National Infection Prevention and Control Manual

Care Home Infection Prevention and Control Manual (CH IPCM)

Home (/) > Care Home Infection Prevention and Control Manual (CH IPCM) >

When an organisation uses products or adopts practices that differ from those stated in this Care Home Infection Prevention and Control Manual, that individual organisation is responsible for ensuring safe systems of work including the completion of risk assessments approved through local governance procedures.

Use of this manual online is advised as printed versions are uncontrolled.

The ARHAI Scotland Transmission Based Precautions (TBPs) literature review is currently ongoing and so the information may be subject to change.

View latest news and updates (/) for the NIPCM and CHIPCM
Last updated: 21 August 2024

What is the Care Home Infection Prevention and Control Manual (CH IPCM)?

The Care Home Infection Prevention and Control Manual (CH IPCM), referred to as 'the manual' throughout, was first published in 2021. It is evidence-based and is intended to be used by all those involved in care home provision in Scotland.
The manual is context specific and has been co-produced with national and local stakeholders. The content of the manual is completely aligned to the evidence based National Infection Prevention and Control Manual (NIPCM) (/) which was first published in 2012, by the Chief Nursing Officer (CNO (2012)1 (http://www.sehd.scot.nhs.uk/cmo/CNO(2012)01.pdf)).
The manual currently contains

- Chapter 1 – Standard Infection Control Precautions (SICPs) (/infection-prevention-and-control-manual-for-older-people-and-adult-care-homes/#a2821)

- Chapter 2 – Transmission Based Precautions (TBPs) (/infection-prevention-and-control-manual-for-older-people-and-adult-care-homes/#a2926)

The manual is a practice guide for use in care homes. When used, it can help reduce the risk of infections and ensure the safety of residents, as well as staff and visitors in the care home environment. It is the Scottish Government expectation that care home settings apply guidance contained within this manual to achieve the aims.
The manual aims to:

- make it easy for staff to apply effective infection prevention and control (IPC) precautions
- help reduce the risk of infection
- reduce variation, promote standardisation, and optimise IPC practices throughout care home settings
- improve the application of staff knowledge and skills in IPC
- help align practice, monitoring, quality improvement and scrutiny

The manual should be adopted for all IPC practices and procedures within care home settings.

Is the manual based on scientific literature?

The recommendations for practice made in the manual are fully aligned to the NIPCM and are based on real-time reviews of the current scientific literature (for example Medical Journals) and best practice. Any major changes identified in the scientific literature may lead to a change being made to the content, and so, it is recommended that the online version is always accessed and used locally.

What's in the appendices?

The appendices (/appendices/) can be used as practical implementation of the manual and contain graphical representations (for example diagrams and charts) that can be used along with the contents of the manual.
Many of the appendices can be printed off as posters for local use throughout the care home.

Are there any other IPC materials that can be used?

There are links throughout the manual to additional resources and the resources page (https://www.nipcm.scot.nhs.uk/resources/) links to IPC campaign materials, education, training links and posters.
In addition you may find it useful to read the literature reviews and SBARs (/resources/literature-reviews/) for the manual.

How can I find out what the scientific and medical words mean?

A glossary (/glossary/) section has been provided.

Does the manual content work on mobile devices?

Yes, all content including appendices work on mobile devices for example laptops and smartphones.

Responsibilities for the CH IPCM

Responsibilities for content of the manual

ARHAI Scotland to ensure:

- that the content of this manual remains evidence based or where evidence is lacking, content is based on consensus of expert opinion

Stakeholders of ARHAI Scotland programme working groups to ensure:

- full participation in the working groups including full engagement with the consultation process outlined in the Terms of Reference associated with each working group

Responsibilities for the adoption and implementation of this manual

The manual should be used by:

- care home organisations
- care home staff including permanent, agency and where required external contractors
- health protection teams
- infection prevention and control teams
- professionals providing support
- individuals visiting the care home

Care home providers to ensure:

- the adoption and implementation of this manual in accordance with existing local governance processes
- that systems and resources are in place to facilitate implementation and compliance monitoring of IPC as specified in this manual in all care areas
  - compliance monitoring includes all staff (permanent, agency and where required external contractors)
- there is an organisational culture which promotes incident reporting and focuses on improving systemic failures that encourage safe IPC working practices including near misses
- there is a nominated lead with responsibility for IPC within the care home

Care home managers to ensure that all staff:

- are aware of and have access to this manual
- have completed appropriate IPC training relevant to their roles and that this is centrally recorded. Training may include resources developed by your organisation, your local NHS board, Health and Social Care Partnership, NHS Education for Scotland (NES) (https://learn.nes.nhs.scot/2482/infection-prevention-and-control-ipc-zone) or the Scottish Social Services Council (SSSC) (https://www.sssc.uk.com/)
- have adequate support and resources available to enable them to implement, monitor and take corrective action to ensure full compliance with this manual
- implement a robust risk assessment including detailing any deviations from the manual and the local mitigation measures that were undertaken and post-approval documented via local governance procedures
- with health concerns (including pregnancy) or those who have had an occupational exposure relating to IPC are timeously referred to the relevant agency, for example general practitioner (GP or doctor), occupational health or if required accident and emergency
- have undergone the required health checks or clearance (including those undertaking exposure prone procedures (EPPs))
- include IPC as an objective in their personal development plans (or equivalent)

Care home staff providing care to:

- understand, adopt and implement the principles of IPC as set out in this manual
- maintain IPC competence, skills, and knowledge through completing appropriate training relevant to their role as directed by their line manager. IPC training, NHS Education for Scotland (NES) (https://learn.nes.nhs.scot/2482/infection-prevention-and-control-ipc-zone) (https://www.nes.scot.nhs.uk/) or the Scottish Social Services Council (SSSC) (https://www.sssc.uk.com/)

- communicate the IPC practices to be taken to appropriate colleagues, residents, relatives and visitors without breaching confidentiality
- have up to date occupational immunisations/health checks/clearance requirements as appropriate
- report to line managers and document any gaps in IPC knowledge, resources, equipment and facilities or incidents that may result in transmission of infection including near misses for example sharps or PPE failures
- do not provide care while at risk of potentially transmitting infectious agents to others - if in any doubt they should consult with their line manager, occupational health department, local infection prevention and control team (IPCT) or local health protection team (HPT)
- contact the local HPT/IPCT if there is a suspected or actual HAI incident/outbreak (/chapter-3-healthcare-infection-incidents-outbreaks-and-data-exceedance/)

Local infection prevention and control teams (IPCTs) and health protection teams (HPTs) to:

- engage with care home staff to develop systems and processes that lead to sustainable and reliable improvements in relation to the application of IPC practice
- provide expert advice on the application of IPC and provide support when requested to develop individual or organisational risk assessments where deviations from the manual are necessary
- have epidemiological or surveillance systems capable of distinguishing resident case or cases requiring investigations and control
- provide local support and advice (when necessary and/or requested) and complete documentation when an incident/outbreak or data exceedance is reported

Chain of infection

In order for infection to occur several things have to happen. This is often referred to as the chain of infection. The six links in the chain are:

1. **infectious agent** or the microorganism which can cause disease

2. **reservoir** or source of infection where the microorganism can live and thrive. This may be a person, an animal, any object in the general environment, food or water

3. **portal of exit** from the reservoir. This describes the way the microorganism leaves the reservoir. For example, in the case of a person with flu, this would include coughing and sneezing. In the case of someone with gastroenteritis microorganisms would be transmitted in the faeces or vomit

4. **mode of transmission.** This describes how microorganisms are transmitted from one person or place to another. This could be via someone's hands, on an object, through the air or bodily fluid contact

5. **portal of entry.** This is how the infection enters another individual. This could be landing on a mucous membrane, being breathed in, entering via a wound, or a tube such as a catheter.

6. **susceptible host.** This describes the person who is vulnerable to infection.

Infection can be prevented by breaking the chain of infection.

Chain of infection diagram

The overall aim of Standard Infection Control Precautions (SICPs) (/infection-prevention-and-control-manual-for-older-people-and-adult-care-homes/#a2821), is to break the chain of infection.

The chain of infection diagram illustrates and gives examples of actions that can be taken to break it.
Select image for full size version.
(/media/1579/care_homes_chain_of_infection_graphic.jpg)
Use the NES SIPCEP Breaking the Chain of Infection (https://learn.nes.nhs.scot/3421/infection-prevention-and-control-ipc-zone/sipcep-foundation-layer/breaking-the-chain-of-infection) module to learn about breaking the chain of infection in care homes.

Hierarchy of controls

Reducing risk

The hierarchy of controls (HoC) (/appendices/appendix-17-hierarchy-of-controls/) is a system used to help prevent the transmission of infection. It details the most to least effective controls. You will note that PPE (/care-home-infection-prevention-and-control-manual-ch-ipcm/#a2884) is the last level of control in the hierarchy, used when all other controls have not reduced the risks sufficiently. To be effective, PPE must be used correctly which means putting it on and removing it correctly and safely (/care-home-infection-prevention-and-control-manual-ch-ipcm/#a2884).
See the Health and Safety Executive's (HSE) toolkit (https://www.hse.gov.uk/simple-health-safety/risk/index.htm) on managing risks and risk assessment at work.

