sink source (i.e. sink isolate observed first), and following 10 days of patient exposure to a ward environment wherein the overlapping strain was previously cultured. We may have significantly underestimated the degree of overlap between these two compartments for several reasons. Firstly, we have shown the diversity in sink niches is substantial, and with a culture-based approach agnostic to any selective marker, even sequencing 444 isolates from 48 sinks will have limited ability to capture the underlying diversity for complete comparison of sink-patient pairs at the isolate-level. Supporting this, screening the metagenomes of a subset of 20 sinks using patient isolates suggests that overlap between these reservoirs may be more common than observed at the isolate-level. Second, clinical isolates represent the tip of the iceberg of any transmission chain, with the majority of transmission events likely occurring between gastrointestinal tract (asymptomatic carriage) and the wastewater environment. Nonetheless, in the context of understanding how sinks may be contributing to infection caused by *Klebsiella* spp. and *E. coli*, focusing on clinical isolates seems appropriate. Third, the interval between sampling dates for our observed patient-sink isolate-pair was

58 days, suggesting that the timeframe between acquisition from the environment and infection may be long, and may not be adequately captured with a study timeframe spanning 3 months. Refining estimates of the risk of patient infection associated with colonized sink sites ideally requires larger studies, over longer timeframes, and which ideally also capture transmission events resulting in gastrointestinal colonisation as an intermediate step to invasive infection.

In addition, a major study limitation is the fact that only 46/107 patient isolates could be successfully retrieved (due to the high turnover of samples in our high-volume service laboratory), and *Klebsiella* spp. cultures were especially limited. The risks of transmission and possibly sink-associated infection could be more clearly defined by more extensive sampling over a greater timeframe, and thorough investigation into the exchange of resistance-associated mobile genetic elements by, for example, using long-read sequencing to reconstruct plasmid sequences [41, 42]. Doing so would require a considerable increment in resource. Characterizing microbial diversity present on sink strainers would also be of benefit, as the risks of droplet-mediated dispersal from sink drains have been shown to be most significant when the sink drain is located immediately below the tap, and if the organisms migrate from the sink trap onto the strainer [43, 44]. However, given the different sink structures across wards, the p-trap was the only site that could be consistently sampled (since ACC had horizontally draining sinks without strainers). Characterizing factors that might be associated with greater predominance of Enterobacterales and drug-resistant Enterobacterales, such as sink usage, ward-level antimicrobial usage and patient populations, would also be of interest.

In conclusion, without conditioning on the presence of resistance markers, we have demonstrated that colonization of ward sink drains with diverse and abundant populations of Enterobacterales, including drug-resistant lineages, is common and persistent. The evidence linking contaminated, unmitigated wastewater reservoirs (including sink drains) in healthcare settings with outbreaks of colonization/disease with drug-resistant Gram-negative bacilli in patients seems clear [5, 45], but no study to our knowledge has focused on the potential risk posed by Enterobacterales in sinks in general. Screening of sinks is not carried out in the absence of observed outbreaks, making it difficult to quantify wider patient-associated risk from the studies available. We demonstrate that contaminated sinks may be contributing to a proportion of healthcare-associated infections caused by Enterobacterales, and further work to investigate how to reduce the risk posed by this hospital environmental reservoir is warranted.

Funding information
This work was funded by the National Institute for Health Research Health Protection Research Unit (NIHR HPRU) in Healthcare Associated Infections and Antimicrobial Resistance at the University of Oxford, in partnership with Public Health England (PHE) [HPRU-2012–10041] and the NIHR Oxford Biomedical Research Centre. This work was supported by an Oxford University Clinical Academic Graduate School (OUCAGS) Career Development Support for Clinical Lecturers grant to N.S. Extensive use was made of The Oxford Biomedical Research Computing (BMRC) facility, a joint development between the Wellcome Centre for Human Genetics and the Big Data Institute supported by Health Data Research UK and the NIHR Oxford Biomedical Research Centre. Financial support was also provided by the Wellcome Trust Core Award Grant Number 203141/Z/16/Z. N.S. is funded by a University of Oxford/Public Health England lectureship. T.E.A.P. and A.S.W. are NIHR Senior Investigators. The views expressed are those of the author(s) and not necessarily those of the NHS, the NIHR or the Department of Health.

SUMMARY

Background: *Stenotrophomonas maltophilia* causes opportunistic infections and remains a problem pathogen on intensive care unit (ICU) due to its multidrug resistance.
Aim: An outbreak of *S. maltophilia* on ICU is described in order to highlight the risk from contaminated devices for supply of drinking water.
Methods: The outbreak was investigated by a combination of epidemiology, environmental sampling and molecular typing.
Findings: From 2009 to 2011 isolates of *S. maltophilia* from 23 patients were found to belong to only two genotypes by contrast with isolates from 52 other patients during this period, which represented distinct strains. The monthly incidence for all *S. maltophilia* strains ranged from 0 to 11% and for the two outbreak strains from 0 to 9%. Admission and weekly pharyngeal screening on ICU showed that the outbreak strains were acquired on ICU (range: 3–90 days). The majority of isolates (74%) were from the respiratory tract. Only two of 12 (17%) colonized intubated patients developed pneumonia. Environmental sampling found the two outbreak strains in two sinks and in the drinking water of the cooling unit in the ICU kitchen. *S. maltophilia* had formed a biofilm in the flexible tube from the carbon filter to the chiller and from the latter to the tap at the kitchen sink. This cooled water was used for providing drinking water and mouth care to ICU patients. The outbreak strains disappeared after removal of the water-cooler and the monthly incidence fell to <2% of ICU admissions.
Conclusion: This outbreak report highlights the risk from biofilms in devices that supply drinking water for ICU patients.

Introduction

Stenotrophomonas maltophilia is one of the nine most common organisms from respiratory specimens of intensive care unit (ICU) patients in Europe. Surveillance on European ICUs showed that 4% of 1409 bronchial lavage specimens grew *S. maltophilia* on quantitative culture.[1] In this surveillance report *S. maltophilia* occurred as frequently as *Acinetobacter baumannii* and was associated with late onset pneumonia.

As *S. maltophilia* is intrinsically resistant to carbapenems, aminoglycosides and polymyxins and as *in vitro* susceptibility testing is unreliable, the antimicrobial choice is limited to co-trimoxazole, ticarcillin–clavulanic acid, aztreonam plus co-amoxiclav and ceftazidime in combination with other agents. These beta-lactams often appear active against isolates of *S. maltophilia* on Iso-Sensitest agar but will appear less active if tested on Mueller–Hinton agar.[2] Its antimicrobial multi-

resistance makes *Stenotrophomonas* spp. a problem in ICU. Though the majority of patients remain colonized, few debilitated patients develop pneumonias.[3]

We observed on the ICU of a district general hospital a high isolation rate from respiratory specimens, which showed on genotyping two predominant strains. When admission screening by throat swabs was introduced in 2010, this allowed us to assess the acquisition dynamics. This report describes the results of the investigation on these two outbreak strains.

Methods

Epidemiological investigations

Cases were defined as ICU patients from whom *S. maltophilia* genotypes designated FR04 and FR06 were isolated. Admission and weekly screening by throat swab was introduced in March 2010 after recognizing the cluster of these two predominant *S. maltophilia* outbreak strains. As admission screening showed that the outbreak strains were acquired in ICU, a questionnaire was applied to cases covering risk factors such as bed space, mechanical ventilation, surgery, bronchoscopy and Acute Physiology and Chronic Health Evaluation (APACHE) II score. During this 27-month period environmental inspection and sampling was performed on three occasions. In October 2011 the plugholes and faucets of 12 handwash basins in ICU were swabbed. Environmental swabs were collected from the ventilator sockets for the circuit tubes, water for suctioning, chlorhexidine mouth gel, bronchoscopes and laryngoscopes. In December 2011 preflush water from the faucets of all 12 handwash basins, three sluice basins, the cold water and drinking water tap in the ICU kitchen were collected for culture.

Microbiological investigations

Throat swabs were streaked on to cysteine-lactose-electrolyte-deficient (CLED) plates (E&O Diagnostics, Bonnybridge, UK), to which a meropenem disc was added on to the inoculum. Non-lactose fermenters growing around the meropenem disc were identified biochemically (API, bioMérieux, Craponne, France) until July 2011, and from then onwards by matrix-assisted laser desorption/ionization time-of-flight (MALDI-TOF) analysis (Bruker, Billerica, MA, USA). Sensitivity testing was only performed for co-trimoxazole using the BSAC (British Society for Antimicrobial Chemotherapy, Birmingham, UK) disc diffusion methodology.

Tap water was collected into sterile 500 mL containers and filtered through a filtration device (Nalgene, Nalge Nunc, Rochester, UK) on to a 0.45 μm pore size membrane (Millipore, Bedford, MA, USA) within 30 min after collection. The membrane was imprinted on to CLED agar and then three imipenem discs were distributed over the plate. The PVC tubings before and after the carbon filter were cut into 0.5-cm-long pieces and cultured in cooked meat broth (Oxoid, Basingstoke, UK) and then subcultured on CLED plates with three imipenem discs. Any non-lactose fermenting colonies growing in the imipenem inhibition zones were identified by MALDI-TOF analysis and, if *S. maltophilia*, sent for typing by pulsed-field gel electrophoresis (PFGE) of *Xba*I-digested genomic DNA. Electrophoresis was carried out at 6 V/cm for 30 h at 12 °C with ramping times of 5—35 s.

All *S. maltophilia* isolates from ICU patients were genotyped by PFGE at the Health Protection Agency Antimicrobial Resistance and Healthcare Associated Infections Reference Unit in Colindale, London.

Investigations on source

Drinking water was supplied by an under-sink water-cooler in the ICU kitchen, which was connected to the mains water supply. A carbon filter was installed between mains and water-cooler via a flexible polyvinylchloride (PVC) tubing (Figure 1), from where a plastic tube led to a special drinking water tap at the kitchen sink. Five hundred millilitres from this tap, 200 mL mains water from the tubing to the carbonfilter and 200 mL of filtered water after the filter were collected on disassembly of the chilling unit and filtered on to a membrane for isolation of *S. maltophilia*.

Results

From August 2009 to November 2011, 23 patients acquired the outbreak strains designated FR04 and FR06 (Figure 2). This resulted in a prevalence of 1.6% among 1411 ICU patients during this period. These 23 representatives of the two outbreak strains accounted for 31% of all 75 *S. maltophilia* isolates. The other 52 *S. maltophilia* strains had unique genotypes and were unrelated to the outbreak strains. The monthly incidence of all *S. maltophilia* cases varied from 0 to 10%, and from 0 to 7% for the outbreak strains (Figure 3). The incidence of these two outbreak strains peaked during the summer months, particularly during June to October 2011, when seven new cases occurred (Figure 2).

Admission and weekly screening by throat swab for culture of *S. maltophilia* was introduced in March 2010 and revealed that none of the outbreak strains was present on admission by contrast with unique genotypes, which were detected on admission. The median duration from ICU admission to first isolation of *S. maltophilia* was 14 days (range: 3—90 days). After the first isolation of *S. maltophilia*, patients remained

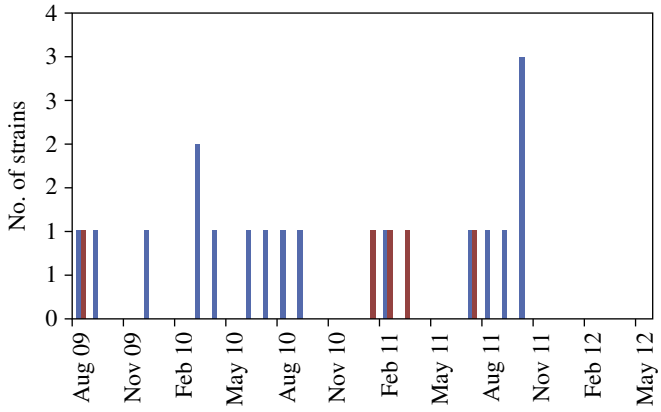

Figure 2. Incidence of outbreak strains in intensive care unit. Blue: FR04; red: FR06.

throat-carriers for up to 4 weeks as could be shown by weekly screening during their ICU stay.

The mean age of patients was 61 years (SD: 17), 74% had recent surgery and 56% were intubated and ventilated. The outbreak strains were isolated in 17 of 23 cases (74%) from respiratory samples such as throat screening swabs and endotracheal aspirates or sputums. Two of 12 (17%) colonized and ventilated patients developed pneumonia, which required treatment with co-trimoxazole. Eighty-two percent received a carbapenem before acquisition for 1–10 days (median: 5). The questionnaire on risk factors did not reveal any common exposure: acquisition was not associated with intubation, certain side-rooms nor bed spaces nor procedures. Only a few cases were overlapping, particularly during the summer months, but there were several months without any cases. This made cross-transmission less likely and suggested a point source for these outbreak strains. In October 2011 the outbreak strains FR04 and FR06 were found in the sinks of the sluice room and one bedside handwash basin. The water stream from the tap was not directed into the drain, which made splash-back unlikely. On review of nursing practices the nurses reported that they had discarded the water from tooth-brushing or patients' drinking water into handwash basins. They revealed also that they had used cooled water from the ICU kitchen from the special tap for cooled water for serving patients drinking water and mouth care. In December 2011 water was cultured for *S. maltophilia* from all 12 handwash basins in ICU, from the two taps in the sluice room and from the tap for the sink and the drinking water tap in the ICU kitchen. Only the narrow-diameter drinking water from the special kitchen tap grew *S. maltophilia* outbreak strains FR04 and FR06 (Figure 4).

This tap was supplied with water via an under-sink water-cooler (Figure 1). The mains water was passed through a carbon filter to remove the chlorine dioxide for better taste before entering into a water-cooler, from where plastic tubing led to the drinking water tap at the kitchen sink. On disassembly the sampled mains water before the carbon filter was free from *S. maltophilia*; however, the water collected after the filter from the unit grew >100 cfu *S. maltophilia* per 100 mL, which matched the two outbreak strains FR04 and FR06. Also the plastic tubing to the tap grew the outbreak strains in enrichment broth. The chilling unit and tubing was removed in December 2011 and chilled bottled water was used as drinking water. Since that time no more FR04 and FR06 genotypes have been found in ICU and the stenotrophomonas prevalence has fallen to <2% of admissions. This chilling unit was installed in 2009 and the carbon filter had been changed quarterly, but not the tubing.

Discussion

Although *S. maltophilia* is one of the nine most frequently sampled organisms from endotracheal aspirates, the pulmonary infection rate among colonized patients was low with 17% patients developing pneumonia with this strain. Laing *et al.* reported an infection rate of 64% among colonized ICU patients; however, their case definition for lung infection comprised physician's clinical judgement and repeated

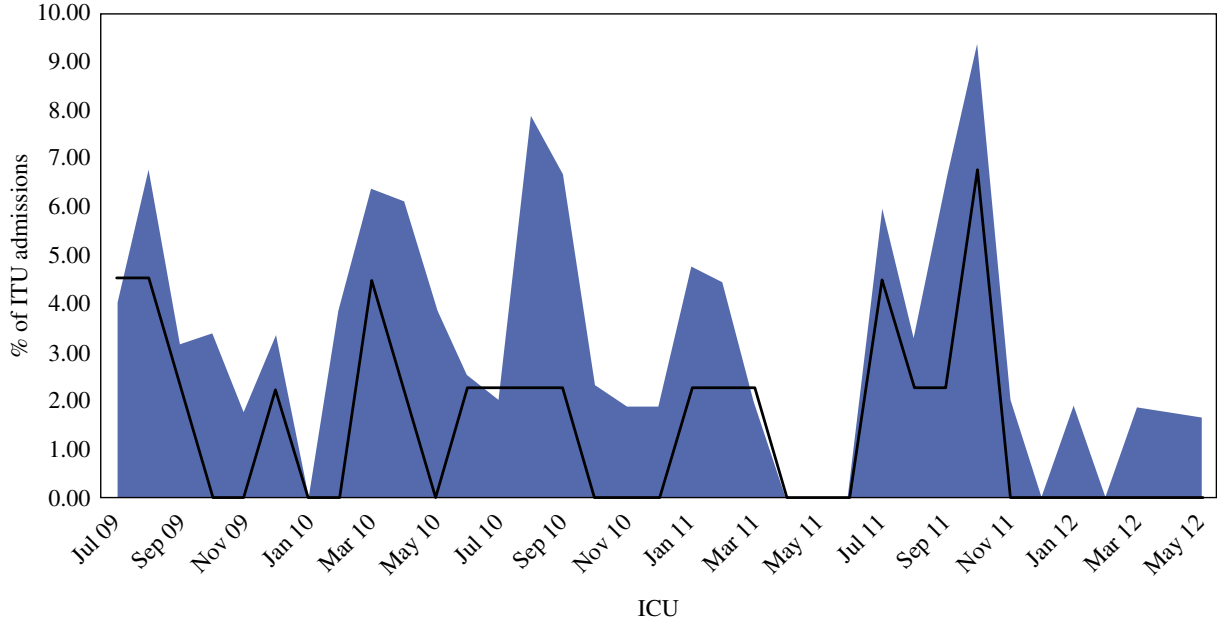

Figure 3. Incidence of outbreak strains and incidence of all *Stenotrophomonas maltophilia* strains on intensive care unit (ICU).

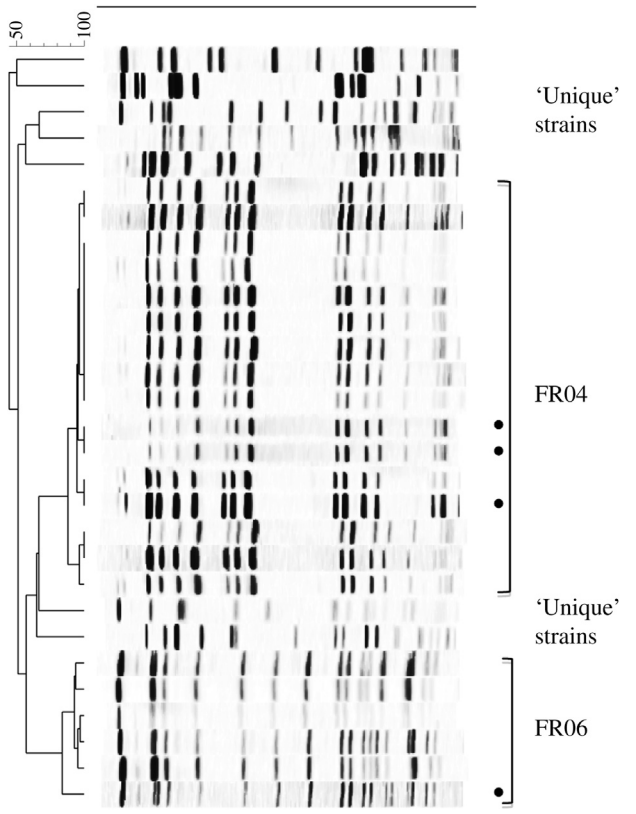

Figure 4. Dendrogram showing pulsed-field gel electrophoresis profiles of *Xba*I-digested genomic DNA from representative isolates of *Stenotrophomonas maltophilia* from patients and water over the period 2009–2011. Only one isolate is included per patient. Water/tap/sink isolates are marked with bullets.

growth.[4] A recent study found that patients with *S. maltophilia* in their respiratory tract and a high lung injury score had a significantly higher mortality than colonized patients with lower scores.[5]

This outbreak report illustrates that a water-cooler for drinking water was the source of *S. maltophilia* on ICU, because a carbon filter had not only removed the disinfectant chlorine dioxide before the water-cooler, but had also accumulated organics, which serve as nutrients for bacteria facilitating the growth of biofilms on downstream tubing. Carbon filters are installed at drinking water dispensers in order to improve the organoleptic quality of mains water by removing chlorine and other ions. Water in our hospital is treated with chlorine dioxide for the control of legionella. The British Standard BS EN 'Chemicals used for treatment of water intended for human consumption' (BS EN 12671:2009) permits on-site generation of chlorine dioxide up to concentrations of 0.5 mg/L, at which limit odour and taste of water change.[6] The absence of the disinfectant chlorine dioxide beyond the carbon filter allowed *S. maltophilia* to form a biofilm on the 6 mm diameter PVC tubes. Flexible pipes are known for colonization with waterborne bacteria and the addendum of HTM01-04 restricts the use of flexible hoses and tubes for water conveyance to few necessary installations, to which water-coolers do not belong.[7]

Drinking water-related outbreaks with opportunistic pathogens in hospitals have been reported previously. Wilkinson and Kerr found high rates of faecal carriage of *S. maltophilia* among patients with haematological malignancies and identified non-carbonated bottled water, which contained up to 49,000 cfu/mL of *S. maltophilia* and other non-fermenters.[8] *S. maltophilia* was able to grow in non-carbonated water over a range of pH and at refrigeration. In a bone marrow transplant unit a high prevalence of *Pseudomonas fluorescens* was detected in pharyngeal surveillance swabs.[9] The same strain was found in the water of one of the drinking water dispensers. *P. fluorescens* was thought to have formed a biofilm in the dispenser, because the water of the second dispenser was sterile, though it was supplied by the same batch of bottled still spring water. Other water-related outbreak reports found that the aerators of the faucets on a neonatal ICU were colonized with a biofilm of *S. maltophilia*, which contaminated the bathwater for the newborns.[10] Five neonates became colonized with *S. maltophilia* and one baby died from bacteraemia. On a haematology unit *S. maltophilia* formed biofilms on faucets and two neutropenic patients developed severe soft tissue infections with the same strain as on the faucets.[11]

In the UK the addendum of HTM 04-01 stipulates control measures for the prevention of *Pseudomonas aeruginosa* growth in distal pipework, where immunosuppressed patients are accommodated.[7] Measures such as 6-monthly sampling of preflush water will detect biofilms in faucets, shower heads and in the peripheral pipes. Remedial measures comprise design such as avoidance of dead legs, blind ends, flow straighteners and unnecessary thermostatic mixing valves and removal of under-used outlets and flexible tubes. Maintenance foresees regular flushing and descaling of taps and showers in augmented care areas. These measures will reduce the risks from taps and pipes; however, the dilemma of providing safe drinking water that is free from non-fermenters has not been fully addressed. The public water supply is monitored for *E. coli*, coliforms, *C. perfringens* and enterococci, but not for *Pseudomonas aeruginosa* and other non-fermenters.[12] According to the European Council Directive 98/83/EC, bottled water is also controlled for *P. aeruginosa*, but not for other non-fermenters, which may be included in the permitted total viable count of 100/mL at 22 °C.[13] The safest drinking water supply is boiled or distilled water. Water filters can be fitted to taps, but they require regular change of cartridges. If bottled or filtered water is offered to immunosuppressed patients for drinking, regular monitoring for non-fermenters is advisable. Chlorine dioxide treatment of hospital water has been used successfully to prevent legionella, but will also reduce the planktonic burden of other water-borne bacteria. Chlorine dioxide levels up to 0.5 mg/L are permitted in drinking water and, if the organoleptic quality is acceptable, this may be another method of providing pseudomonas-free drinking water, provided that no carbon filters are attached to the dispensers.

In augmented care areas it is advisable that any water additions that have narrow-diameter tubing or carbon filters attached are regularly controlled for growth of non-fermenting bacteria.

Outbreak-investigation

Background: Nosocomial Stenotrophomonas *maltophilia-related* cases are rising and pose a threat to immunocompromised patients. Twelve patients from our pediatric intensive care unit (PICU) presented with S *maltophilia-associated* bloodstream infection.
Methods: This outbreak investigation includes 12 patients from PICU between the ages of 2 months and 4 years (mean 16 months, 7 male). To identify the origin, samples from all possible sources throughout the hospital were collected and ran through DNA isolation and Pulse Field Gel Electrophoresis.
Results: 120 samples were collected during the outbreak. 31 samples (26%) were positive for *S maltophilia.* 30 *S maltophilia* isolates were analyzed, 10 different genotypes were identified. Clustering isolates were grouped into 3 different clusters (tolerance and optimization 1.0, cutoff 90%). The largest cluster was genotype 1, which included 19 isolates, those belong to patients' samples and a sample from a pull-out faucet inside the PICU. The Pull-out faucet was the origin of the bloodstream infection.
Discussion: Pull-out faucets allow biofilm production, due its structure. Pulse Field Gel Electrophoresis identifies the transmission dynamics of the outbreak, with its high discriminatory power.
Conclusions: Water sources should be monitored on a regular basis. Pull-out faucets enable bacterial overgrowth; therefore, we recommend water surveillance during outbreak investigations.

BACKGROUND

Stenotrophomonas maltophilia is the third most common non-fermenting gram-negative rod, which infects humans after *Pseudomonas aeruginosa* and *Acinetobacter spp.*[1,2] In the last few decades *S maltophilia* occurrences have multiplied, making it increasingly recognized as an important cause of nosocomial infections. Therefore, many outbreaks have been reported within the last few years in hospitals and intensive care units (ICUs).[3,4] A study conducted in a European center for pediatric hematology and oncology reported an incidence of 2.3% of *S maltophilia* infections among pediatric patients admitted to the ICU.[5]

S maltophilia presents with minimal invasiveness in immunocompetent individuals, but it can lead to severe even fatal infections in immunocompromised patients. Its high resistance to many antimicrobial agents may result in unsuccessful treatments and a significant mortality rate in patients.[6–8]

METHODS

This is an outbreak investigation, and the project was deemed IRB-exempt.

Subjects

In the PICU of Istanbul Medipol University Mega Hospital, between August 6, 2021, and December 2, 2021, 12 patients between the ages of 2 months and 4 years (mean 16 months, 7 males, 5 female) were diagnosed with bloodstream infection (BSI) due to *S maltophilia*. All patients were positive ≥48 hours of their PICU admission and therefore fulfilled the criteria for hospital-acquired BSI.[9] Each patient was reviewed for their history of known disorders, immunosuppression status, presence of any type on intravenous instruments, peak C-reactive protein, white blood cells, and neutrophil levels at the time of BSI.

As a part of the investigation process environmental samples had been swabbed from all possible sources, especially from damp environments, (such as faucets, pull out-faucets, wash trays, water hoses, water reservoirs of humidifiers, ventilators, nebulizers, continuous positive airway pressure machines, nasal cannulas, oxygen masks, tracheostomy tubes, central lines, medicine pumps, nasogastric and gastrostomy tubes, feeding bottles, baby pacifiers, inflatable cuffs, temperature probes, heart monitors, pulse oximeters, hospitals bed head surfaces and sheets, shelving and care trolleys, foley, indwelling catheters). In addition, patient surveillance samples were obtained from endotracheal aspirates, rectal and skin swabs.