The HoC principles can be broadly interpreted for care home settings and include:

- reducing hazards in the care home
- changing practice in the care home
- making the care home as safe as possible
- changing how we organise and work in the care home
- use of PPE

Examples of HoC principles

Here are some examples of how to apply the HoC principles in care home settings. These examples do not cover every situation where you might need to use HoC principles.

Reducing hazards in the care home

Measures such as vaccination, testing and isolation help to reduce the risk of infection. Not coming to work when ill, isolating while infectious and recognising and reporting infections promptly, all help to prevent infections spreading.

Changing practice in the care home

When faced with a particular risk, such as an outbreak, we may need to change what we do. This might include reducing communal activities, considering limiting visiting for a short period of time, or cleaning the care home environment more frequently. The local IPCT and/or HPT should always be contacted for advice and support in outbreak situations.

Making the care home as safe as possible

It is very unlikely that we will be able to change where we work but the care home setting should be made as safe as possible.
You can reduce opportunities for pathogens to survive in the care home by ensuring fixtures and fittings are in good repair and can be easily cleaned and following water safety guidelines.
Ventilation is also an effective measure to reduce the risk of some respiratory infections, by diluting and dispersing the pathogens which cause them. Consider opening windows and vents more than usual, even opening a small amount can be beneficial. Opening windows and doors may present security and safety

issues and so a local risk assessment should always be undertaken.

Changing how we organise and work in the care home

Changing the way, we organise and work in the care home can also help reduce risk. This might include reducing the number of people in a space at any one time and minimising the movement of staff between different settings as well as using administrative controls.
Administrative controls include local risk assessments, staff training, IPC audits, and providing clear signage and instructions throughout the care home.

Chapter 1: Standard Infection Control Precautions (SICPs)

The basic IPC measures that should be used in your care home are called **Standard Infection Control Precautions (SICPs).**

SICPs are used to reduce the risk of transmission of infectious agents from known and unknown sources of infection.

These should be used by **all staff, in all care settings, at all times, for all residents** whether infection is known to be present or not to ensure the safety of residents, staff and visitors in the care home.

SICPs should be part of everyday practice and applied **consistently** by everyone in the care home.
It is essential that optimal IPC measures are applied continuously as residents living in care homes are more vulnerable, therefore increasing their risk of acquiring infections which may then be serious and potentially life threatening. By applying optimum IPC precautions you will provide a safe environment and effective care.

There are 10 Standard Infection Control Precautions (SICPs)

1. resident placement/assessment for infection risk
2. hand hygiene
3. respiratory and cough hygiene
4. personal protective equipment
5. safe management of care equipment
6. safe management of care environment
7. safe management of linen
8. safe management of blood and body fluid spillage
9. safe disposal of waste
10. occupational safety: prevention and exposure management (including sharps)

1. Resident placement/assessment for infection risk

Before a resident is admitted to the care home it is important to risk assess for infection as part of resident's care plan, an IPC admission assessment should be undertaken by staff.
If you suspect or are aware that a resident has an infection, then details should be confirmed for the correct IPC precautions to be put in place for the safety of the resident and others.
Obtaining infection details may include appropriate clinical samples and/or screening to establish the causative organism which may be on advice from your local GP, IPCT or HPT.

Residents who may present a cross-infection risk include those with:

- diarrhoea

- vomiting, being sick
- unexplained rash
- fever or temperature of 37.8 C or higher
- respiratory symptoms such as coughing and sneezing
- known to have been previously positive with a Multi-drug Resistant Organisms (MDRO), for example Meticillin Resistant *Staphylococcus aureus* (MRSA), Carbapenemase Producing Enterobacterales (CPE)

Further information regarding general respiratory screening questions (/media/2147/2023-08-23-respiratory-screening-questions-aide.pdf) can be found within the resources section of the NIPCM.

> **Note:** If a resident requires isolation because of infection or in an outbreak situation, this should be individually risk assessed to ensure the safety and health and wellbeing needs of the resident. Isolation periods must be monitored on daily basis and be for the minimum period specified.

Resources

Appendix 11 (/appendices/appendix-11-best-practice-aide-memoire-for-optimal-patient-placement-and-respiratory-protective-equipment-rpe-for-infectious-agents-whilst-a-patient-is-in-hospital/) of the NIPCM gives you further information on the precautions required for different infections.

Read the **placement literature review** (/web-resources-container/patient-placement-isolation-and-cohorting-standard-infection-prevention-control-and-transmission-based-infection-control-precautions/) to understand the evidence base for resident placement.

2. Hand hygiene

> Please note that the term ‘alcohol-based hand rub (ABHR)’ has now been updated to ‘hand rub’. A hand rub (alcohol or non-alcohol based) can be used if it meets the required standards. Please see further information in the hand hygiene products literature review (/web-resources-container/sicp-literature-review-hand-hygiene-products/).

The most important thing you can do to prevent the spread of infection in a care home is to keep your hands clean. This is called **hand hygiene**.
Adherence with the following points is essential to ensure effective hand hygiene:

- expose forearms (known as bare below the elbows)
- remove all hand/wrist jewellery including any embedded jewellery (a single, plain metal finger ring or ring dosimeter (radiation ring) is permitted but should be removed (or manipulated) during hand hygiene). Bracelets or bangles such as the Kara which are worn for religious reasons should be able to be pushed higher up the arm and secured in place to enable effective hand hygiene which includes the wrists
- ensure fingernails are clean, short and that artificial nails or nail products are not worn
- cover all cuts or abrasions with a waterproof dressing

Hand washing should be extended to the forearms if there has been exposure of forearms to blood and/or body fluids.

Hand washing sinks should **only** be used for hand hygiene and should not be used for the disposal of other liquids.

To perform hand hygiene:

- hand rub should be available for staff as near to point of resident care as possible. Where this is not practical, personal hand rub dispensers should be used
- application of sufficient volume of hand rub to cover all surfaces of the hands is important to ensure effective hand hygiene
- manufacturer's instructions should be followed for the volume of hand rub required to provide adequate coverage for the hands. In the absence of manufacturer's instructions, volumes of approximately 3ml are recommended to ensure full coverage
- wall mounted or personal hand rub dispensers (cartridges/bottles) should not be refilled and should be replaced when empty or if outwith manufacturer expiry date

The World Health Organization's '4 moments for hand hygiene' should be used to highlight the key indications for hand hygiene:

1. before touching a resident
2. before clean/aseptic procedures. If hand rub cannot be used, then antimicrobial liquid soap should be used
3. after body fluid exposure risk
4. after touching a resident

Some additional examples of hand hygiene moments include, but are not limited to:

- after touching a resident's immediate surroundings
- before handling medication
- before preparing food
- before donning (putting on) and after doffing (taking off) PPE
- after visiting the toilet
- before putting on and after removing PPE
- between carrying out different care activities on the same resident
- after cleaning and disinfection procedures
- after handling used linen
- after handling waste

It is important that residents are routinely encouraged to perform hand hygiene and given assistance if required.

The **four moments for hand hygiene poster** (/media/1444/who-4-moments-residential-care.pdf) can be used in your care home to show staff when hand hygiene should be done and the reasons why.

Select image for full size version.
(https://www.nipcm.scot.nhs.uk/media/1444/who-4-moments-residential-care.pdf)

Hands should be washed with liquid soap and water if/when:

- they are visibly soiled or dirty
- they are potentially contaminated with blood, other body fluids or excretions
- caring for a resident with vomiting or diarrhoeal illness
- caring for a resident with a suspected or known gastro-intestinal infection such as norovirus or a spore forming organism such as *Clostridioides difficile*

> **Note:**
>
> Hands should be washed with warm/tepid water to mitigate the risk of dermatitis associated with repeated exposures to hot water and to maximise hand washing compliance. Compliance may be compromised where water is too hot or too cold.
>
> Hands should be dried thoroughly following hand washing using a soft, absorbent, disposable paper towel from a dispenser which is located close to the sink but beyond the risk of splash contamination.
>
> The use of antimicrobial hand wipes is only permitted where there is no access to running water. Staff should perform hand hygiene using hand rub immediately after using the hand wipes and perform hand hygiene with soap and water at the first available opportunity.
>
> In all other circumstances use hand rub for routine hand hygiene.

Skin care

- Hand rubs should contain emollients in their formulation.
- Pat hands dry after hand washing using disposable paper towels. Avoid rubbing which may lead to skin irritation/damage.
- Use an emollient hand cream during breaks and when off duty. These should be applied all over the hands including between the fingers and the back of the hands.
- Staff with skin problems should seek advice from the local occupational health department if available or their GP.
- Barrier creams should not be used in the workplace.

Do not use refillable containers or communal tubs of hand cream in the care home setting.

Resources

Read the hand hygiene literature reviews (/resources/literature-reviews/hand-hygiene/) to find out more about the evidence base for hand hygiene.

To make sure you clean your hands properly with soap and water you should follow the steps in the poster **‘How to hand wash step by step images (/appendices/appendix-1-best-practice-how-to-hand-wash)’**. This poster can be printed off and displayed throughout the care home to ensure that all staff and visitors are aware of and practice this hand hygiene method when required in the care home.

Select image for full size version (/appendices/appendix-1-best-practice-how-to-hand-wash)

To make sure you clean your hands properly with hand rub you should follow the steps in the poster **'How to hand rub step by step images** (/appendices/appendix-2-best-practice-how-to-hand-rub/)'. This poster can be printed off and displayed throughout the care home to ensure that all staff and visitors are aware of and practice this hand hygiene method when required in the care home.
Select image for full size version (/appendices/appendix-2-best-practice-how-to-hand-rub/)

3. Respiratory and cough hygiene

Infections can spread by coughing and sneezing, therefore it is very important that respiratory and cough hygiene is used by everyone including staff, residents and visitors.
Any resident displaying symptoms of respiratory illness should be encouraged to wear a surgical (for instance TYPE IIR FRSM) face mask where it is clinically safe and can be tolerated by the wearer, especially in communal areas.

What you need for respiratory and cough hygiene

• disposable tissues

• waste bin and waste bags

• hand hygiene products

If a resident has a cough, cold or other respiratory symptoms then they should be supported and encouraged to:

- cover their nose and mouth with a disposable tissue when sneezing, coughing, wiping and/or blowing the nose. If a disposable tissue is not available encourage the use of elbow/sleeve to cover the nose and mouth when coughing or sneezing
- put used tissues and face masks into a waste bin immediately after use
- wash their hands with soap and water after coughing, sneezing, using tissues, or after contact with respiratory secretions or objects contaminated by these secretions
- keep contaminated hands away from the eyes nose and mouth

Staff should:

- promote respiratory and cough hygiene and help residents who need assistance
- ensure that residents are provided with the necessary products for respiratory and cough hygiene including tissues, waste bag and hand hygiene products and make sure that products are in close vicinity for the resident to access
- use hand wipes followed by hand rub if there is no running water available or if hand hygiene facilities are out of reach then wash hands at the first available opportunity.

Read the **respiratory and cough hygiene literature review** (/web-resources-container/standard-infection-control-precautions-sicp-literature-review-cough-etiquetterespiratory-hygiene-in-the-hospital-setting/) to find out the evidence for respiratory and cough hygiene practice.

4. Personal Protective Equipment (PPE)

PPE products you might need in the care home:

• gloves

• aprons

• masks

• eye/face protection

See PPE for visitors

Deciding which PPE to use

Before doing any procedure or task staff should risk assess any likely exposure to blood and/or body fluids and ensure PPE is worn that provides adequate protection against the risks associated with the procedure or task being undertaken.
All PPE should be:

- located close to the point of use
- stored in a clean and dry area to prevent contamination until needed for use
- within expiry dates
- single-use only items unless specified by the manufacturer
- changed immediately after individual use and/or following completion of a procedure or task
- disposed of after use into the correct waste stream as per local risk assessed processes

Reusable PPE items, for example non-disposable goggles, face shields or visors must be cleaned/decontaminated once removed or placed within a designated container for subsequent cleaning/decontamination with decontamination schedules in place and responsibility assigned.

Read further information on best practice for PPE (/appendices/appendix-15-selection-of-personal-protective-equipment-ppe-by-health-and-care-workers-hcws-during-the-provision-of-care/) in Appendix 15.

Donning (putting on) personal protective equipment (PPE)

The order for putting on PPE is:

1. apron or gown
2. surgical mask
3. eye/face protection (where required)
4. gloves

Doffing (taking off) personal protective equipment (PPE)

It is important that PPE is removed in the correct order.
The order for taking off PPE is:

1. gloves
2. apron or gown

3. eye/face protection (if worn)
4. surgical mask

> **Note:**
>
> Always carry out hand hygiene immediately after taking off PPE.
>
> All PPE should be removed before leaving the area and disposed of as healthcare waste

Resources

A video demonstrating the order for donning and doffing PPE (https://vimeo.com/393951705) is available.

COVID-19 - the correct order for donning, doffing and disposal of PPE for HCWs in a primary care setting

NHS National Services Scotland

06:12

The correct order for donning, doffing and disposal of PPE for healthcare workers (https://vimeo.com/393951705) from NHS National Services Scotland (https://vimeo.com/nationalservicesscotland) on Vimeo (https://vimeo.com).

A poster showing the order for putting on and removing PPE (/appendices/appendix-6-best-practice-putting-on-and-removing-ppe/) is available to print.

Select image for full size version (/media/1808/nipcm-appendix6-march_2022.pdf)

Gloves

Gloves should be:

- worn when it is likely or anticipated that you will be exposed to blood, body fluids (including but not limited to secretions and/or excretions), non-intact skin, mucous membranes, lesions and/or vesicles, hazardous drugs, and chemicals for example cleaning agents
- single-use and should be donned (put on) immediately prior to exposure risk and should be doffed (taken off) immediately after each use or upon completion of a task
- appropriate for use, fit for purpose and well-fitting. The glove selection chart (/appendices/appendix-5-best-practice-gloves-use-and-selection/) can help you select the correct gloves
- changed if damaged or a perforation or puncture is suspected

> **Note:**
>
> Using gloves reduces the risk of contamination but does not remove all risk.
>
> Gloves should not be used instead of carrying out hand hygiene.
>
> Gloves should not be worn inappropriately in situations such as to go between residents, move around a care area or whilst at workstations (on the telephone or computer).
>
> Gloves should never be decontaminated or cleaned with hand rub or by washing with cleaning products.

Use the **glove selection chart** (/appendices/appendix-5-best-practice-gloves-use-and-selection/) to support you to select the correct glove type.
Select image for full size version
(/appendices/appendix-5-best-practice-gloves-use-and-selection/)

Aprons and gowns

Aprons should be:

- worn by care staff when there is a risk of clothing being contaminated with blood or other body fluids
- worn during direct care, for example oral hygiene, bed-making or when undertaking the decontamination of equipment
- changed between residents and following completion of a procedure or task

The choice of apron or gown is based on an individual risk assessment and anticipated level of blood/body fluid exposure. Routine sessional use of gowns/aprons is not permitted.

Eye/face protection

Eye/face protection should:

- be worn when there is an anticipated risk of splashing or spraying of blood or bodily fluids and always during Aerosol Generating Procedures (AGPs)

> **Note:**
>
> Eye/face protection should not be touched when worn or worn around the neck or on top of the head when not in use.
>
> Eye/face protection should be compatible with other items of PPE and worn in accordance with manufacturer's instructions.
>
> Prescription eyeglasses and contact lenses should not be considered a form of eye/face protection.

Fluid Resistant Type IIR surgical face masks (FRSM)

Fluid Resistant Type IIR surgical face masks should be:

- worn if splashing or spraying of blood, body fluids, secretions or excretions onto the respiratory mucosa (nose and mouth) is expected/likely. (As part of SICPs a full-face visor may be used as an alternative to fluid resistant Type IIR surgical face masks to protect against splash or spray)
- well-fitting, fully covering the mouth and nose and fit for purpose. Manufacturer's instructions should be followed to ensure effective fit/protection
- removed or changed:
  - at the end of a procedure/task
  - if the mask is damaged or there is a build up from moisture after prolonged use or from gross contamination with blood or body fluids
  - following specific manufacturers' instructions

If you are using droplet precautions, you should always wear a Type IIR surgical face mask as well as eye/face protection (droplet precautions will be discussed further in Chapter 2 Transmission Based Precautions (/infection-prevention-and-control-manual-for-older-people-and-adult-care-homes/#a2926)).

Transparent face masks

Transparent face masks may be used to aid communication with residents where required.
Transparent face masks should:

- meet the specification standards of the Transparent face mask technical specification (https://azuksappnpdsa01.blob.core.windows.net/datashare/Transparent-Mask-Specifications-December-2023.pdf)

and

- have been approved for use within health and social care settings
- only be worn in areas where Fluid Resistant Type IIR surgical face masks are used as personal protective equipment

Resources

Read the aerosol generating procedures literature review (/web-resources-container/tbp-literature-review-aerosol-generating-procedures/)and surgical face masks literature review (/web-resources-container/standard-infection-control-precautions-and-transmission-based-precautions-literature-review-surgical-face-masks/) for further information regarding the evidence base.

(/appendices/appendix-11-best-practice-aide-memoire-for-optimal-patient-placement-and-respiratory-protective-equipment-rpe-for-infectious-agents-whilst-a-patient-is-in-hospital/)

See appendix 11 (/appendices/appendix-11-best-practice-aide-memoire-for-optimal-patient-placement-and-respiratory-protective-equipment-rpe-for-infectious-agents-whilst-a-patient-is-in-hospital/) for further information.