Antimicrobial sensitivity tests for Stenotrophomonas maltophilia

Antimicrobial sensitivity tests were conducted on 30 strains of *S maltophilia* using the standard disk diffusion method (Bioanalyze). The tests were performed with 5 different antibiotics: ceftazidime (5 μg), minocycline (30 μg), ciprofloxacin (5 μg), levofloxacin (5 μg), and trimethoprim/sulfamethoxazole (1.25 μg/23 μg). These tests were performed at the Medical Microbiology Research Laboratory of Recep Tayyip Erdogan University, Faculty of Medicine. The results were evaluated according to the EUCAST 2022 (v. 12.0) (European Committee on Antimicrobial Susceptibility Testing) criteria.[10]

DNA isolation and integron gene cassette screening

Total DNA isolation was performed using the boiling method.[11] Integron gene cassettes and resistance genes were screened by protein chain reaction from all bacterial strains using sequences described previously.[12–17]

Pulse field gel electrophoresis (PFGE) protocol

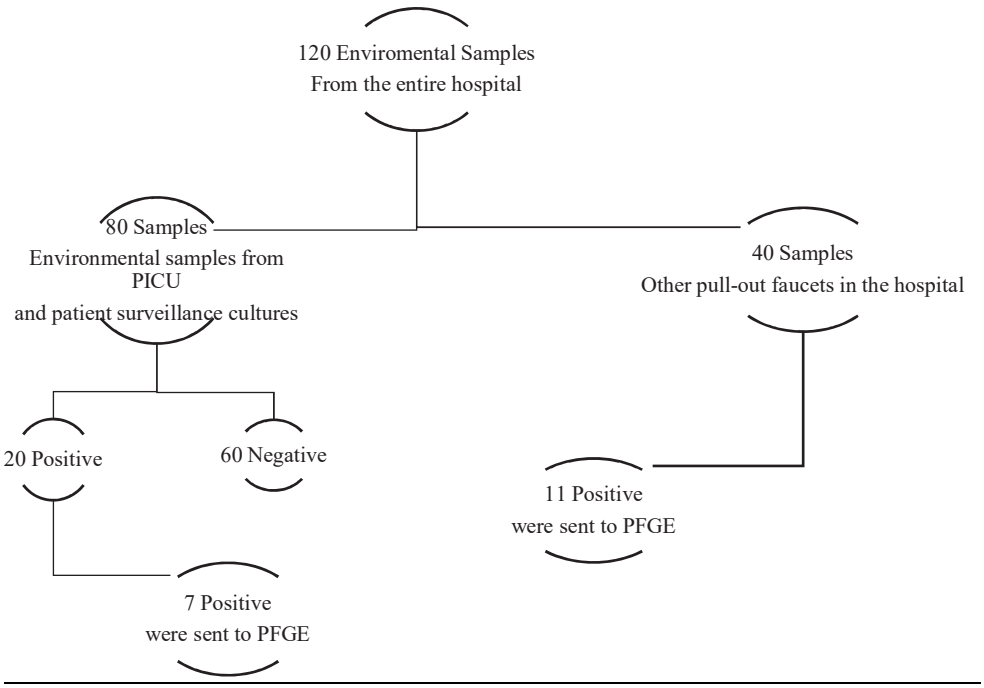
All 30 *S maltophilia* isolates were typed by PFGE according to a protocol published by Durmaz et al with modifications. All strains recovered from patient clinical samples and environmental sources were taken for PFGE study from Medipol Mega hospital in İstanbul. Genotypes were grouped for this outbreak investigation.

Results

Patients' demographics and lab findings are given in Table 1.

A total of 120 samples were collected from the hospital during the outbreak (80 samples from the PICU and 40 samples from the other pull-out faucets in the hospital) and 31 samples (26%) were positive for *S maltophilia*. In addition to 18 environmental isolates, 12 BSI isolates were analyzed with PFGE (Table 2). Epi-curve for the outbreak is given in Figure 2.

Table 2
Flowchart of the collected environmental samples



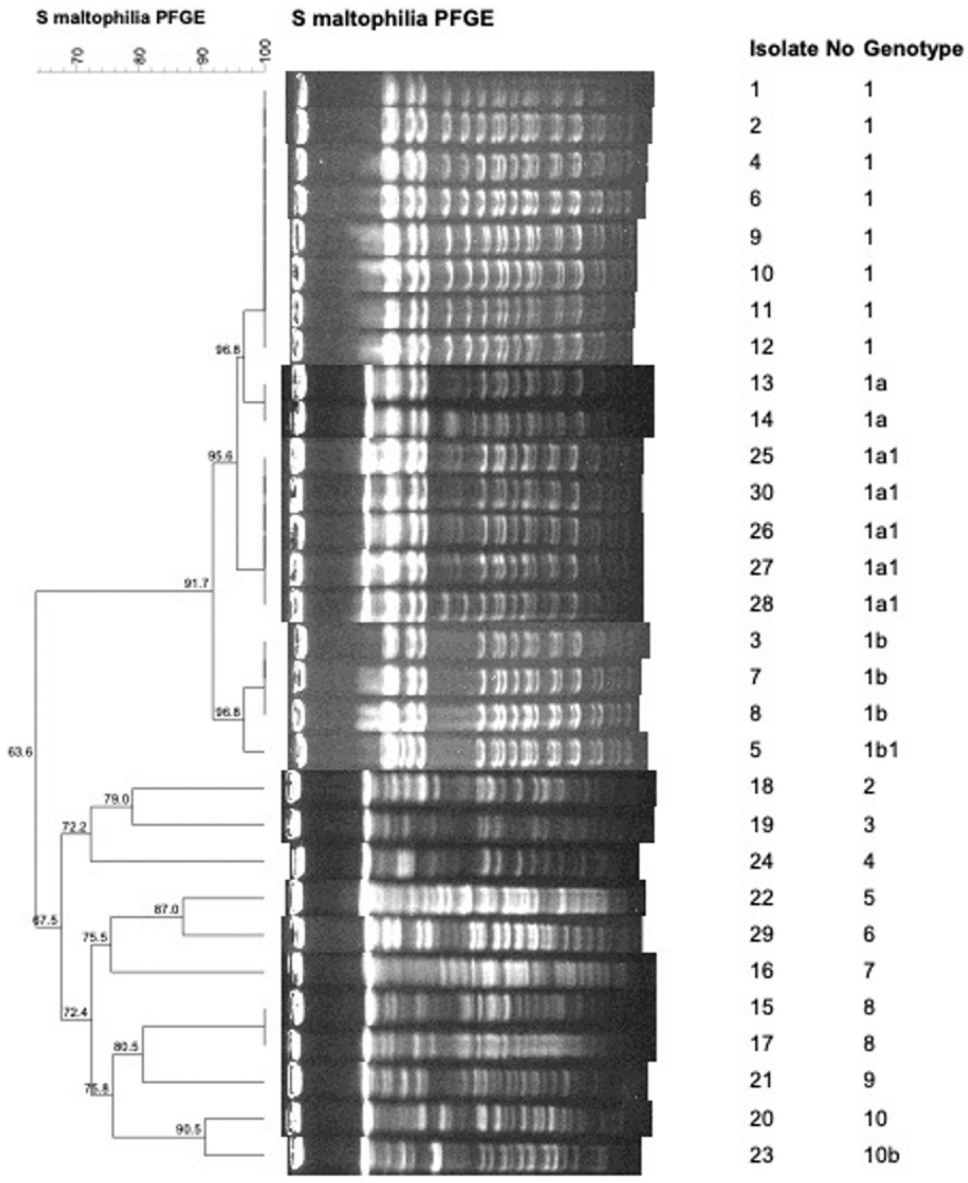


Fig. 1. The PFGE results of 8 environmental and 12 bloodstream infection isolates.

Among the 30 *S maltophilia* isolates, 10 different genotypes were identified, and the isolates showing clustering were grouped into 3 different clusters (tolerance 1.0, optimization 1.0, cutoff 90%). The largest cluster was genotype 1, which included 19 isolates (Fig 1). It is likely that the isolates within genotype 1 were associated with an outbreak. Isolate numbers 1, 2, 4, 9, 10, 11, 12, 13, 14, 25, 26, and 30 are isolates recovered from patients' blood cultures. Isolate numbers 3, 5, 7, 8, 27, and 28 were environmental isolates. Isolate number 6 was recovered from the pull-out faucet inside the PICU. In Figure 3 the rooms that patients stayed during the outbreak is represented with star sign. Overall, in the PICU, there were 6 faucets (shown with a tap sign) and a pull-out faucet (isolate no: 6, represented with a star sign), which were located in the medicine preparation room. Only the pull-out faucet was positive for *S maltophilia* . When the contaminated pull-out faucet was replaced in December 2021, the outbreak ceased, which clarified the origin. The other clusters were genotype 8 and genotype 10, each containing 2 isolates. 23 out of the 30 *S maltophilia* isolates were included in any of the clusters, with a clustering rate of 76.6%. According to the protein chain reaction results, no gene cassettes were found. All isolates recovered from blood cultures were susceptible to ceftazidime and trimethoprim/sulfamethoxazole. We treated all our patients with trimethoprim/sulfamethoxazole.

DISCUSSION

S maltophilia is frequently recognized as a pathogen that thrives in immunocompromised hosts because of its low virulence and consequent opportunistic nature. According to genomic diversity

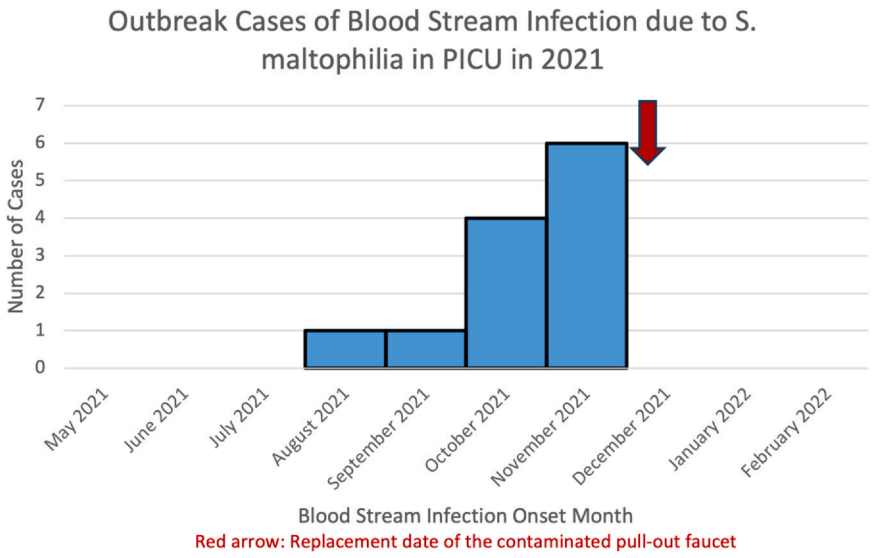

Fig. 2. The epicurve of the outbreak.

among isolates associated with nosocomial cases, there is a strong suggestion of multiple independent environmental sources of transmission.[18,19] *S maltophilia* can attach to and survive on abiotic surfaces within clinical settings via its charged cell wall surface and biofilm production, such as central venous catheters, disinfectant, and handwashing solutions, solutions for hemodialysis, endoscopes, inspiration and expiration circuits of ventilators, nebulizers, tap water, and showerheads.[20–22] Moreover, patient-to-patient transmission has also been reported.[17,18]

E. Sakhnini et al reported 2 infants in a neonatal ICU had *S maltophilia* BSI originating from faucets in the room of one of the patients.[23] Another study from the Netherlands reported 1 *S maltophilia* BSI, which was cultured from tap water from 3 outlets in the neonatal ICU.[24] Data by Weber et al demonstrated that 2 patients were colonized by strains of *S maltophilia* contaminating the faucet aerators in the sink.[25]

WHO has classified *S maltophilia* as one of the leading multidrug-resistant organisms in hospital settings.[19] The risk factors of *S maltophilia* BSI include underlying malignancy (especially hematologic malignancy), organ transplantation, HIV infection, underlying cardiovascular disease, prolonged hospitalization, ICU admission, indwelling catheters (vascular, urinary, and biliary), corticosteroid or immunosuppressive therapy, and prior antibiotic treatment with carbapenem.[21,26–29] Analyzing our patients' profiles, 75% of them were immunocompromised, 50% had underlying cardiovascular disease, and 66.6% had central venous catheters.

We employed various methodologies to assess the contributing factors and identify the transmission patterns. The infection control team observed PICU-staff through the surveillance cameras for 24/7 and weekly meetings were done to give feedback. Our investigation revealed that a pull-out faucet within the PICU and the pipeline attached to it was completely covered with biofilm, which grew *S maltophilia* . Flexible polymeric pipe materials are commonly used as shower hoses or connections to faucets in the last meters of building plumbing. These tend to leach high concentrations of carbon, which may encourage bacterial growth.[30]

There were few theories on how the bacteria located in the pull-out faucet could have caused the outbreak. The theories include a lack of appropriate hand hygiene, incompatible use of medical gloves, asepsis, and cleaning techniques, and not following the isolation rules properly. After pinpointing the outbreak, the hospital's infection control team arranged mandatory training and replaced the pull-out faucet with standard faucets. Training on isolation procedures was provided to resident doctors, whereas new nurses entering the field received training on bedside and mock scenarios. Auxiliary staff were also trained on cleaning procedures.

Our outbreak investigation had several strengths, including access to comprehensive medical records and evaluation of the relevant risk factors. Differentiating true BSI from pseudo-outbreaks due to contamination is crucial for accurate analysis. To address this issue, we used peak C-reactive protein levels as an indicator of true BSI. This approach helped us distinguish genuine infections from contamination-related incidents, thereby enhancing the reliability of our findings. To identify the transmission dynamics of the outbreak, we employed PFGE, which has high discriminatory power. Previous studies conducted in newborns and PICUs have successfully used molecular typing to identify the cross-transmission of *S maltophilia.* [31,32] Furthermore, we took extensive measures to explore all possible sources of contamination by collecting samples from various environmental sources. This comprehensive approach allowed us to thoroughly investigate potential reservoirs and contributing factors within the PICU.