PPE for visitors

At times, PPE may be offered to visitors to protect them from acquiring a transmissible infection. If a visitor declines to wear PPE when it is offered, then this should be respected, and the visit must not be refused. PPE use by visitors cannot be enforced and there is no expectation that staff monitor visitor PPE use. However, if staff or visitors identify the need for PPE, advice on correct use should be provided by staff. Table 1 below is a guide to the PPE which should be worn where appropriate and when the visitor chooses to do so

Table 1: PPE for use by visitors

IPC Precaution	Gloves	Apron/Gown	Face covering/mask	Eye/face protection
Standard Infection Control Precautions (SICPs)	Not required unless providing direct care which may expose the visitor to blood and/or body fluids, for instance toileting.	Not required unless providing care resulting in direct contact with the resident, their environment or blood and/or body fluid exposure, for instance toileting, bed bath.	Where splash/spray to nose/mouth is anticipated during direct care	Not required unless splash/spray to the eyes/face is anticipated during direct care.
Transmission Based Precautions (TBPs)	Not required unless providing direct care which may expose the visitor to blood and/or body fluids, for instance toileting.	Not required unless providing care resulting in direct contact with the resident, their environment or blood and/or body fluid exposure, for instance toileting, bed bath.	If within 2 metres of resident with suspected or known respiratory infection	If within 2 metres of resident with suspected or known respiratory infection

Read the PPE literature reviews (/resources/evidence-and-research/personal-protective-equipment-ppe/) to find out more information about the evidence base for PPE use.

5. Safe management of care equipment

Care equipment is easily contaminated with blood, other body fluids, secretions, excretions and infectious agents and this can spread infection.

Important words and what they mean

Routine cleaning is regular cleaning which is carried out on a scheduled basis, not on an unplanned basis and not in response to an outbreak. For routine cleaning general purpose detergent and water solution or detergent impregnated wipes are sufficient.

Cleaning is the removal of any dirt by use of an appropriate cleaning agent such as detergent.

Decontamination is removing, or killing pathogens on an item or surface to make it safe for handling, re-use or disposal, by cleaning, disinfection and/or sterilisation.

Disinfectant is a chemical used to reduce the number of infectious agents from an object or surface to a level that means they are not harmful to health.

Detergent is a chemical cleansing agent that can dissolve oils and remove dirt.

If the resident has a known infection or the equipment is contaminated with blood or body fluids, then a disinfection agent needs to be used.

Note:

Do not use household bleach as the required dilution cannot be guaranteed.

Do not refill bottles for cleaning products as there is a risk of contamination.

What you need for safe management of care equipment

- Cleaning/disinfectant products:
  - general purpose detergent and water solution/detergent impregnated wipes

    or

  - combined detergent/disinfectant solution at a dilution of 1,000 parts per million available chlorine (ppm available chlorine (av.cl.)

    or

  - a general purpose neutral detergent in a solution of warm water followed by disinfection solution of 1,000ppm av.cl.
- Paper towels/disposable cloths.

Types of equipment

There are three different types of care equipment that you will use in your care home and it is important that you know how to deal with each type.
You should follow manufacturers guidance for all equipment and products you use including those used for cleaning and decontamination.
Before using any **sterile equipment**, you should check that:

- the packaging is intact
- there are no obvious signs of packaging contamination
- the expiry date remains valid

1. **Single-use** - equipment which is used once on a single resident and then discarded.

Single-use equipment **must never be reused** even on the same resident. The packaging carries the symbol.

> **Note:**
>
> Needles and syringes are single-use devices. They should **never** be used for more than one resident or reused to draw up additional medication.
>
> **Never** give medications from a single-dose vial or intravenous (IV) bag to multiple residents.

2. Single individual use – equipment which can be reused by same resident for example a sling and decontaminated following use as per manufacturers instructions.

3. Reusable non-invasive equipment (often referred to as 'communal equipment') – equipment which can be reused on more than one resident following decontamination between each use for example commode, moving and handling equipment or bath hoist.

Cleaning or decontaminating reusable non-invasive equipment

Residents should be given their own reusable (communal) non-invasive equipment where possible. Reusable equipment should be checked frequently for cleanliness and signs of integrity. This will include mattresses and pillows which should be clean, have a waterproof covering which is in a good state of repair.
Pillows used on resident's beds may not require a waterproof cover if they are single resident use and are subject to regular checks/laundering. Resident pillows may require labelling where appropriate.
Reusable equipment should be cleaned or decontaminated:

- between individual use
- after blood and/or body fluid contamination
- as part of the regular scheduled cleaning schedules/process
- before inspection, servicing or repair

Staff should:

- follow the local cleaning protocol/schedule which should include responsibility for, frequency of and method of decontamination required
- use a general purpose detergent and water solution/detergent impregnated wipes

  or
  a combined detergent/disinfectant solution at a dilution of 1,000 parts per million available chlorine (ppm available chlorine (av.cl.)
  or
  a general purpose neutral detergent in a solution of warm water followed by disinfection solution of 1,000ppm av.cl;
- make up cleaning/disinfection solution following manufacturers guidance
- follow the manufacturer's contact time for the cleaning/disinfection solution
- rinse and dry reusable equipment then store it clean and dry

> **Note:** When an organisation use products or adopts practices that differ from those stated in this manual, that individual organisation is responsible for ensuring safe systems of work including the

completion of risk assessments approved through local governance procedures.

Resources

Read the **management of care equipment literature review** (http://www.nipcm.hps.scot.nhs.uk/web-resources-container/standard-infection-control-precautions-and-transmission-based-precautions-literature-review-management-of-care-equipment/) to find out more about why we do things this way for care equipment.

The **decontamination of non-invasive care equipment** (http://www.nipcm.hps.scot.nhs.uk/appendices/appendix-7-best-practice-decontamination-of-reusable-non-invasive-care-equipment/) poster can help staff decide how to clean equipment.

Select image for full size version

(http://www.nipcm.hps.scot.nhs.uk/appendices/appendix-7-best-practice-decontamination-of-reusable-non-invasive-care-equipment/)

6 - Safe management of the care environment

There are many areas in care homes that become easily contaminated with microorganisms (germs) for example door handles, toilets, waste bins, surfaces.
Furniture and floorings in a poor state of repair can have microorganisms (germs) in hidden cracks or crevices.
To reduce the spread of infection, the environment should be kept clean and dry and where possible clear from clutter and equipment.
Non-essential items should be stored and displayed in such a way as to aid effective cleaning
Keeping a high standard of environmental cleanliness is important in the care home as the residents are often elderly and vulnerable to infections.
The care home environment should be:

- visibly clean, free from non-essential items and equipment to help make cleaning effective
- well maintained and in a good state of repair
- routinely cleaned in accordance with the specified cleaning schedules:
  - a fresh solution of general purpose neutral detergent in warm water is recommended for routine cleaning. This should be changed when dirty or at 15 minutes' intervals or when changing tasks
  - routine disinfection of the environment is not recommended. However, 1,000 parts per million available chlorine (ppm available chlorine (av.cl.) should be used routinely on sanitary fittings

Staff should:

- report any issues with the environment cleanliness or maintenance to the person in charge to ensure that the care environment is safe. The person in charge should then act on problems reported to them
- be aware of the environmental cleaning schedules and clear on their specific responsibilities

Cleaning schedules should include:

- staff responsibilities
- cleaning frequencies
- cleaning methods

Managing cleaning services

Cleaning services should be managed in a systematic way, and staff responsible for cleaning should be appropriately trained to carry out the tasks they are responsible for.

The **care home manager** is responsible for managing the cleaning service which has a number of **essential** elements outlined in the cleaning services diagram.
Select the **Care Homes Cleaning Specification** (https://www.nss.nhs.scot/publications/safe-management-of-the-care-environment-shfn-01-05/) for full size version of cleaning services diagram.
Select the diagram for full size version

Cleaning Services

(https://www.nss.nhs.scot/publications/safe-management-of-the-care-environment-shfn-01-05/)
An effective service will include all of the elements above.

Care Homes Cleaning Specification

The **Care Homes Cleaning Specification** (https://www.nss.nhs.scot/publications/safe-management-of-the-care-environment-shfn-01-05/) provides a guide to planning cleaning services. It has tools to help with the planning and recording of cleaning activities and with the management activities marked with a * in the diagram above. These include:

- a structure to identify all spaces within a care home and plan appropriate cleaning tasks and frequencies
- a set of weekly and monthly **cleaning templates** to be assigned to each space within a care home. These can be used to develop a schedule and to provide a method for recording all cleaning activity

The tools within the Cleaning Specification should be used by the care home manager in the planning, training of staff, delivery, and checking of standards of the cleaning services they provide.
Manufacturer's instructions and recommended contact times should be adhered to.