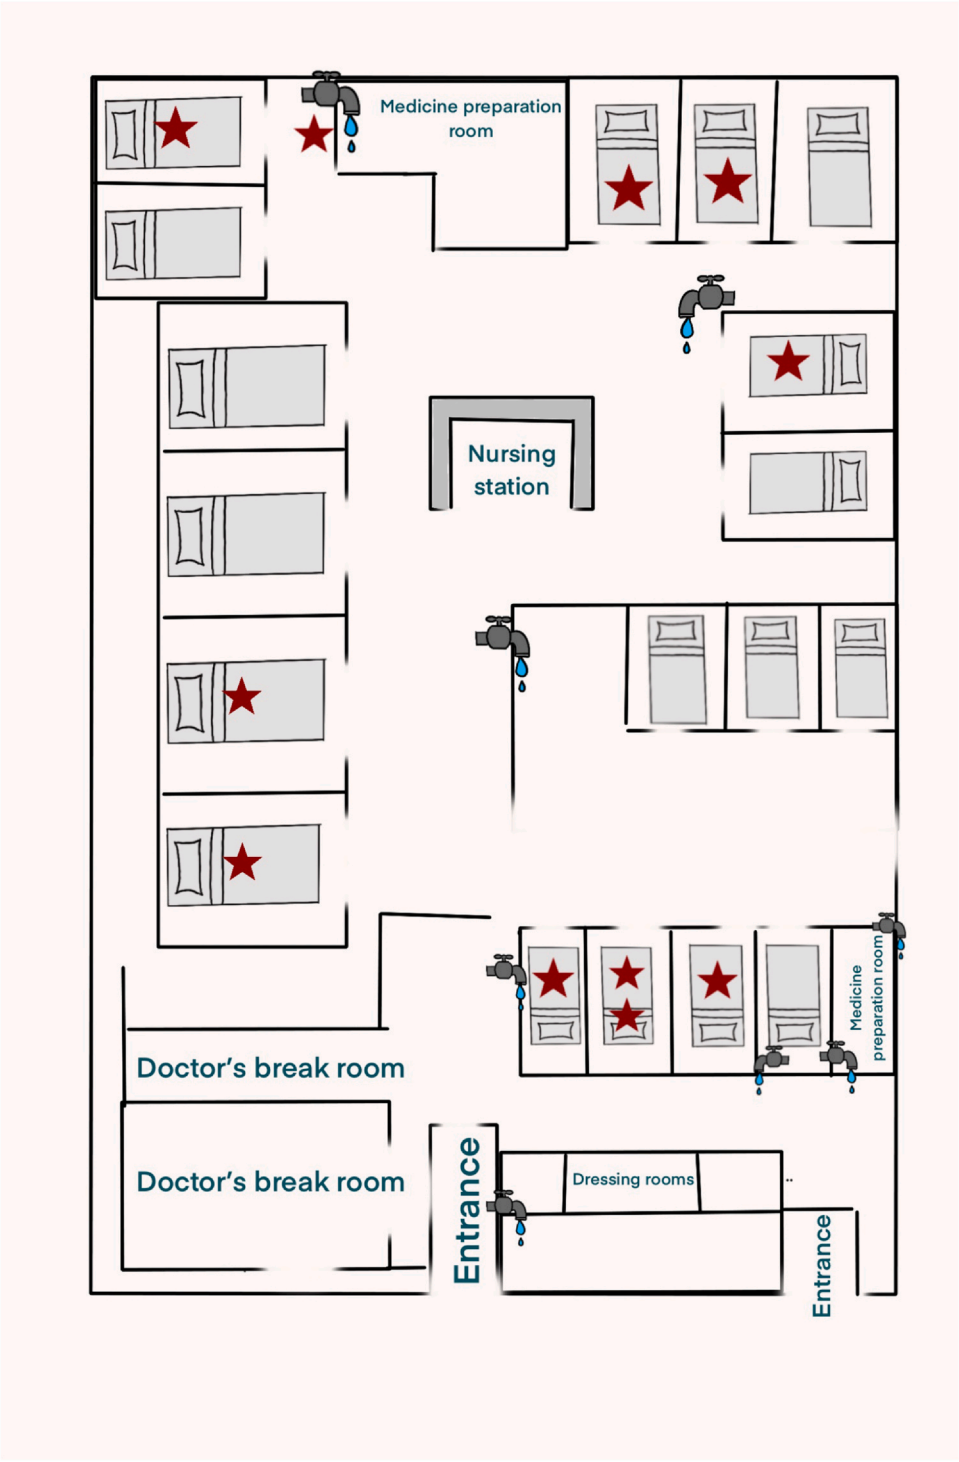

Fig. 3. The map of the pediatric intensive care unit during the outbreak.

CONCLUSIONS

Our outbreak investigation highlights a significant positive link between waterborne *S maltophilia* prevalence rates in PICU patients and tap water supply contamination. The molecular correlation between pull-out faucet originating *S maltophilia* and clinical strains isolated from vulnerable patients was a remarkable finding. Even though pull-out faucets allow easier access to water, it is susceptible to biofilm formation. Therefore, we do not recommend the use of pull-out faucets inside the PICU. Our research highlights the importance of mandating the use of sterile water in PICUs, training hospital staff to spot breaks in sterilization techniques, and including water surveillance during outbreak investigations.

Environmental cleaning

Summary An outbreak of *Acinetobacter baumannii* colonization and infection occurred in 19 patients over a 14-month period during 1998–1999 on a neurosurgical intensive care unit. During efforts to control the outbreak a significant correlation was observed between the number of environmental isolates of *A. baumannii* obtained during each monthly screening and the number of patients with *A. baumannii* colonization/infection in the same calendar month ($P = 0.004$). Use of 1000 ppm hypochlorite solution and the introduction of new cleaning protocols reduced the number of environmental isolates. Failure to maintain low levels of environmental contamination with *A. baumannii* resulted in increases in patient colonization. This study showed that high standards of cleaning play an integral role in controlling outbreaks of *A. baumannii* in the intensive care unit setting.

Introduction

Outbreaks of *Acinetobacter baumannii* colonization and infection on intensive care units are a common problem, particularly in Europe[1–4] and North America.[5–8] A propensity to tolerate drying[9,10] and resistance to multiple classes of antibiotics[1,4,7] are key factors in enabling the organism to survive and spread in the nosocomial environment. Although the importance of cleaning in controlling epidemics of *A. baumannnii* has been emphasized in previous studies[7] little is known about the optimum approach to environmental cleanliness in an endemic situation. We report an outbreak of *A. baumannii* colonization and infection on a neurosurgical intensive care unit (NICU) where the intensity of environmental cleaning closely

correlated with the number of positive environmental sites and, subsequently, the number of affected patients.

Materials and methods

Description of the outbreak

During one month of 1998 seven cases of colonization and infection with *A. baumannii* were noted on the NICU of a 1000 bed tertiary-care teaching hospital. This is a seven-bedded unit, five in an open-plan area and two in single rooms. The ward environment was screened revealing that 27 of 51 (53%) sampled sites were contaminated with an indistinguishable strain of *A. baumannii*, as determined by pulsed-field gel electrophoresis (PFGE). The unit was then closed and existing patients moved to an adjacent intensive care unit for eight days whilst the ward environment was thoroughly cleaned using detergent and water. However, after re-opening, patient cases continued and re-sampling of the environment again revealed significant contamination with *A. baumannii*. An environmental cleaning policy using 1000 ppm sodium hypochlorite solution was instigated and monthly environmental sampling of the same 51 sites continued. Over the next 13 months a further 12 cases of infection/colonization were identified. Patient's details are listed in Table I.

Ward databases were also analysed to provide information on bed occupancy rates and mortality during the period of the outbreak. During this period a number of issues with cleaning protocols were also identified and addressed. These included problems with recruiting and retaining cleaning staff, proper training and supervision, failure to follow agreed cleaning procedures, clear designation of cleaning responsibilities between nursing and cleaning staff, and failure to adequately dry cleaning equipment, e.g. mop heads between use.

Isolate origin and identification

All oxidase-negative, non-lactose fermenting, Gram-negative bacilli obtained from clinical samples were identified as *A. baumannii* using API 20NE (bioMérieux, Marcy l'Etoile, France). After isolation they were stored at −70 °C in 15% glycerol broth.

Antibiotic susceptibility testing

Antibiotic susceptibility to eight antimicrobial agents (ampicillin, cefradine, gentamicin, ciprofloxacin, cefotaxime, aztreonam, piperacillin-tazobactam, and meropenem) was performed on Isosensitest agar (Oxoid Ltd., Hampshire, United Kingdom) using Stokes' method.

Environmental screening

Environmental sampling was carried out on the NICU after the identification of the first seven cases. A total of 51 sites were sampled from the patients' immediate environment, particularly sites where dust accumulated. These included

Table I Details of cases involved in the outbreak

Case no.	Age	Sex	Diagnosis	Sources

patient monitors, bed frames, X-ray illuminators, curtain rails, and equipment trolleys. Ventilation grilles from the air-conditioning unit were also targeted. The same 51 sites were sampled monthly with sterile swabs, moistened in 1/4 strength Ringers solution, which were then applied directly onto Columbia agar containing 5% horse blood supplemented with 6 mg/L vancomycin. Plates were incubated overnight at 37 °C in air. All oxidase-negative Gram-negative coccobacilli were confirmed as *A. baumannii* using API 20NE.

PFGE

The method used was that of Gautom[11] with modifications as follows. Each strain was grown in 5 mL tryptone soya broth for 5 h at 37 °C on an orbital shaker at 100 rpm. Point six millilitres of culture was pelleted in an Eppendorf tube using a low-speed centrifuge, washed with 1 mL SE buffer (75 mm NaCl; 25 mM EDTA, pH 8.5), and resuspended in 0.3 mL EC lysis buffer (6 mM Tris pH 8.0; 1 M NaCl; 100 mM EDTA Na_2 0.5 polyoxyethelene 20 cetyl ether (Brij 58); 0.5% N-lauryl sarcosine; 0.2% deoxycholic acid). Point three millilitres of 2% low melting point agarose in SE buffer was added, the mixture dispensed into block moulds, and left to set at 4 °C for 20 min. Blocks were then placed into 1 mL EC lysis buffer including 1 mg/mL proteinase K and incubated overnight in a 55 °C water-bath. Blocks were then removed and washed four times in 5 mL TE buffer (10 mM Tris; 1 mM EDTA, pH 8.0) whilst placed on a roller mill. Blocks were then stored at 4 °C until use. Before digest each block was washed in 5 mL TE buffer and a 2 mm slice placed in a 0.5 mL Eppendorf with 10 U/50 mL *Sma*I (Boehringer Mannheim, Penzberg, Germany). These were incubated at 30 °C for 6 h in a water-bath. Blocks were loaded into wells of a 1.2% agarose gel in 0.5 × TBE buffer and sealed with 1% low melting point agarose. Gels were placed into a PFGE tank containing 2.5 L 0.5 × TBE buffer and subject to PFGE using pulses 5–20 s for 18 h at 14 °C. Gels were stained using ethidium bromide, visualized by UV light and photographed using a gel documentation system (VDU Image Master, Pharmacia, Uppsala, Sweden).

Statistical analysis

Statistical analysis was performed using Pearson's correlation coefficient.[12]

Results

The 19 colonized/infected patients (13 males) had a median age of 39 years. Twenty-seven isolates of *A. baumannii* were obtained from these patients over a 14 month period. They were cultured from a variety of sites, including sputum ($N = 12$), central line tips ($N = 5$), wounds ($N = 5$), blood ($N = 2$), CSF ($N = 2$), and drain tips ($N = 1$). All the clinical and environmental isolates had the same antibiogram (susceptible to ciprofloxacin, gentamicin, meropenem, resistant to ampicillin, aztreonam, cefotaxime, cefradine, and piperacillin-tazobactam) and PFGE profile. The relationship between the monthly total of clinical isolates and environmental isolates is shown in Figure 1. There was a significant correlation between the number of environmental isolates obtained during each monthly screening and the number of patients with *A. baumannii* colonization/infection in the same calendar month ($P = 0.004$). There was no significant correlation between the number of patient isolates per calendar month and bed occupancy or mortalities during the same period ($P > 0.05$).

Discussion

Environmental cleanliness is a key factor in the control of hospital-acquired infection. Guidelines for the control of nosocomial pathogens, such as methicillin-resistant *Staphylococcus aureus*, recommend high standards of ward cleaning.[13] Such recommendations are, however, based more on strong rationale and circumstantial evidence than on the significant findings of definitive scientific

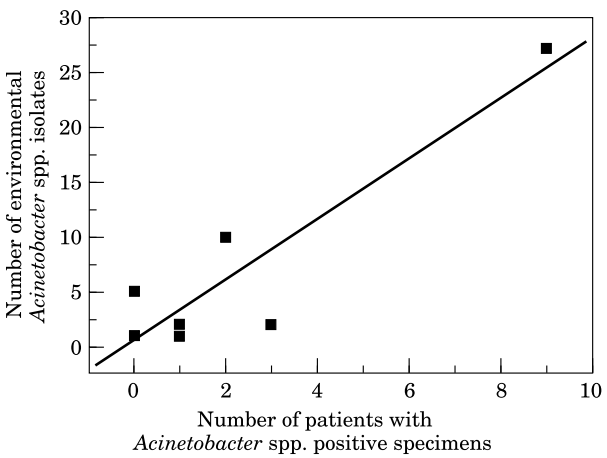

Figure 1 Graph showing relationship between number of patient isolations and environmental isolations of the outbreak strain of *Acinetobacter baumannii* obtained during the same calendar month.

studies. Attempts to reduce infection rates by enhancing environmental cleaning have generally proved unsuccessful.[14–16] As expected, floor cleaning with either detergent or disinfectant was found not to affect nosocomial infection rates.[14] Also, Dharan and colleagues recently observed that the incidence of nosocomial infections did not change during a four months trial of different cleaning agents.[16] A quaternary ammonium compound was inadequate for disinfecting bathrooms and toilets but an active oxygen-based compound was satisfactory. The detergent being examined was actually contaminated and so environmental surface counts of microbes increased post cleaning. In contrast, two recent studies have suggested that hypochlorite-based environmental cleaning may be associated with a reduced incidence of hospital-acquired *Clostridium difficile* infection.[17,18]

While *Acinetobacter* spp. do not form spores, their persistent survival when desiccated is at least partly analogous to that seen with *C. difficile*.[10] We did not measure *A. baumannii* hand contamination rates for the staff working in the NICU in the present study. Elsewhere, during an outbreak of gentamicin-resistant *A. baumannii* infection on an intensive care unit, 11% of staff hand samples versus 3% of environmental samples yielded the outbreak strain.[19] Larson[20] found that *Acinetobacter* spp. were the most frequent Gram-negative species persistently contaminating the hands of healthcare workers, both for frequent and less regular hand washers.[20] The frequency of *C. difficile* positive hand cultures in healthcare workers is known to correlate with the intensity of *C. difficile* environmental contamination.[17,21] Thus, it is plausible that the significant correlation observed in the present study between environmental contamination with *A. baumannii* and recovery of the bacterium from patients is explainable by concomitant increased hand carriage of this bacterium.

Over a period of several months this study showed a significant correlation between the number of positive environmental sites and the number of patients positive for *A. baumannii* colonization and/or infection in the same calendar month. There was no significant correlation with either bed occupancy or mortality during the same period, suggesting that rises in the number of colonized patients was not related to increased throughput or significant changes in patient population.

A number of cleaning issues were also addressed in order to control the outbreak. Responsibility for cleaning environmental infrastructure, e.g. floors, curtain rails, was delegated to ward cleaning staff whereas responsibility for cleaning patient equipment, e.g. monitors, bed frames, trolleys, was delegated to nursing staff. Additional cleaning staff were employed to ensure all bed spaces could be cleaned between patient admissions. Cleaning of areas inaccessible from ground level, e.g. ceiling ventilation grills, was instigated on a three-monthly basis. Additional storage trolleys were purchased to allow decanting and cleaning of stored medical equipment on a monthly basis. However, given the complexity of the cleaning protocols introduced, there were occasions when these new procedures were not followed. On one occasion the number of positive environmental sites increased shortly after additional cleaning input had been withdrawn because of recruitment and retention problems with ward cleaning staff.

This outbreak study has shown that levels of environmental contamination with *A. baumannii* correlate with patient colonization and infection. Failure to follow strict cleaning protocols, often because of problems recruiting, retaining and training cleaning staff, appeared to exacerbate the problem. Healthcare planners need to be aware that hospital cleaning is an invaluable in controlling outbreaks and further studies regarding the cost-effectiveness of cleaning are urgently required.

Acknowledgements

We thank Paul Verity and Val Keer from the Infection Control Laboratory of the Leeds Teaching Hospitals NHS Trust for assistance in obtaining environmental samples and carrying out the PFGE. We also thank staff in the Microbiology Department at the Leeds General Infirmary for isolating and saving clinical isolates of *A. baumanni*.

Stenotrophomonas maltophilia Associated Factors and Outcomes in a Neonatal Intensive Care Unit

A Retrospective Matched Case-control Study

Susannah Franco, PharmD,† Ashraf Abdelhemid, MBBCh, PhD,† Lawrence Fordjour, MD,‡ Stephan Kohlhoff, MD,† and Margaret R. Hammerschlag, MD†*

Background: *Stenotrophomonas maltophilia* is a multi-drug-resistant, hospital-acquired Gram-negative bacillus associated with significant morbidity and mortality. The objective of this study is to identify risk factors and outcomes associated with *S. maltophilia* isolation in a high-risk neonatal population.

Methods: This was a retrospective matched case-control study. Cases were matched 1:2 for years of neonatal intensive care unit admission, completed weeks' gestational age and birth weight in 250-gram incremental categories.

Results: A total of 15 cases and 35 controls were included in the analyses. Risk factors for *S. maltophilia* isolation included days of antibiotics (24 vs. 18, $P = 0.036$), days of broad-spectrum antibiotics (19 vs. 12 days, $P = 0.027$), days of meropenem (9 vs. 6 days, $P = 0.018$) and any meropenem exposure (100% vs. 22%, $P = 0.005$). Other risk factors were any corticosteroid exposure (66.7% vs. 20%, $P = 0.001$), days of total parenteral nutrition (55 vs. 31 days, $P = 0.017$) and days of invasive mechanical ventilation (28 vs. 7, $P = 0.015$). *S. maltophilia* isolation was associated with increased length of neonatal intensive care unit stay (134 vs. 69 days, $P < 0.001$) and mortality (33.3% vs. 0%, $P = 0.001$).

Conclusions: Antibiotic stewardship efforts should be made to decrease the risk of *S. maltophilia* isolation and associated mortality. Carbapenem overuse should be specifically addressed with institutional policies and unit-based guidelines. Additional neonatal studies are needed to confirm these findings and explore other possible risk factors.

Key Words: *Stenotrophomonas maltophilia*, neonatal infection, risk factors, carbapenems, antimicrobial stewardship

(*Pediatr Infect Dis J* 2025;44:69–73)

Stenotrophomonas maltophilia is an aerobic, nonfermenting, Gram-negative bacillus typically associated with opportunistic infections.[1–3] Although *S. maltophilia* is usually found in the environment in soil and water, the World Health Organization classifies it as one of the most significant multidrug-resistant organisms isolated in hospitalized patients.[1,4] *S. maltophilia* is most frequently found in the respiratory tract and can cause chronic respiratory infections.[1,3,5] The most common clinical manifestations of *S. maltophilia* infection are pneumonia and bacteremia followed by urinary tract infection, peritonitis, ophthalmological infection and meningitis.[2] Other manifestations include endocarditis and bone and joint, skin and soft tissue and gastrointestinal infections.[2–4]

S. maltophilia is associated with increased length of hospital stay and significant morbidity and mortality.[1] The mortality rate in adults is about 37%; data in children are more variable, with mortality ranging from 10% to 60%.[4] Neonatal mortality data are limited. One study from a neonatal intensive care unit (NICU) in Turkey reported a mortality rate of 17%.[3] Neither outcomes nor risk factors have been adequately studied in the neonatal population, as the majority of clinical studies focus on the adult and, to a lesser extent, pediatric populations.[3] Known risk factors that may apply to neonates include indwelling devices, chronic respiratory disease, immunocompromised state, exposure to antibiotics and long-term NICU stay.[1] Our urban medical center houses a 29-bed Level IIIB NICU and serves a diverse and clinically complex neonatal patient population. From 2010 to 2019, our unit experienced an increase in *S. maltophilia* infections, prompting a retrospective investigation. The objective of this study is to determine what potential risk factors and outcomes are associated with neonatal *S. maltophilia* isolation in our critically ill neonatal population.

METHODS

This is a retrospective, age-matched case-control study of neonates admitted to the NICU at the University Hospital at Downstate between January 1, 2008, and April 1, 2020. The study was approved by the Institutional Review Board at University Hospital at Downstate as a minimal-risk study with a waiver of informed consent. Microbiology records between January 1, 2008 and April 1, 2020 were manually reviewed for *S. maltophilia* cultured from any site. Admission and medical records of those neonates with positive cultures were then reviewed, and neonates were included as cases in the study if their NICU admission was at least 72 hours. Cases were then stratified by year of admission.

Within each year of admission, controls were selected randomly, then individually matched 2:1 to cases first for gestational age (GA) and then for birth weight by incremental 250-gram categories. Controls were identified by manual review of NICU admission records if the desired year of admission was before the installation of our electronic medical record system in 2011. Upon successful matching of admission year, GA and birth weight, medical records were reviewed to confirm an admission of at least 72 hours. Those neonates who met matching and inclusion criteria were then removed from the pool of controls for subsequent cases.

Medical charts of all neonates were reviewed for birth weight, GA, race, sex, *S. maltophilia* infection risk factors and adverse outcomes. The presence of premature rupture of

membranes (more than 24 hours before delivery), maternal chorioamnionitis and Apgar scores <5 at 5 minutes of life were extracted from delivery history records. All data for analysis of risk factors for infection were recorded before time of collection of the first positive *S. maltophilia* culture in cases or until discharge in controls. Neutropenia was defined as an absolute neutrophil count less than 1.5×10^9/L. An antibiotic course was defined as the uninterrupted administration of 1 or more antibiotics for at least 48 hours. A prolonged antibiotic course was defined as the uninterrupted administration of 1 or more antibiotics for more than 5 days in duration. Antibiotic days were defined as days of exposure rounded to the nearest half-day at the end of the dosing interval. Third- and fourth-generation cephalosporins, piperacillin/tazobactam, meropenem, amikacin, vancomycin and linezolid were classified as broad-spectrum antibiotics.

Data were not normally distributed and thus analyzed nonparametrically. Categorical values were counted, then percentages and odds ratios were calculated. The χ^2 test was used for between-group comparisons of categorical variables. Fisher exact test was used for comparisons of categorical variables if any value was expected to be <5 and for all comparisons between tracheal isolates and other isolates. Medians and interquartile ranges (IQR) were calculated for continuous variables and then analyzed with the Mann–Whitney *U* test. An alpha of 0.05 was deemed statistically significant.

RESULTS

A total of 21 individual neonates were identified as *S. maltophilia* cases; all were included in the study as they were admitted to the NICU for at least 72 hours and matched 1:2 to 42 controls. Six cases and 7 controls were ultimately excluded from analyses due to incomplete data, for example, delivery history was unknown, total parenteral nutrition (TPN) or antibiotic administration data was incomplete, or duration of mechanical ventilation and records of invasive procedures were unclear. Neonates were predominantly Black or African American (98%) with a median GA at birth of 26 (25–28) weeks. All neonates included received mechanical ventilation, antibiotics and TPN during their admission (cases before their culture and controls at any point before discharge). Baseline characteristics were not different between the 15 cases and 35 controls that were included in the analysis (Table 1).

Potential risk factors for infection are presented in Table 2. Total days of TPN were significantly higher in cases compared with controls (55 vs. 31 days, $P = 0.017$). Cases were exposed to more days of invasive mechanical ventilation compared with controls (28 vs. 7 days, $P = 0.015$). Cases had more occurrences of any corticosteroid exposure versus controls (66.7% vs. 20%; $P = 0.001$) and were 8 times more likely to receive corticosteroids than controls. Calculated odds ratios are summarized in Table 3. The total number of antibiotic days was higher in cases than in controls (24 vs. 18 days, $P = 0.036$); total number of broad-spectrum antibiotic

Bold values indicate statistical significance.

days was higher in cases compared with controls (19 vs. 12 days, $P = 0.027$). Total days of third- or fourth-generation cephalosporins, piperacillin/tazobactam and vancomycin were similar between cases and controls; total days of meropenem were higher in cases compared with controls (9 vs. 6 days; $P = 0.018$). Additionally, 100% of neonates were exposed to meropenem before isolation of *S. maltophilia* compared with 62.9% of controls ($P = 0.005$). Postnatal age and postmenstrual age at time of culture collection (cases) or discharge (controls) were not different.

Adverse outcomes associated with *S. maltophilia* are shown in Table 4. *S. maltophilia* isolation was associated with increased length of NICU stay (134 vs. 69 days, $P < 0.001$) and mortality (33.3% vs. 0%; $P = 0.001$) Mortality among infants with peritoneal infection was 100% (3/3). Mortality among infants with polymicrobial infection was 37.5%. We also compared the incidence of any culture-proven sepsis (other than *S. maltophilia*) during NICU stay to assess sepsis as a confounding risk factor for mortality which was not different between cases and controls (46.7% vs. 31.4%, $P = 0.304$). Incidence of necrotizing enterocolitis (NEC) was also analyzed as a potential confounder for mortality and length of stay which was significantly higher in cases versus controls (40% vs. 8.6%, $P = 0.015$). *S. maltophilia* was most frequently isolated in the trachea, with 9 isolates; 3 cases were isolated from the peritoneum, 2 from the conjunctiva and 1 from the blood (Table 5). Most cases occurred between 2014 and 2019; see Figure, Supplemental Digital Content 1, http://links.lww.com/INF/F683. Time to *S. maltophilia* culture positivity, susceptibility of *S. maltophilia* to levofloxacin and sulfamethoxazole-trimethoprim (TMP-SMX) and presence of polymicrobial infection are presented in Table 5.

TABLE 4. Adverse Outcomes

	Cases (N = 15)	Controls (N = 35)	Significance (*P* value)
Total length of NICU stay (days), median (IQR)	134 (113.5–231)	69 (60–96.5)	**< 0.001**

Staphylococcus epidermidis	3 (20)

R, resistance based on institutional susceptibility testing.

We also compared potential risk factors in the cases of *S. maltophilia* isolated in the trachea to cases isolated from all other sites (peritoneum, conjunctiva and blood), as the assessment of tracheal isolates as colonization versus infection was limited. As shown in Table, Supplemental Digital Content 2, http://links.lww.com/INF/F684, tracheal isolates were associated with greater postnatal age (78 vs. 36 days, $P = 0.018$), more days of TPN (58 vs. 34 days, $P = 0.013$), more days of mechanical ventilation (64 vs. 34.5 days, $P = 0.046$) and more antibiotic courses (4 vs. 3 courses, $P = 0.029$) before culture collection.

DISCUSSION

Limited data exist to assess potential risk factors for *S. maltophilia* infection in critically ill neonates. A retrospective matched case-control study in Turkey by Mutlu et al[3] in 2011 was the first to assess risk factors and clinical outcomes associated with *S. maltophilia* infection in neonates. They compared 23 cases with 45 matched controls and, in agreement with our study, reported that meropenem exposure, corticosteroid exposure, duration of TPN and duration of invasive mechanical ventilation were associated with *S. maltophilia* infection.[3] Postnatal age (ie, length of NICU stay) at the time of first positive culture (cases) or at discharge (controls) did not affect risk for *S. maltophilia* isolation in our study as has been previously reported in the literature of all age groups.[2,3,6,7] The extended admissions among extremely preterm neonates may have affected the analysis of this risk factor; it is unclear at what duration of hospital stay infection risk increases.