Cleaning schedule and record

Table 2 provides an example of a cleaning schedule and record. These tools are examples and designed to support local practice, however care homes can use their own tools if preferred. If a local tool is used, it should reflect the standards set out in the Care Homes Cleaning Specification (https://www.nss.nhs.scot/publications/safe-management-of-the-care-environment-shfn-01-05/).
Table 2: Example cleaning schedule residents room

Standard operating procedures (SOPs) for all cleaning tasks.

Each SOP outlines the correct equipment, safety considerations, method, and outcomes required for each task. Table 3 shows the important steps that must be taken during the cleaning of floors.
Table 3: Example cleaning SOP: Floors

Process for checking

A **process for checking** the cleanliness of the care environment, to ensure standards are being maintained and to identify areas for improvement.

Decontamination of soft furnishings

Decontamination of soft furnishings may require to be discussed with the local HPT/ICT. If the soft furnishing is heavily contaminated with blood or body fluids, it may have to be discarded. If it is safe to clean with standard detergent and disinfectant alone then follow appropriate procedure.
If the item cannot withstand chlorine releasing agents staff are advised to consult the manufacturer's instructions for a suitable alternative to use following or combined with detergent cleaning.

> **Note:** When an organisation adopts decontamination processes not recommended in the CH IPCM the care organisation is responsible for governance of and completion of local risk assessment(s) to ensure safe systems of work.

Read the **routine cleaning of the care environment** (http://www.nipcm.hps.scot.nhs.uk/web-resources-container/standard-infection-control-and-transmission-based-precautions-literature-review-safe-management-of-the-care-environment/) literature review to find out more about why we do things this way for the care environment.

7 - Safe management of linen

Examples of linen you may have in the care home includes:

- bed linen (bed sheets, duvet, duvet covers, pillowcases)
- blankets
- curtains
- hoist slings
- towels
- resident clothing

There are three categories of linen:

Clean – Linen washed and ready for use
Used – All used linen in the care setting not contaminated by blood or body fluids
Infectious – All linen used by a person known or suspected to be infectious and/or linen that is contaminated with blood or body fluids for example faeces
Used or infectious linen may also be categorised as heat-labile: usually personal clothing where the clothing may be damaged (shrinking/stretching) by washing at a higher than recommended temperature than the label advises and therefore, cannot be subject to thermal disinfection. If such linen needs to be washed at a higher temperature for example if soiled or resident has a known infection they or their relatives need to be advised that the clothing may be damaged.
All clean, used and infectious linen should be handled with care and attention paid to the potential spread of infection. Appropriate temperatures for processing all used and infectious linen should be adhered to achieve thermal disinfection.

Clean linen

- Should be stored in a clean, allocated area. This should be an enclosed cupboard but a trolley could be used as long as it is completely covered with a waterproof covering that is able to withstand cleaning.
- Perform hand hygiene, in accordance with Section 2 (/care-home-infection-prevention-and-control-manual-ch-ipcm/#a2828), prior to handling clean linen.

Used linen

Staff should:

- refer to Appendix 15 (/appendices/appendix-15-selection-of-personal-protective-equipment-ppe-by-health-and-care-workers-hcws-during-the-provision-of-care/) for decision making regarding PPE use
- check that linen is free from inappropriate items before placing into the laundry receptacle, for example used equipment, service user personal belongings
- make sure that a laundry trolley or container is available as close as possible to the point of use for immediate linen deposit

Staff should **not**:

- rinse, shake or sort linen on removal from beds or trolleys
- place used linen on the floor or any other surfaces for example on a locker or tabletop
- re-handle used linen once bagged
- overfill laundry receptacles or trolleys

Infectious linen

Staff should:

- wear disposable gloves and apron before handling infectious linen
- put infectious linen directly into a water soluble laundry bag and secure before putting into a clear plastic bag and placing into a laundry receptacle/trolley

If using external laundry services both used and infectious linen bags/receptacles should follow local procedure and arrangements. Store all used/infectious linen in a designated, safe, lockable area whilst awaiting uplift.
All linen that is deemed unfit for re-use, for example torn or heavily contaminated, should be categorised at the point of use and disposed of in the appropriate local healthcare waste stream.

Washing residents personal linen

Appendix 1 National Guidance for Safe Management of Linen in NHSScotland Health and Care Environments - For laundry services/distribution (https://www.nss.nhs.scot/publications/national-guidance-for-safe-management-of-linen-in-nhsscotland-health-and-care-environments-for-laundry-servicesdistribution-v22/) contains information that is particularly relevant and may be useful for residential care settings where domestic-type (household) washing machines may be in place for laundering resident's personal items and clothing.
Domestic-type washing machines are not typically programmed with the temperature settings required for thermal disinfection, therefore domestic-type machines may only be used for laundering personal items of clothing belonging to residents, such as those that are heat-labile.
Other types of used linen such as sheets should be reprocessed using a machine that is capable of a validated temperature disinfection stage.
If using a domestic type washing machine to launder resident's personal items:

- wash items using the highest temperature you can and following the washing instructions
- use your normal washing powder or detergent and follow the instructions on the correct amount to use
- tumble-dry (if possible) following the washing instructions
- iron according to washing instructions. If possible, use a hot steam iron.

It is considered best practise to launder a resident's personal items separately, that means not to mix items from multiple persons within a single load.
If visitors wish to take their relatives clothes home to be laundered, place laundry in an appropriate bag and provide them with a **washing clothes at home leaflet** (https://hpspubsrepo.blob.core.windows.net/hps-website/nss/2639/documents/1_washing-clothes-home-english.pdf).
If the residents clothing is very soiled or infectious, staff may recommend that the clothing is washed in the care home's laundry service if available, otherwise, the item should be disposed of in the appropriate healthcare waste stream following discussion with the resident or their relative(s).

Read the **safe management of linen** (http://www.nipcm.hps.scot.nhs.uk/web-resources-container/standard-infection-control-precautions-sicp-literature-review-safe-management-of-linen-in-the-hospital-setting/) literature review to find out more about why we do things this way when dealing with linen.

8 - Blood and body fluid spillages

Spillages of blood and other body fluids may transmit blood borne viruses.

Important words and what they mean

A **blood borne virus** is a virus carried or transmitted by blood, for example Hepatitis B, Hepatitis C and HIV.

Body fluids are fluids produced by the body such as urine, faeces, vomit or diarrhoea. These body fluids may also contain blood.

Blood and body fluid spillages must be decontaminated:

- immediately by staff trained to undertake this safely
- using body fluid spill kits/equipment available

Responsibilities for the decontamination of blood and body fluid spillages should be clear within each area/care setting.

Resources

Read the **management of blood and body fluid spillages** (http://www.nipcm.hps.scot.nhs.uk/web-resources-container/standard-infection-control-precautions-sicp-literature-review-management-of-blood-and-body-fluid-spillages-in-the-hospital-setting/) literature review to find out more about why we do things this way for blood and body fluid spillages.

Use the poster **management of blood and body fluids** (http://www.nipcm.hps.scot.nhs.uk/appendices/appendix-9-best-practice-management-of-blood-and-body-fluid-spillages/) to help you when you clean up blood and body fluid spillages.

Select the image for full size (http://www.nipcm.hps.scot.nhs.uk/appendices/appendix-9-best-practice-management-of-blood-and-body-fluid-spillages/)

9 - Safe disposal of waste (including sharps)

Classification of waste

Waste regulations require the classification of waste based on hazardous characteristics.

- **Special (hazardous) waste**. Special waste includes a range of controlled wastes, defined by legislation, which contain dangerous or hazardous substances. Examples of special (hazardous) waste resulting from healthcare activities includes sharps, infectious or potentially infectious clinical waste and some pharmaceuticals or medicinal wastes.
- **Non-hazardous waste** is residual waste produced in both clinical and non-clinical settings which may include dry recyclates (glass, paper and plastics, metals, cardboard), food waste, packaging waste and furniture.

Segregation (separating) of waste

Waste bags in care homes should be colour coded to denote the different waste streams.
Different types of waste will be produced within care homes.
Some waste may be considered non-hazardous, for example paper hand towels, while other types of waste need special handling and disposal because of their hazardous properties for example, sharps and waste from service users who have or may have an infection.
SHTN 03-01 (https://www.nss.nhs.scot/media/5724/shtn-03-01-v8-dec-2024.pdf) contains a full colour-coded waste segregation guide however, the most frequently used waste streams are summarised below.

- **Black (non-hazardous)**

- residual waste remaining after all source segregated recyclates have been removed.

- **Orange (infectious)**
  - consists of infectious or potentially infectious substances or items.
  - orange lidded leak resistant receptacles may be used for solidified infectious liquids.
  - orange bags may be used for items such as PPE, spillage kits, swabs or dressings contaminated or likely to be contaminated with blood and/or body fluids including saliva.
  - orange lidded sharps box used for sharps disposal only

Local risk assessed processes for waste disposal should be followed and guidance from local contractors may apply.