The majority of antibiotics used in the neonatal population, including ampicillin and gentamicin, have been linked to *S. maltophilia* isolation in children and adults.[3,6] Exposure to broad-spectrum antibiotics, including carbapenems, third- and fourth-generation cephalosporins, vancomycin and piperacillin/tazobactam, is a commonly reported risk factor for *S. maltophilia* colonization and infection.[3,6,8] We therefore analyzed days of all broad-spectrum antibiotics as well as days of third- and fourth-generation cephalosporins, piperacillin/tazobactam, vancomycin and meropenem individually. Days of amikacin and linezolid were not analyzed individually as only 4 patients were exposed. Adult, pediatric and neonatal studies of *S. maltophilia* infection risk factors show that carbapenem exposure in particular increases the risk of *S. maltophilia* infection and mortality.[2,4,9] Mutlu et al[3] reported that 78% of neonates with *S. maltophilia* infection had been exposed to a carbapenem. In our study, 100% of neonates were exposed to meropenem before isolation of *S. maltophilia* compared to 62.9%

of controls ($P = 0.005$). More days of meropenem was also associated with *S. maltophilia* infection (9 vs. 6 days, $P = 0.018$). We did not find that days of any other broad-spectrum antibiotic were associated with infection. While total broad-spectrum antibiotic days were significantly greater in cases, this may have been driven by meropenem specifically. We also compared exposure to prolonged meropenem courses to further elucidate how meropenem was used and to investigate the influence of prolonged courses versus total days of meropenem exposure on *S. maltophilia* infection. Among cases, exposure to prolonged meropenem courses was signifcantly higher than among controls (93.3% vs. 48.6%, $P = 0.004$).

NEC could have contributed to adverse outcomes otherwise attributable to *S. maltophilia*. However, the higher incidence among cases also illustrates the association between NEC and antibiotic days and broad-spectrum antibiotic exposure.[10] Isolation of *S. maltophilia* was associated with an almost 2-fold longer total length of NICU stay. The mortality rate of 33.3% is higher than that reported by Mutlu et al[3] (17%) and comparable to rates reported in adults (37%) and children (10%–60%) with *S. maltophilia* infection.[4] Peritoneal *S. maltophilia* infection was associated with 100% mortality (3/3 cases). These infants had undergone abdominal surgery to repair a perforated gut secondary to NEC. Pediatric studies report higher mortality with polymicrobial infections.[1] In our study, 8 cases (53.3%) were polymicrobial with a mortality rate of 37.5%. The 4 polymicrobial tracheal cultures grew *Klebsiella aerogenes* (1), *Staphylococcus epidermidis* (1) and *Klebsiella pneumoniae* (2). The other 4 polymicrobial cases were nonrespiratory infections, which is inconsistent with neonatal and pediatric literature.[9,11] The 2 polymicrobial conjunctival cultures grew *K. pneumoniae* (1) and *S. epidermidis* (1). Two of the 3 peritoneal cultures were polymicrobial; 1 grew *K. pneumoniae* and *Enterococcus faecium*; the other grew *S. epidermidis.*

S. maltophilia is intrinsically resistant to beta-lactams, carbapenems and aminoglycosides.[1] We tested the isolates against drugs of choice, TMP-SMX and levofloxacin. All 15 isolates were initially susceptible to levofloxacin and 14 to TMP-SMX. Resistance to levofloxacin developed during treatment after 8 days in 3 cases. In 1 case, levofloxacin resistance developed after 16 days followed by TMP-SMX resistance after 2 months, which may have contributed to this neonate's death. Otherwise, susceptibilities did not appear to be associated with mortality or length of stay, as has been previously reported in the literature.[1]

The trachea was the most common site of isolation with 60% (9/15) of isolates. Mutlu et al[3] similarly found that the most common site of infection was the respiratory tract. In contrast with our study, they excluded 54% of tracheal aspiration samples before analysis, identifying these samples as colonization versus infection. Neonates with *S. maltophilia* in that study were notably larger and older than those reported in our study, with a mean birth weight of 2.18 kg and GA of 33.9 weeks.[3] Colonization was suspected in 4 neonates and infection suspected in 2 neonates with *S. maltophilia* isolated in the trachea in our study by the pediatric infectious disease team based on review of chest radiographs, C-reactive protein, complete blood count with differential, culture data (polymorphonucleated white cells and presence of additional organisms) and susceptibility patterns of repeat isolates; categorization as colonization or infection was not described (or data were not available) in the medical records for the remaining 3 neonates. Tracheal cultures are typically performed in invasively mechanically ventilated, critically ill neonates; differentiating S. *maltophilia* infection from colonization is challenging. We attempted to determine if tracheal isolates were less likely to be infection by comparing risk factors for infection between tracheal isolates and all other isolates (see Table, Supplemental Digital Content 2, http://links.lww.com/INF/F684); we did not find tracheal isolates were less associated with *S. maltophilia* infection risk factors, but these secondary analyses are extremely limited by potential confounders and by even smaller sample sizes. We might expect about half of our cases of *S. maltophilia* isolation in the trachea to be colonization according to Mutlu et al.[3] However, based on the documented management of these infants and overall mortality, most tracheal isolates in our study likely represent true infection.

There are several additional limitations in this study that have not yet been discussed. Confounders for infection risk and mortality were controlled for by matching.[7] However, 6 cases and 7 controls were removed from analysis after matching which may have skewed baseline comparisons and is a major limitation. Apgar score < 5 at 5 minutes of life was used as a baseline indicator of mortality risk in addition to birth weight and GA; all baseline characteristics were comparable between groups despite the exclusion of 6 cases and 7 controls after matching.[12] We compared the incidence of any other culture-proven sepsis (including after *S. maltophilia* isolation among cases) which was not different between cases and controls (46.7% vs. 31.4%, $P = 0.304$), but we could not compare the incidence of sepsis-related mortality due to limitations in our medical record documentation. Furthermore, underlying illness (eg, gastrointestinal, neurologic and cardiovascular diseases) and other contributors to mortality (eg, culture-negative infection) were not compared. We also did not assess cholestasis incidence or total days of corticosteroid exposure, which may be additional *S. maltophilia* risk factors.[3] Duration of central venous catheter access could not be collected for 7/15 cases and 14/35 controls due to documentation limitations; while we found no difference between cases and controls, this analysis should be interpreted cautiously. It should also be noted that the case-control study design limits the interpretation of our results to associations, as causality cannot be established. Despite these limitations, this study provides valuable insight on the topic as it is, to our knowledge, the only case-control study on *S. maltophilia* risk factors in neonates in the United States.

CONCLUSIONS

In accordance with the limited neonatal literature, meropenem exposure, days of TPN, days of invasive mechanical ventilation and corticosteroid exposure were significantly associated with *S. maltophilia* isolation at our institution.[3] Pediatric and adult data support our findings that days of antibiotic exposure, and especially days of broad-spectrum antibiotic exposure, increase risk.[2,8] Days of meropenem may be the most important potential risk factor for *S. maltophilia* isolation. Antibiotic stewardship efforts should be made to decrease the risk of S. *maltophilia* infection and associated mortality. Carbapenem overuse should be specifically addressed with institutional policies and unit-based guidelines. Broad-spectrum antibiotic restrictions (including meropenem) were implemented in our NICU in December 2023 in response to our study's findings. We intend to study the impact of these restrictions on the incidence of *S. maltophilia* colonization and infection in the future. Additional studies in extremely preterm neonates are needed to confirm these findings and to further explore the contribution of broad-spectrum antibiotics, particularly carbapenems, to *S. maltophilia* colonization and infection.

Risk Factors for Infection and Mortality Associated With *Stenotrophomonas maltophilia* Bloodstream Infections in Children; Comparison With *Pseudomonas aeruginosa* Bloodstream Infections

Nimet Melis Bilen, MD, Zumrut Sahbudak Bal, MD,* Gizem Güner Özenen, MD,* Sema Yildirim Arslan, MD,* Gulcihan Ozek, MD,† Nihal Ozdemir Karadas, MD,‡ Pınar Yazıcı, MD,§ Feriha Cilli, MD,¶ and Zafer Kurugöl, MD**

Introduction: The increasing incidence of *Stenotrophomonas maltophilia* (*S. maltophilia)* infections raises concern because of the high fatality/case ratio. This study aimed to evaluate the risk factors for infection and mortality associated with *S. maltophilia* bloodstream infections (BSIs) in children and compare them with *Pseudomonas aeruginosa* BSIs.

Methods: All BSIs caused by *S. maltophilia* (n:73) and *P. aeruginosa* (n:80) were enrolled in this study between January 2014 and December 2021 at the Medical School of Ege University.

Results: Previous Pediatric Intensive Care Unit (PICU) admission, prior glycopeptide, and carbapenem use were significantly more common in patients with *S. maltophilia* BSIs ($P = 0.044$, $P = 0.009$, and $P = 0.001$, respectively) than with *P. aeruginosa* BSIs. C-reactive protein (CRP) levels were significantly higher in *S. maltophilia* BSIs ($P = 0.002$). Multivariate analysis showed that prior carbapenem use was associated with *S. maltophilia* BSIs ($P = 0.014$, adjusted odds ratio [AOR]: 2.710; 95% confidence interval [CI]: 1.225–5.992). PICU admission because of BSI, prior carbapenem and glycopeptide use, neutropenia, and thrombocytopenia were significantly more common in patients with mortality because of *S. maltophilia* BSIs ($P < 0.001$, $P = 0.010$, $P = 0.007$, $P = 0.008$, $P = 0.004$, respectively), while only PICU admission because of BSI, and prior glycopeptide use were significant in multivariate analysis (AOR, 19.155; 95% CI: 2.337–157.018; $P = 0.006$ and AOR, 9.629; 95% CI: 1.053–88.013; $P = 0.045$, respectively).

Conclusion: Prior carbapenem use is a significant risk factor for developing *S. maltophilia* BSIs. PICU admission because of BSI and prior glycopeptide use are risk factors associated with the mortality rate in patients with *S. maltophilia* BSIs. Therefore, *S. maltophilia* should be considered in patients with these risk factors, and empirical treatment should include antibiotics for *S. maltophilia*.

Key Words: *Stenotrophomonas maltophilia*, Bloodstream infections, mortality, children, *Pseudomonas aeruginosa*

DOI: 10.1097/INF.0000000000003845

Stenotrophomonas maltophilia (*S. maltophilia*) is a bacteria of rising concern that has been increasingly reported as a cause of healthcare-associated infection and significant morbidity and mortality.[1,2] It is a non-fermentative, aerobic, Gram-negative bacillus usually isolated from humid places such as water, soil and sewage.[1,2] It can form biofilms and colonize surfaces of medical devices.[3] The most common *S. maltophilia* infection types are bloodstream infections (BSIs) and pneumonia. Urinary tract, gastrointestinal, skin, and soft tissue infections, bone and joint infections, meningitis, and endocarditis caused by *S. maltophilia* have also been reported.[1,4,5]

Indwelling central venous catheters (CVC), previous use of broad-spectrum antibiotics, prolonged hospitalization, intensive care unit admission, malignancy, neutropenia, mechanical ventilation and malignancy have been described as possible risk factors for *S. maltophilia* BSIs.[1,4,5] *S. maltophilia* is intrinsically resistant to various antibiotics, including carbapenems which are commonly used to treat nosocomial infections.[1,6–8] Therefore, a delay in treatment can be life-threatening for the patients until culture results are available.

Patients with *S. maltophilia* BSIs usually have significant underlying diseases. Therefore, it is hard to estimate the attributable mortality directly caused by this pathogen. Reported crude mortality rates range from 21% to 69% in adult studies.[9,10] In a limited number of pediatric studies to evaluate the mortality caused by these infections, mortality rates vary between 10% and 60%, which were similar to adult studies.[5,11–13]

S. maltophilia infections are a therapeutic challenge because of limited treatment options. Infectious Diseases Society of America (IDSA) guidelines suggested trimethoprim-sulfamethoxazole (TMP/SMX) monotherapy as a first-line treatment.[14] Levofloxacin, minocycline and cefiderocol are other treatment options. Combination therapies can be used in treatment-resistant strains or patients unresponsive to treatment.[14]

This study aimed to evaluate the risk factors for infection and mortality associated with *S. maltophilia* BSIs in children and compare them with *Pseudomonas aeruginosa* (*P. aeruginosa*) BSIs.

MATERIALS AND METHODS

Study Design and Study Population

Ege University Children's Hospital is a 216-bed tertiary care facility in Izmir, Turkey, with bone marrow transplantation, hematology, oncology and Pediatric Intensive Care Units (PICU). A retrospective observational study was performed between January 2014 and December 2021. All patients aged under 18 years with *S. maltophilia* and *P. aeruginosa* BSIs were conducted in the study. Medical records of 73 patients with *S. maltophilia* BSIs and 80 with *P. aeruginosa* BSIs were evaluated retrospectively through medical records obtained from the Ege University Clinical Microbiology Laboratory. A standardized form was used to collect

Copyright © 2023 Wolters Kluwer Health, Inc. Unauthorized reproduction of this article is prohibited.

epidemiologic data, including demographic characteristics, risk factors such as underlying medical conditions, PICU stay before or because of infection, duration of PICU stay before or because of infection, presence of a central venous catheter, invasive procedures such as previous surgeries, laboratory findings including antimicrobial susceptibility, neutropenia and prognosis. Patients older than 18 years with positive blood cultures and/or without clinical symptoms compatible with infection were excluded.

Microbiologic Methods

The automated Matrix-Assisted Laser Desorption Ionization Time of Flight mass spectrometry (MALDI TOFF MS, Biomerieux, France) was used for species-level identification of isolated strains. Sensitivity testing for *S. maltophilia* was performed with E-test, and sensitivity testing for *P. aeruginosa* was performed with VITEK 2 (Biomerieux, France) automated microdilution method and evaluated according to the "European Committee for Antimicrobial Susceptibility Testing (EUCAST)"[15] criteria.

Definitions

Clinically significant *S. maltophilia* and *P. aeruginosa* BSIs were defined if the bacteria was isolated from one or more blood samples obtained from a peripheral vein and/or central venous catheter and the patient had clinical symptoms compatible with the infection. Infection that occurred 48 hours after admission was classified as nosocomial infection. Infections detected within the first 48 hours of admission in patients without previous healthcare contact were classified as community-acquired infections.[16]

Previous PICU admission was defined as being hospitalized in the PICU within 1 month before the BSI. Thrombocytopenia was defined as a blood platelet <150,000/mm^3, neutropenia was defined as absolute neutrophile count <1500/mm^3 and lymphopenia was defined as absolute lymphocyte count <1500/mm^3. Prior antibiotic treatment was defined as antibiotic therapy within 14 days before BSI. Prior glycopeptide use was defined as the use of teicoplanin or vancomycin, and prior carbapenem use was defined as the use of meropenem, ertapenem or imipenem. Previous corticosteroids, chemotherapy and immunosuppressive therapies were defined as the use of corticosteroids, chemotherapy and immunosuppressive therapy within 3 months before BSI. Mortality was defined as death within the first 14 days of BSI.

Statistical Analysis

Statistical analysis was performed with SPSS statistical package (version 25 for Windows). Numerical data were expressed as medians. Mann-Whitney *U* and Wilcoxon tests were used for intervariable analysis. Categorical variables were evaluated with the Chi-square test or the 2-tailed Fisher exact test and presented as percentages. A *P* value of <0.05 was considered statistically significant. A multivariate logistic regression analysis model was used to identify the independent risk factors for infection and mortality of *S. maltophilia* BSIs. The results of this regression analysis were reported as an AOR with a 95% confidence interval (CI). All variables with a *P* value <0.05 were included in the multivariate analysis.

Ethics

Necessitated permission was obtained from the Ethical Board of Ege University (ethical decision No 2112.1T/35).

RESULTS

Demographic and Clinical Data

We identified 73 *S. maltophilia* BSIs and 80 *P. aeruginosa* BSIs. The median age of the patients with *S. maltophilia* BSIs was 2.35 (IQR: 7.93) years, and 60.3% were male. The median age of the patients with *P. aeruginosa* BSIs was 3.07 (IQR: 6.78) years, and 57.5% were male. The most common underlying disease was bone marrow transplantation (21.9%), followed by cardiopathy (11%) and hematologic malignancy (9.6%) in patients with *S. maltophilia* BSIs. Five patients were previously healthy. The most common underlying disease in patients with *P. aeruginosa* BSIs was hematologic malignancy (21%), followed by solid organ malignancy (16.3%) and cardiopathy (13.8%). In *S. maltophilia* BSIs, 80.8% of episodes were nosocomial infections, and 95% were in *P. aeruginosa* BSIs. *S. maltophilia* infection was most commonly detected in the PICU (34.2%), followed by the bone marrow transplant unit (21.9%) and gastroenterology ward (8.2%). *P. aeruginosa* BSIs were most common in PICU (32.5%), followed by the oncology ward (16.3%) and hematology ward (12.5%). The comparison of demographic characteristics, clinical characteristics, and laboratory findings of the patients with *S. maltophilia* BSIs and *P. aeruginosa* BSIs are presented in Table 1.

Risk Factors for Infection

Age, the length of hospital stay before the onset of infection, and the total length of hospital stay showed no statistical difference between the patients with *S. maltophilia* BSIs and *P. aeruginosa* BSIs. Previous PICU admission was significantly more common in patients with *S. maltophilia* BSIs than in *P. aeruginosa* BSIs (57.5% vs. 41.2%; odds Ratio [OR], 1.930; 95% CI: 1.014–3.671; $P = 0.044$). Invasive procedures such as mechanical ventilation, tracheostomy, nasogastric tubes, urinary catheters or CVC did not show significant differences among groups. Steroid use and immune suppressive therapy were not significantly different. Chemotherapy use and malignancy were more common in patients with *P. aeruginosa* BSIs (42.5% vs. 17.8%; OR, 3.411; 95% CI: 1.618–7.191; $P = 0.001$ and 40% vs. 17.8% OR, 1.923; 95% CI: 1.180–3.134; $P = 0.003$, respectively). Prior glycopeptide and carbapenem use were significantly higher in patients with *S. maltophilia* BSIs. (41% vs. 21.2%; OR, 2.544; 95% CI: 1.250–5.180; $P = 0.009$ and 52% vs. 23.7%; OR, 3.429; 95% CI: 1.719–6.840; $P = 0.001$, respectively). The attributable mortality rate was not significantly different among groups. There was no significant difference in leukocyte count, absolute neutrophil or lymphocyte count, and platelet levels between *S. maltophilia* BSIs and *P. aeruginosa* BSIs. C-reactive protein (CRP) significantly showed higher levels in patients with *S. maltophilia* BSIs (Median, 31 vs. 9.8, $P = 0.002$). Multivariate analysis showed that only prior carbapenem use was associated with *S. maltophilia* BSIs (adjusted odds ratio [AOR], 2.710; 95% CI: 1.225–5.992; $P = 0.014$) (Table 2).

Risk Factors for Mortality

PICU admission because of BSI was significantly associated with mortality in patients with both *S. maltophilia* and *P. aeruginosa* BSIs (OR, 1.663; 95% CI: 1.130–2.449: $P < 0.001$ and OR, 6.875; 95% CI: 1.762–26.824; $P = 0.002$, respectively). PICU admission before infection was a risk factor for mortality in patients with *P. aeruginosa* BSIs (OR, 8.438; 95% CI: 1.686–42.223; $P = 0.003$), while it was insignificant in patients with *S. maltophilia* BSIs.

The total length of hospital stay, PICU stay before infection, and length of hospital stay before the infection did not associate with mortality in both *S. maltophilia* and *P. aeruginosa* BSIs. Steroid, chemotherapy, and immune suppressive therapy use were similar among survivors and non-survivors in both *S. maltophilia* and *P. aeruginosa* BSIs. Invasive procedures such as mechanical ventilation, indwelling CVCs, nasogastric tubes, or urinary catheters were not associated with mortality in patients with *S. maltophilia* BSIs ($P > 0.05$). Mechanical ventilation and CVCs were significantly

associated with mortality in patients with *P. aeruginosa* BSIs (OR, 4.605; 95% CI: 1.209–17.539; $P = 0.018$ and OR, 1.234; 95% CI: 1.090–1.398; $P = 0.028$, respectively). However, these risk factors were not associated with mortality in patients with *S. maltophilia* BSIs. Neutropenia and thrombocytopenia were the risk factors for mortality in patients with *S. maltophilia* BSIs (OR, 5.765; 95% CI: 1.416–23.506; $P = 0.008$ and OR, 8.600; 95% CI: 1.672–44.236; $P = 0,004$, respectively). The higher levels of CRP were significantly associated with mortality in patients with *S. maltophilia* BSIs (Median, 100 vs. 29, $P = 0.010$). Among the patients with *P. aeruginosa* BSIs, thrombocytopenia was not a risk factor for mortality; however, platelets were significantly lower in non-survivors (median, 36,000 vs. 143,000, $P = 0.007$). Neutropenia at the onset of infection was a risk factor for mortality in patients with *P. aeruginosa* BSIs (OR, 3.739; 95% CI: 0.990–14.118; $P = 0.042$). Prior carbapenem use was significantly higher in non-survivors in patients with *S. maltophilia* BSIs (OR, 10.552; 95% CI: 1.261–88.309; $P = 0.010$), while insignificant in patients with *P. aeruginosa* BSIs. Prior glycopeptide use was significantly higher in non-survivors in both groups (OR, 7.455; 95% CI: 1.455–38.191; $P = 0.007$ and OR, 3.889; 95% CI: 1.018–14.871; $P = 0.037$, respectively). A comparison of risk factors for mortality because of *S. maltophilia* and *P. aeruginosa* BSIs are presented in Table 3. Multivariate analysis showed PICU admission because of BSI and prior glycopeptide use were independently associated with mortality in patients with *S. maltophilia* BSIs (AOR, 19.155; 95% CI: 2.337–157.018; $P = 0.006$ and AOR, 9.629; 95% CI: 1.053–88.013; $P = 0.045$, respectively). Multivariate analysis results for risk factors associated with mortality are presented in Table 4.

Treatment

The susceptibility rate of *S. maltophilia* was highest for TMP/SMX (88.6%), followed by levofloxacin (81.4%) and ceftazidime (68.6%). Ceftazidime was the most commonly administered antibiotic (39.7%), followed by TMP/SMX (30.1%) and levofloxacin (8.6%) because of culture results. Eight of 10 deceased patients did not receive proper empiric treatment for *S. maltophilia.* The most commonly administered empiric antibiotics were glycopeptides and carbapenems. Despite appropriate empiric treatment, mortality occurred in 2 patients; 1 with a liver transplant and 1 with

Bold lines represent statistically significant results.

a metabolic disorder. Of deceased patients with *P. aeruginosa* BSIs, 8 were receiving appropriate empirical treatment. In 3 patients, *P. aeruginosa* was carbapenem resistant. Carbapenem resistance did not show any significant difference between survivors and nonsurvivors in patients with *P. aeruginosa* BSIs ($P = 0.187$). Empirical treatment of 10 patients with attributable mortality because of *S. maltophilia* BSIs and 11 patients with attributable mortality because of *P. aeruginosa* BSIs were summarized in Table 5. Five of the 10 patients who died because of *S. maltophilia* BSI did not receive proper antibiotic treatment because they died before the culture results were obtained.

DISCUSSION

This study included 73 *S. maltophilia* BSIs and 80 *P. aeruginosa* BSIs. Previous PICU admission and prior glycopeptide use were more common in *S. maltophilia* BSIs than in *P. aeruginosa* BSIs. Multivariate analysis revealed prior carbapenem use was significantly associated with *S. maltophilia* BSIs. PICU admission because of bacteremia, neutropenia, thrombocytopenia and higher levels of CRP at the onset of infection, prior glycopeptide and carbapenem use were risk factors for patient mortality because of *S. maltophilia* BSIs. Multivariate analysis revealed PICU admission because of infection and prior glycopeptide use increased mortality risk in patients with *S. maltophilia* BSIs. To our knowledge, this study is the largest one that evaluated *S. maltophilia* BSIs in pediatric patients in the literature and was the first study that compared with *P. aeruginosa* BSIs.

S. maltophilia is a nosocomial pathogen that forms biofilms on surfaces of devices such as mechanical ventilators and CVC.[3] Previous studies reported that *S. maltophilia* BSIs were more common in patients with an immunocompromised status, such as immunosuppression, organ transplantation and malignancies.[10,17] In our study, immunocompromised status did not significantly associate with *S. maltophilia* BSIs. In previous studies, well-defined risk factors for developing *S. maltophilia* BSIs were prolonged hospital stay, previous PICU admission, CVCs, mechanical ventilation, nasogastric tubes and urinary catheters.[5,6,11,17–19] Most of our patients with *S. maltophilia* BSIs (82%) had a CVC; however, the presence of CVC did not increase the risk for *S. maltophilia* BSIs compared with *P. aeruginosa* BSIs in our study. When laboratory parameters were evaluated, univariate analysis showed that CRP was significantly higher in patients with *S. maltophilia* BSIs than in those with *P. aeruginosa* BSIs. However, no statistically significant difference was found in the multivariate analysis. Although insignificant in the multivariate analysis, it should be kept in mind that high CRP may indicate *S. maltophilia* BSIs. Consistent with previous studies, our study identified PICU admission before BSI as a risk factor for *S. maltophilia* BSIs. Therefore, *S. maltophilia* should be considered in patients with previous PICU admission while initiating empirical antibiotic treatment.

The mortality rate among children with *S. maltophilia* infections ranges between 10% and 60%.[12,13] A recent study by Latzer et al[1] among critically ill pediatric patients determined that the crude mortality was 42% and attributable mortality was 18%. Alsuhaibani et al[5] stated that 33.8% of their patients died within 7 days of infection. In our study, attributable mortality was 13.7%, which was less than in previous studies.[4,5,13] Our heterogeneous study group can explain this difference, which consisted of both critically ill and stable patients.

The risk factors of attributable mortality associated with *S. maltophilia* BSIs are prior use of broad-spectrum antibiotics, neutropenia, mechanical ventilation, prior PICU stay, and malignancy.[8,20] Alsuhaibani et al[5] demonstrated that previous PICU admission and neutropenia were risk factors for mortality in children with *S. maltophilia* BSIs. Senol et al[10] compared patients with *S. maltophilia* BSIs to control groups and stated that neutropenia and previous antibiotic use were associated with increased mortality rates. In our study, PICU admission, neutropenia, thrombocytopenia, and higher levels of CRP at the onset of infection were significantly associated with mortality in patients with *S. maltophilia* BSIs. Consistent with previous studies, our study showed that neutropenia was associated with higher mortality.[5,10] This study demonstrated thrombocytopenia, and higher CRP levels increased the risk for mortality with a limit of statistical significance revealed by multivariate analysis. Unlike previous studies, mechanical ventilation and the presence of a central venous catheter were not associated with mortality in patients with *S. maltophilia* BSIs in our study. However, mechanical ventilation and catheter presence were significantly higher in the patients with mortality because of *P. aeruginosa* BSIs. There was no significant difference between the 2 groups regarding mechanical ventilation and catheter use. The most significant difference was a higher hematologic and oncologic malignancy rate in patients with *P. aeruginosa* BSIs. The underlying disease was hematologic or oncologic malignancy in 54.5% of patients who died because of *P. aeruginosa* BSIs. Of the 11 deceased patients, ten died while they were already treated in the PICU, which the severity of their underlying condition can explain.