Safe management of waste

Care home staff should ensure:

- all waste is managed according to relevant legislation and any local risk assessed processes
- the appropriate PPE is used when handling any special (hazardous) waste
- waste is disposed of as close to the point of use as possible, and segregated using the correct colour-coded waste bag or container compliant with UN and relevant industry standards
- liquid waste is disposed of via the toilet or macerator, or where this is not possible, solidified and placed in an appropriate rigid leak resistant receptacle
- clearly marked and secure containers for sharps disposal are available where sharps are used
- schedules are in place for the cleaning, emptying and uplifting of waste bins and waste does not accumulate in corridors, rooms, care areas or other publicly accessible areas
- waste bags are never overfilled and have been appropriately sealed, labelled and marked with the date and location before being stored for uplift.
- waste bags are securely sealed using a closure technique such as a ‘swan neck’
  - a ‘swan neck’ is a way of closing bag by tying in a loop and securing with a zip tie or tape to make a handle
- there is a dedicated area for the storage of waste that is secure and not accessible to residents or the public
- any PPE is removed, and hand hygiene is performed after handling waste

Read the **safe disposal of waste** (http://www.nipcm.hps.scot.nhs.uk/web-resources-container/standard-infection-control-precautions-literature-review-the-safe-disposal-of-waste/) literature review to find out more about why we do things this way when dealing with waste.

10. Occupational Safety: Prevention and Exposure Management (including sharps)

All care homes should have policies in place to ensure that staff are protected from occupational exposure to microorganisms (germs), particularly those that may be found in blood and body fluids.

Important words and what they mean

Occupational exposure is exposure of staff to blood or body fluids in the course of their work.

A **sharp** is a device or instrument such as needles, lancets and scalpels which are necessary for the exercise of specific healthcare activities and are able to cut, prick and/or have the potential to cause injury.

Safety device or safer sharp is a medical sharps device which has been designed to incorporate a feature or mechanism that minimises and/or prevents the risk of accidental injury. Other terms include (but are not limited to) safety devices, safety-engineered devices and safer needle devices.

The **Health and Safety (Sharp Instruments in Healthcare) Regulations (2013)** (https://www.legislation.gov.uk/uksi/2013/645/made#:~:text=The%20Health%20and%20Safety%20%28Sharp%20Instruments%20in%20Healthcare%29,event%20of%20injury%207%20Notification%20of%20injuries.%20) outline the regulatory requirements for employers and contractors in the healthcare sector in relation to:

- arrangements for the safe use and disposal of sharps
- provision of information and training to employees
- investigations and actions required in response to work related sharps injuries

Safe management of sharps in the care home

Sharps handling must be assessed, kept to a minimum and eliminated if possible with the use of approved safety devices.

Sharps safety

- **Always** dispose of needles and syringes as a single unit immediately at the point of use.
- **Always** assemble and label sharps containers correctly as per manufacturers instructions.
- **Always** use the temporary closure mechanisms on sharps containers in between use.
- **Always** follow manufacturers' instructions for safe use and disposal.

- **Never** re-sheath used needles or lancets.
- **Never** store sharps containers on the floor.
- **Never** allow access of sharps containers to residents or the public.
- **Never** fill sharps containers more than three-quarters full.

Significant occupational exposure

A significant occupational exposure is when someone is injured at work from using sharps or exposed to risk from blood or body fluids which may then result in a blood borne virus (BBV) or other infection. Examples of this would be:

- a percutaneous injury for example injuries from needles, instruments, bone fragments, or bites which break the skin
- exposure of broken skin for example abrasions, cuts, eczema

- exposure of mucous membranes including the eye from splashing and/or spraying of blood or bodily fluids

If you think or know you have had a significant occupational exposure you should:

- report this immediately to the designated person in your care home**, this is a legal requirement**
- follow the local agreed process for management of an occupational exposure incident and follow the management of occupational injuries flow chart

Resources

Read the **management of occupational exposure to Blood Borne Viruses (BBVs)** (http://www.nipcm.hps.scot.nhs.uk/web-resources-container/standard-infection-control-precautions-sicp-literature-review-occupational-exposure-management-including-sharps/) literature review to find out more about why we do things this way for occupational exposure.

The **management of occupational exposure incidents flowchart (http://www.nipcm.hps.scot.nhs.uk/appendices/appendix-10-best-practice-management-of-occupational-exposure-incidents/)** should be used within your care home so you know what to do for an occupational exposure.

Select the image for full size (http://www.nipcm.hps.scot.nhs.uk/appendices/appendix-10-best-practice-management-of-occupational-exposure-incidents/)

Transmission-based precautions (TBPs) definitions literature review update

Why are transmission descriptors (contact, droplet, airborne) being reviewed?

> The pandemic highlighted that the way in which respiratory transmission is currently described (droplet and airborne transmission) may not reflect what is happening in real life and so, there is a need to identify alternatives ways to describe respiratory transmission routes.
>
> Understanding how infectious agents are released into the air and the risks associated with particle size and distance from source will help inform this. Reviewing the evidence to understand if there is increased risk associated with certain medical procedures will also inform IPC practice.
>
> The World Health Organization (WHO) and Centers for Disease Control (CDC) have also reviewed transmission descriptors indicating a global shift in the way transmission routes are described. ARHAI Scotland were invited to meet with the WHO global IPC unit to discuss the topic and our literature review findings were well received.

What is likely to change in the CHIPCM?

> ARHAI are currently developing recommendations for practice. It is likely that ‘droplet transmission’ and ‘airborne transmission’ will be replaced with new definitions to describe respiratory transmission. This will mean changes throughout the CHIPCM to update the terminology including the addition of resources to support any guidance changes.

What might this mean for care home staff in practice?

It is too early to understand what might change in practice, but it is likely that there will be a need for care home staff to consider more factors when risk assessing what PPE to wear.

The goal of the CHIPCM is to provide care home staff in Scotland with guidance that is evidence based, up-to-date, effective, practical, and as a result, safe.

Update announcements

Use of the CHIPCM online is always advised to ensure access to up to date guidance. Updates to the CHIPCM content are communicated to stakeholders via the Care Home IPC Oversight and Advisory Group in addition to the news section of the NIPCM.

For further detail please use this link to the Transmission Based Precautions Definitions Literature Review (/resources/evidence-and-research/transmission-based-precautions-definitions/). (/resources/evidence-and-research/transmission-based-precautions-definitions/)

Transmission based precautions (TBPs)

In certain circumstances using standard infection control precautions (SICPs) won't be enough to stop an infection spreading and you will need to use some extra precautions. **These extra precautions are called Transmission Based Precautions or TBPs.**
Clinical judgement and decisions should be made by staff to determine the necessary IPC precautions required (the local IPCT and/or the HPT should be contacted for advice and support where required).
Clinical judgement and decisions should be based on the:

- suspected or known infectious agent
- transmission route of the infectious agent
- care setting and procedures undertaken
- severity of the illness caused

When TBPs should be used

TBPs should be used if a resident has a suspected or known infection or colonisation.

Important words and what they mean

Colonisation is the presence of microorganisms on a body surface (such as the skin, mouth, intestines or airway) that does not cause disease in the person or signs of infection.

Infection transmission routes

Infections can be transmitted or spread by:

- **contact** with microorganisms (germs) on hands or from contaminated equipment or environment
- **droplet infection** by inhaling infectious droplets, for example flu or COVID-19
- **aerosol infection** which are inhaled or directly contaminate a mucosal surface or conjunctivae (eyes, nose, and mouth)

Different transmission routes need different TBPs

TBPs are categorised by the route of transmission of infectious agents (some infectious agents can be transmitted by more than one route). **Appendix 11** (https://www.nipcm.scot.nhs.uk/appendices/appendix-11-best-practice-aide-memoire-for-patient-placement-considerations-and-respiratory-protective-equipment-rpe-or-fluid-resistant-surgical-facemasks-frsms-for-infectious-agents/) provides details of the type of precautions, optimal resident placement, isolation requirements and any respiratory precautions required. Application of TBPs may differ depending on the setting and the known or suspected infectious agent.

- **Contact precautions** are used to prevent infections that spread through direct contact with the resident or indirectly from the resident's immediate care environment and care equipment. This is the most common route of cross-infection transmission.
- **Droplet precautions** are used to prevent and control infections spread over short distances (at least 3 feet or 1 metre) via small droplets from the respiratory tract of one individual directly onto the mucosal surface of another person's mouth or nose or eyes. Droplets penetrate the respiratory system to above the alveolar level.
- **Airborne precautions** are used to prevent and control infections spread without necessarily having close contact via from the respiratory tract of one individual directly onto the surface of another person's mouth or nose or eyes. Aerosols penetrate the respiratory system to deep into the lung.