Several studies determined that previous use of antibiotics, particularly carbapenems, was associated with increased frequency and mortality of these infections.[4,6,11,19] Consistent with previous studies, we showed a higher previous carbapenem and glycopeptide use in deceased patients with *S. maltophilia* BSIs than in *P. aeruginosa* BSIs. Glycopeptide use was a risk factor for mortality in both groups, and carbapenem use was a risk factor for mortality in patients with *S. maltophilia* BSIs. Multivariate analysis revealed only glycopeptide use was independently associated with mortality in patients with *S. maltophilia* BSIs. These findings remind the importance of rational antibiotic use in preventing these infections and reducing the mortality associated with these infections.

S. maltophilia infections cause therapeutic challenges for clinicians because of intrinsical resistance to many antibiotics primarily used to treat nosocomial infections.[5,8,19,21] TMP/SMX, quinolones, minocycline, and ceftazidime are the most commonly used antibiotics in these infections.[2,5,11] The first-line recommended treatment is TMP/SMX for *Stenotrophomonas* spp. caused infections.[14,19,22] IDSA guidelines suggest TMP/SMX as monotherapy or in combination with levofloxacin in more severe or unresponsive cases.[14] Metan et al[19] showed that carbapenem and glycopeptide administration, the presence of a CVC, and longer hospitalization increased the risk for *S. maltophilia* infections, and patients with these risk factors should receive TMP/SMX empirically. Przygonska et al[23] determined that empirical TMP/SMX treatment in patients with hematologic malignancies and bone marrow transplants lowered mortality because of *S. maltophilia* infections. The most common empirical antibiotic

treatment in our study was TMP/SMX. Combination therapies with TMP/SMX and ciprofloxacin were also initiated in 28.7% of the patients. Only 20% of deceased patients received appropriate empiric antibiotics for *S. maltophilia* BSIs. It was observed that the remaining 8 deceased patients had been receiving carbapenems and glycopeptides. In these patients, death usually occurred within 2–3 days while the bacterial culture results were pending. This result shows us the importance of *S. maltophilia* infections and expanding empirical treatment in patients with risk factors. The most commonly administered empirical antibiotics were carbapenems and piperacillin-tazobactam in deceased patients with *P. aeruginosa* BSIs. *P. aeruginosa* was carbapenem resistant in 3 of the 11 deceased patients, and they were not receiving appropriate treatment. However, carbapenem resistance did not show any significant difference between survivors and non-survivors in patients with *P. aeruginosa* BSIs.

The limitations of our study are its retrospective nature; therefore, some clinical data may have been missed. It is a single-center study; resistance patterns and risk factors may differ between centers. Despite the highest number of pediatric patients in the literature, the low number of patients is another limitation of this study.

In conclusion, our study showed that prior carbapenem use is a risk factor for developing *S. maltophilia* BSIs in children. PICU admission because of infection and prior glycopeptide use are risk factors for mortality in these patients. Among deceased patients, 8 of 10 patients could not receive appropriate therapy for *S. maltophilia*. Therefore, we suggest *S. maltophilia* should be considered in patients with well-defined risk factors, such as prior PICU admission, PICU admission because of bacteremia, neutropenia, thrombocytopenia and higher levels of CRP at the onset of infection, prior glycopeptide and carbapenem use. This study emphasizes the importance of rational antibiotic use in reducing these infections and the mortality caused by these infections. More extensive prospective studies are needed to confirm these risk factors associated with *S. maltophilia* infection and mortality in children.

Molecular epidemiology of multiresistant *Escherichia coli* isolates from community-onset urinary tract infections in Cornwall, England

Neil Woodford[1]*, Mary E. Kaufmann[1], Edi Karisik[1] and John W. Hartley[2]

[1]Centre for Infections, Health Protection Agency, London, UK; [2]Department of Clinical Microbiology, Royal Cornwall Hospital, Truro, UK

Received 9 August 2006; returned 25 September 2006; revised 2 October 2006; accepted 3 October 2006

***Objectives*: To study the clonality of gentamicin-resistant, extended-spectrum β-lactamase (ESBL)-negative and ESBL-producing *Escherichia coli* isolated from community-onset urinary tract infections (UTIs) in Cornwall.**

***Methods*: Isolates were identified by API, susceptibilities were determined by local disc testing, and MICs were determined at the reference laboratory, both interpreted using BSAC guidelines. *bla*$_{CTX-M}$ genes were sought by PCR, and isolates were compared by PFGE.**

***Results*: In the years 2004 and 2005, 69 *E. coli* were submitted by Truro (Cornwall) laboratory for reference laboratory testing: these included 14 gentamicin-resistant, ESBL-negative isolates; 45 with group 1 CTX-M enzymes; seven with group 9 CTX-M enzymes; and three with non-CTX-M ESBLs. By PFGE, nine gentamicin-resistant, ESBL-negative *E. coli* were distinct (<85% similarity) from all the ESBL producers, but three were related to producers of group 1 CTX-M enzymes, and two isolates were related to a non-CTX-M ESBL producer. An outbreak strain was identified, represented by 11 gentamicin-resistant and one gentamicin-susceptible isolates, all with group 1 CTX-M enzymes, and two gentamicin-resistant, ESBL-negative isolates. This was distinct by PFGE from nationally distributed CTX-M-producing strains. Five of nine patients infected with this strain had been on the same ward in a local hospital; four presented with community-onset UTIs; one inpatient developed a hospital-acquired bacteraemia. Of the other four patients presenting with community-onset UTIs, three were admitted to different hospitals and the fourth had only attended an outpatient clinic.**

***Conclusions*: Community-onset, ESBL-producing and non-producing *E. coli* were diverse. Two ESBL-negative isolates were closely related to a local CTX-M-producing outbreak strain, suggesting gain or loss of a *bla*$_{CTX-M}$-carrying plasmid. An outbreak strain was linked with prior hospital admission and appeared not to represent genuine community acquisition.**

Keywords: cephalosporins, ESBLs, resistance, Enterobacteriaceae

Introduction

Multiresistant *Escherichia coli* strains from community-onset infections are an increasing public health concern, especially those with CTX-M extended-spectrum β-lactamases (ESBLs).[1] In the UK, ~90% of CTX-M-producing *E. coli* produce group 1 enzymes (mainly CTX-M-15) and PFGE analysis of a national collection has defined five major strains.[1] The local epidemiology of *E. coli* producing CTX-M enzymes may, however, differ from this national picture with, for example, dominance of different strains, or higher prevalence of those with group 9 CTX-M enzymes.

In Cornwall (the south-west peninsula of England), concern was raised over the emergence of gentamicin-resistant *E. coli* isolates recovered from urines of patients attending general practice. Gentamicin is rarely prescribed in such settings. Several, but not all of these resistant isolates were ESBL producers. We therefore studied the clonality of gentamicin-resistant, ESBL-negative isolates from urines of patients attending general practitioners (GPs) in Cornwall and compared them with

ESBL-producing *E. coli*, many also gentamicin-resistant and also isolated from GP urines.

Materials and methods

Bacterial isolates and initial susceptibility testing

Most *E. coli* isolates included in this study were associated with community-onset urinary tract infections (UTIs) in patients attending GPs' surgeries in Cornwall during 2004 and 2005. One isolate was from a case of hospital-acquired bacteraemia (onset >48 h after admission).

The isolates were identified as *E. coli* (API system; bioMerieux, Basingstoke, UK), and their antibiotic susceptibilities were determined by disc testing using BSAC criteria[2] in the Department of Clinical Microbiology, Royal Cornwall Hospital. Fourteen gentamicin-resistant, ESBL-negative isolates and 55 ESBL-producing isolates, variably gentamicin-resistant, were referred to the Health Protection Agency's Centre for Infections for further investigation. Multiple isolates were referred from some patients.

Investigation in the reference laboratories

MICs were determined and interpreted using BSAC methodology,[2] and $bla_{CTX\text{-}M}$ genes were sought by multiplex PCR.[3] Selected isolates were compared by PFGE of *Xba*I-digested genomic DNA, and banding patterns were analysed using BioNumerics software (Applied Maths, Sint-Martens-Latem, Belgium).

Investigation of an outbreak strain

The clinical notes for selected patients were analysed to determine any obvious common factors associated with acquisition of a PFGE-defined outbreak strain.

Results and discussion

Reference investigations and recognition of a 'Cornish outbreak' strain

During 2004–2005, the reference laboratories received 69 *E. coli* isolates from Truro (Cornwall) laboratory for inclusion in this study. These included: 14 gentamicin-resistant, ESBL-negative isolates; 45 with group 1 CTX-M enzymes; seven with group 9 CTX-M enzymes and three with non-CTX-M ESBLs.

All 14 ESBL-negative isolates, and 16 ESBL-producing isolates dating from 2004, were compared by PFGE (Figure 1). Nine gentamicin-resistant, ESBL-negative isolates were distinct (<85% similarity) from the ESBL producers, but three were related to isolates with CTX-M group 1 enzymes, and two isolates from one patient were related to an isolate with a non-CTX-M ESBL.

One major outbreak strain was identified, and comprised 11 gentamicin-resistant and one gentamicin-susceptible CTX-M group 1 producers and two gentamicin-resistant, ESBL-negative isolates (12 of these are shown in Figure 1); the 14 isolates were from nine patients. This 'Cornish outbreak' strain was distinct by PFGE from five nationally distributed CTX-M-producing strains, including the UK epidemic strain A (Figure 1),[1] which accounted for only three of the 69 *E. coli* isolates referred from Truro laboratory.

Geometric mean MICs for the 'Cornish outbreak' strain are shown in Table 1. CTX-M ESBL-producing isolates of this strain were resistant to penicillins, all cephalosporins tested (but with potentiation by clavulanate), and also to ciprofloxacin, gentamicin and tobramycin. Isolates of the outbreak strain were susceptible to piperacillin/tazobactam, amikacin and carbapenems.

Two gentamicin-resistant, ESBL-negative isolates (unrelated by PFGE and distinct from the 'Cornish outbreak' strain) were highly resistant to the veterinary aminoglycoside apramycin (MICs > 512 mg/L), which is consistent with AAC(3)-IV activity;[4] the range of apramycin MICs for all other isolates was 2–32 mg/L.

Analysis of case notes

Recognition of the 'Cornish outbreak' strain was unexpected and prompted analysis of clinical notes for the nine patients (5 male and 4 female) affected to determine any obvious common factors that might be associated with its acquisition. The average age of these patients was 80 years (range, 57–93 years).

One patient developed a hospital-acquired bacteraemia (defined as onset >48 h after admission) with the 'Cornish outbreak' strain while an inpatient on ward G of a local hospital (RCH) in March to May 2004 during a cluster of infections on this ward caused by ESBL-producing *E. coli*. This blood culture isolate was the only saved representative from the ward cluster. The other eight patients infected by the 'Cornish outbreak' strain had presented at various GP surgeries, separated by up to 30 miles. The strain was isolated from urine in eight patients, from sputum in three, from a peg site in one, and two patients were widely colonized. Despite the community-onset of their UTIs, seven of these eight patients had prior, and in some instances multiple, hospital inpatient admissions, and multiple transfers between wards. The eighth only attended an outpatient clinic. The average time after hospital discharge before presentation with a UTI at their GP's surgery was 39 days (range 6–89 days). Four of the eight GP patients had been inpatients on ward G of RCH during March–May 2004. Another had been in other wards at RCH during this period, though not on ward G. Two other patients had been on ward L of a second hospital (CRH), but there was no temporal overlap; one had been an inpatient from December 2003 to March 2004; the other was transferred from ward G of RCH in April 2004 and was discharged in May 2004. Six of the nine affected patients died. Mortality was not directly attributable to the ESBL-producing strain in five cases, but the sixth died with ESBL-producing *E. coli* septicaemia, implying causality.

These data suggest that the 'Cornish outbreak' strain may have caused the cluster of infections on ward G at RCH during March–May 2004, although only one isolate was available for testing. The alarming finding of a CTX-M-producing *E. coli* strain presenting in the community, but that could be traced to a hospital source led to a rapid review of susceptibility testing of all 'coliforms' in the clinical laboratory, as advocated previously,[1,5] and methodology for detecting ESBLs was in place within two months of these findings.

In summary, most gentamicin-resistant, ESBL-negative isolates from community-onset UTIs in Cornwall were diverse and were distinct from ESBL-producing *E. coli* from community-onset UTIs. However, two ESBL-negative, gentamicin-resistant isolates were closely related to a local CTX-M-producing and gentamicin-resistant outbreak strain, suggesting gain or loss of

[a]Two non-CTX-M-producing isolates of the outbreak strain were excluded from this analysis.

the $bla_{\text{CTX-M}}$ gene or a plasmid carrying it. Most of the patients infected by this outbreak strain had hospital admissions in the three months prior to onset of their UTIs. This has been identified previously as a risk factor for infections caused by ESBL producers in non-hospitalized patients.[6,7] Old age (>60 years), as seen in patients described here, is also a known risk factor.[6]

Although manifesting in the community, many of the UTIs of these Cornish patients appeared to have their origins in local hospitals and did not represent genuine community acquisition. This study highlights weaknesses in the concept of a clear distinction between hospital- and community-acquired infections caused by CTX-M-producing and other multiresistant *E. coli*. Clearly, acquisition in hospital may be followed by a period of colonization, which may be prolonged in some instances, prior to infection. Screening for faecal colonization at discharge, especially during on-going hospital clusters with ESBL-producing strains, would identify those patients most at risk of developing subsequent community-onset infections with multiresistant strains.