Different infections need different TBPs

You might have heard of some infections like norovirus, Meticillin-resistant *Staphylococcus aureus* (MRSA), *Clostridioides. difficile* (C.diff/CDI) and flu but there are lots of others.
You can find out more information about the infection the individual has and the precautions you should use in **Appendix 11** (http://www.nipcm.hps.scot.nhs.uk/appendices/appendix-11-best-practice-aide-memoire-for-optimal-patient-placement-and-respiratory-protective-equipment-rpe-for-infectious-agents-whilst-a-patient-is-in-hospital/) and/or **A-Z of pathogens** (http://www.nipcm.hps.scot.nhs.uk/a-z-pathogens/) in the NIPCM.
You can also contact your local IPCT or HPT for further advice if required.
Before using transmission based precautions you need to find out:

- what the suspected or known infection/colonisation is?
- how is it transmitted?
- how severe is the resident's illness?
- what is the care setting and required procedures?

There are different ways you can find out if a resident has an infection that needs TBPs to be put in place. You can get information about a resident's infection status from:

- their GP
- local health protection team
- local infection prevention and control team
- laboratory
- hospital or care homes staff from where the resident has been discharged or transferred

Local processes should be followed when obtaining this information.

Further information on transmission based precautions can be found in the definitions of (http://www.nipcm.hps.scot.nhs.uk/web-resources-container/transmission-based-precautions-literature-review-definitions-of-transmission-based-precautions/)Transmission Based Precautions literature review. (http://www.nipcm.hps.scot.nhs.uk/web-resources-container/transmission-based-precautions-literature-review-definitions-of-transmission-based-precautions/)

1. Resident placement/assessment for infection risk

All residents require to be regularly monitored for infection throughout their stay for the correct IPC precautions to be put in place to minimise the risk of infection being spread.
Residents may be an infection risk if they have:

- diarrhoea, vomiting, an unexplained rash, fever or respiratory symptoms
- a known (laboratory confirmed) or suspected infectious pathogen for which **appropriate** duration of precautions as outlined in A-Z of pathogens (https://www.nipcm.scot.nhs.uk/a-z-pathogens/)are not yet complete
- been previously positive with a Multi-drug Resistant Organism (MDRO) for example Meticillin-resistant Staphylococcus aureus (MRSA); Carbapenemase Producing Enterobacterales (CPE)*

*CPE should be considered if the resident meets **any** of the following criteria within the 12-month period before admission:

- been an inpatient in a hospital outside of Scotland
- received holiday dialysis outside of Scotland
- been a close contact of a person who has been colonised or infected with CPE.

See the CPE toolkit for non-acute settings (https://www.nss.nhs.scot/publications/toolkit-for-managing-carbapenemase-producing-enterobacteriaceae-cpe-in-scottish-non-acute-care-settings/) for further information and requirements.

Staff should do the following if any resident displays signs and/or symptoms of infection:

- obtain advice on the resident's clinical management from their GP and advice on appropriate IPC management from either the local HPT or IPCT
- make resident placement decisions based on advice received or sound judgement by clinical staff who are involved in the resident's management
- advise the ambulance service of the resident's infectious condition if transport to hospital is required

Residents should **not** be moved within the care home if they have signs and symptoms of infection unless essential.

Resident isolation requirements within the care home

Residents may require to be isolated in their own room because of a known or suspected infection. During this time it is important that:

- residents remain in their rooms whilst considered infectious and the door should remain closed. If it is not possible for safety reasons, for example the resident has dementia, an individual risk assessment should be done and any decisions or actions should be documented. The local HPT or IPCT should be contacted for advice
- suitable discrete signage is placed on the door advising others not to enter the room
- there should be as much consistency in staff allocation as possible to care for residents in isolation room areas as an additional IPC measure. This is known as 'staff cohorting'
- resident isolation requirements should remain under continuous review considering individual risk factors and the impact on the resident. The local HPT or IPCT should be contacted for advice in these circumstances

> **Note:** If a resident requires isolation because of infection or in an outbreak situation, this should be individually risk assessed to ensure the safety and health and wellbeing needs of the resident. Isolation periods must be monitored on daily basis and be for the minimum period specified.

Read the **patient placement, isolation and cohorting** (http://www.nipcm.hps.scot.nhs.uk/web-resources-container/patient-placement-isolation-and-cohorting-standard-infection-prevention-control-and-transmission-based-infection-control-precautions/) literature review to find out more about why we do things this way for resident placement for TBPs.

2. Safe management of care equipment in an isolation room

Cleaning and decontamination of care equipment is essential to reduce the spread of infection when infection is confirmed/suspected.
When dealing with the equipment used in the resident's isolation room staff should:

- use single use or dedicated reusable care equipment, for example commodes, for the resident in isolation where possible
- clean and decontaminate all care equipment after each use as per Appendix 7 (/appendices/appendix-7-best-practice-decontamination-of-reusable-non-invasive-care-equipment/)

Read the **management of care equipment** (http://www.nipcm.hps.scot.nhs.uk/web-resources-container/standard-infection-control-precautions-and-transmission-based-precautions-literature-review-management-of-care-equipment/) literature review to find out more about why we do things this way for patient care equipment for TBPs.

3 - Safe management of the care environment

Isolation room cleaning

Staff should:

- clean and decontaminate the isolation room at least daily or more frequently if advised to do so. If you have been advised to clean more than daily this should be documented in the environmental cleaning schedule
- clean frequently touched surfaces like door handles, bed frames and bedside cabinets at least twice daily
- use correct cleaning products which are either:

  a combined detergent/disinfectant solution at a dilution of 1,000 parts per million available chlorine (ppm available chlorine (av.cl.));
  or
  a general purpose neutral detergent in a solution of warm water followed by disinfection solution of 1,000ppm av.cl.
- follow manufacturers guidance and instructions on how to use the product and what the recommended contact time is for the product to work. This may include rinsing off the disinfection solution to prevent damage to surfaces.

Do not **refill spray containers** for cleaning products as there is a risk of contamination.

Terminal clean

> A **terminal clean** is carried out when the resident is no longer considered infectious and/or when the environment is cleaned/decontaminated to ensure it is safe for a new resident.

A terminal clean is carried out by:

- removing all healthcare waste and other disposable items from the room

- removing bedding, curtains (bagged before removal from the room) and then wash as infectious linen
- cleaning and decontaminating all reusable care equipment in the room (prior to removal from the room)

The room should then be decontaminated using either:

- a combined detergent disinfectant solution at a dilution (1,000ppm av.cl.) or
- a general purpose neutral detergent clean in a solution of warm water followed by disinfection solution of 1,000ppm av.cl.

The room should be cleaned from the highest to lowest point and from the least to most contaminated point.
Manufacturers' guidance and recommended product "contact time" should be followed for all cleaning/disinfection solutions.

(/appendices/appendix-7-best-practice-decontamination-of-reusable-non-invasive-care-equipment/) (/appendices/appendix-7-best-practice-decontamination-of-reusable-non-invasive-care-equipment/)Appendix 7 (/appendices/appendix-7-best-practice-decontamination-of-reusable-non-invasive-care-equipment/) is a poster flowchart for decontamination of reusable non-invasive care equipment that you may wish to print off and place in the care home.

> **Note:** When an organisation use products or adopts practices that differ from those stated in this manual, that individual organisation is responsible for ensuring safe systems of work including the completion of risk assessments approved through local governance procedures.

4. Personal Protective Equipment (PPE): Respiratory Protective Equipment (RPE)

In addition to PPE used for Standard Infection Control Precautions, appendix 15 (/appendices/appendix-15-selection-of-personal-protective-equipment-ppe-by-health-and-care-workers-hcws-during-the-provision-of-care/) of the NIPCM outlines what type of PPE and RPE you will need to wear for infections spread by different transmission routes.
AGPs (/care-home-infection-prevention-and-control-manual-ch-ipcm/#AGP)

Gloves

Gloves are a single-use item and should be donned immediately prior to exposure risk and should be doffed immediately after each use or upon completion of a task.
Gloves should:

- be worn when exposure to blood, body fluids, (including but not limited to secretions and/or excretions), non-intact skin, lesions and/or vesicles, mucous membranes, hazardous drugs, and chemicals for example cleaning agents, is anticipated/likely
- never be worn inappropriately in situations such as to go between residents, move around a care area, work at IT workstations
- be changed if a perforation or puncture is suspected or identified
- be appropriate for use, fit for purpose and well-fitting
- not be worn as a substitute to hand hygiene
- never be decontaminated with ABHR

Resources

For appropriate glove use and selection see the flowchart poster (https://www.nipcm.scot.nhs.uk/appendices/appendix-5-best-practice-gloves-use-and-selection/) which may be printed off and placed in the care home. (https://www.nipcm.scot.nhs.uk/appendices/appendix-5-best-practice-gloves-use-and-selection/)

Further information can be found in the Gloves literature review (https://www.nipcm.scot.nhs.uk/web-resources-container/sicp-literature-review-personal-protective-equipment-ppe-gloves/).

Aprons/gowns

An apron should be worn when caring for residents known or suspected to be colonised/infected with antibiotic resistant bacteria including contact with the resident's environment.
Plastic aprons should be used in care home settings for protection against contamination with blood and/or body fluids.
A fluid repellent gown should be used if excessive splashing or spraying is anticipated.
A full body fluid repellent gown should be worn when conducting AGPs on residents known or suspected to be infected with a respiratory infectious agent.
Further information can be found in the Aprons/Gowns literature review (https://www.nipcm.scot.nhs.uk/web-resources-container/standard-infection-control-precautions-sicp-literature-review-personal-protective-equipment-ppe-apronsgowns/).

Eye/face protection

Eye and face protection should be used in combination with:

- a fluid resistant Type IIR surgical mask when caring for symptomatic residents infected with **droplet** transmitted infectious agents
- a fluid resistant FFP3 respirator when caring for symptomatic residents infected with an **airborne** transmitted infectious agent

Eye/face protection should be worn:

- by all of those in the room if potentially infectious AGPs are conducted
- for the care of residents with novel infectious agents including pandemic influenza

Read Appendix 11 (/appendices/appendix-11-best-practice-aide-memoire-for-patient-placement-considerations-and-respiratory-protective-equipment-rpe-or-fluid-resistant-surgical-facemasks-frsms-for-infectious-agents/) for details of the type of precautions, optimal resident placement, isolation requirements and any respiratory precautions required.

Surgical masks

A Type IIR fluid resistant surgical mask (FRSM) should be worn when caring for a resident with a suspected/confirmed infectious agent spread by the droplet route.
FRSMs should be worn (where tolerated) by residents with suspected/confirmed infectious agents spread by the droplet or airborne routes, as a form of source control and should meet type II or IIR standards.
Read Appendix 11 (/appendices/appendix-11-best-practice-aide-memoire-for-patient-placement-considerations-and-respiratory-protective-equipment-rpe-or-fluid-resistant-surgical-facemasks-frsms-for-infectious-agents/) for details of the type of precautions, optimal resident placement, isolation requirements and any respiratory precautions required.

Respiratory Protective Equipment (RPE)

PPE should still be used in accordance with SICPs when using respiratory protective equipment (RPE). See Chapter 1.4 (/infection-prevention-and-control-manual-for-older-people-and-adult-care-homes/#a2884) for PPE use for SICPs.

The use of FFP3s is governed by health and safety regulations and they must be fit tested to the user to ensure the required protection is provided.

The Health and Safety Executive (HSE) provides information regarding fitting and fit checking of RPE (https://www.hse.gov.uk/respiratory-protective-equipment/basics.htm).

Respiratory Protective Equipment (RPE), for instance FFP3 and eye/face protection, should be considered when:

- a resident is admitted or develops a known/suspected infectious agent/disease spread wholly by the airborne route
- carrying out AGPs on residents with known/suspected infectious agent spread wholly or partly by the airborne or droplet route

FFP3 respirators

It is an HSE requirement that staff who need to wear an FFP3 respirator must be fit tested.

FFP3 respirators should **not** be worn by staff who are not trained in their use or who have not been fit tested.

All FFP3 respirators must be:

- fit tested (by a competent fit test operator) on all staff who may be required to wear a respirator to ensure an adequate seal/fit according to the manufacturers' guidance
- fit checked (according to the manufacturers' guidance) every time a respirator is donned to ensure an adequate seal has been achieved
- single-use (disposable) and fluid resistant
- compatible with other items of PPE and worn in accordance with manufacturer's instructions. Prescription eyeglasses and contact lenses should not be considered a form of eye/face protection
- put on before entry into the resident's room and removed in a safe area once outside the resident's room
- changed after each use

Signs that a change in respirator is required include:

- breathing becomes difficult
- the respirator is wet or moist
- the respirator is damaged
- the respirator is obviously contaminated with body fluids such as respiratory secretions

Resources

A poster (/media/1491/facial-hair-and-ffp3-respirators.png) containing information on compatibility of facial hair and FFP3 respirators can be used when fit testing and fit checking.

Further information regarding fitting and fit checking of respirators can be found from the Health and Safety Executive (http://www.hse.gov.uk/respiratory-protective-equipment/basics.htm)

Aerosol Generating Procedure (AGP)

An AGP is a medical procedure that can result in the release of airborne particles from the respiratory tract and is associated with an increased risk of transmission when treating someone who is suspected or known to be suffering from an infectious agent transmitted wholly or partly by the airborne or droplet route.

The most common AGPs undertaken in the Care Home Setting are Continuous Positive Airway Pressure Ventilation (CPAP) or Bi-level Positive Airway Pressure Ventilation (BiPAP) or tracheostomy procedures (insertion or removal) and open suctioning beyond the oro-pharynx.
The full list of medical procedures that have reported to be aerosol generating and are associated with an increased risk of respiratory transmission can be found in appendix 16 (/appendices/appendix-16-aerosol-generating-procedures-agps-and-post-agp-fallow-time-pagpft/).
A poster (/media/1898/2022-07-22-v4-ppe-when-undertaking-agps-poster.pdf) is also available on PPE when undertaking AGPs within health and social care settings.
Rooms should always be decontaminated following an AGP. Clearance of infectious particles after an AGP is dependent on the ventilation and air change within the room. In an isolation room with mechanical ventilation 10-12 air changes per hour (ACH) a minimum of 20 minutes is required; in a side room with 6 ACH this would be approximately one hour.
It is often difficult to calculate air changes in areas that have natural ventilation only, meaning no mechanical ventilation. Natural ventilation, particularly when reliant on open windows can vary depending on the climate. An air change rate in these circumstances has been agreed as 1-2 air changes/hour.
Rooms should always be decontaminated following the completion of an AGP. Regardless of the number of air changes, a period of 10 minutes should pass to allow larger droplets to settle before the room can be cleaned. Staff are required to wear the appropriate PPE until the fallow time (https://www.nipcm.scot.nhs.uk/appendices/appendix-17-aerosol-generating-procedures-agps-and-post-agp-fallow-time-pagpft/) has been met.

Resources

For further information on fallow times refer to Table 1 in Appendix 16. (/appendices/appendix-16-aerosol-generating-procedures-agps-and-post-agp-fallow-time-pagpft/)

Further information can be found in the literature reviews aerosol generating procedures, (/web-resources-container/tbp-literature-review-aerosol-generating-procedures/)Respiratory Protective Equipment (RPE) (https://www.nipcm.scot.nhs.uk/web-resources-container/transmission-based-precautions-literature-review-respiratory-protective-equipment-rpe/), Personal Protective Equipment (PPE) for Infectious Diseases of High Consequence (IDHC) (https://www.nipcm.scot.nhs.uk/web-resources-container/literature-review-personal-protective-equipment-ppe-for-infectious-diseases-of-high-consequence-idhc/)

Post AGP fallow time (PAGPFT)

Time is required after an AGP is performed to allow the aerosols still circulating to be removed/diluted. This is referred to as post AGP fallow time (PAGPFT) and is a function of the room ventilation air change rate.
The post aerosol generating procedure fallow time (PAGPFT) calculations are detailed in appendix 16 (/appendices/appendix-16-aerosol-generating-procedures-agps-and-post-agp-fallow-time-pagpft/). It is often difficult to calculate air changes in areas that have natural ventilation only.
If the area has zero air changes and no natural ventilation, then AGPs should not be undertaken in this area.
The duration of AGP is also required to calculate the PAGPFT and clinical staff are therefore reminded to note the start time of an AGP. It is presumed that the longer the AGP, the more aerosols are produced and therefore require a longer dilution time. During the PAGPFT staff should not enter this room without FFP3 masks. Other residents, other than the resident on which the AGP was undertaken, should not enter the room until the PAGPFT has elapsed and the surrounding area has been cleaned appropriately. As a minimum, regardless of air changes per hour (ACH), a period of 10 minutes should pass before rooms can be cleaned. This is to allow for the large droplets to settle. Staff should not enter rooms in which AGPs have been performed without airborne precautions for a minimum of 10 minutes from completion of AGP.
Airborne precautions may also be required for a further extended period of time based on the duration of the AGP and the number of air changes. Cleaning can be carried out after 10 minutes regardless of the extended time for airborne PPE.
Contact your local HPT/IPCT if further advice is required.

Read the RPE (http://www.nipcm.hps.scot.nhs.uk/web-resources-container/transmission-based-precautions-literature-review-respiratory-protective-equipment-rpe/) literature review to find out more about why we do things this way for respiratory protective equipment.

Use of FFP3 respirators

- Where staff have concerns, they may choose to wear an FFP3 respirator rather than a fluid-resistant surgical mask (FRSM) when providing patient care, provided they are fit tested. This is a personal PPE risk assessment.

5. Infection prevention and control during care of the deceased

If a resident dies when in the care home SICPs and TBPs should still be applied. This is due to the ongoing risk of infectious transmission via contact although the risk is usually lower than for the living.
It is important that information on the infection status of the deceased is sought and communicated at each stage of handling and risk assessments performed.
Viewing, washing and/or dressing of the deceased see Appendix 12 - Application of infection prevention precautions in the deceased (http://www.nipcm.hps.scot.nhs.uk/appendices/appendix-12-mandatory-application-of-transmission-based-precautions-to-key-infections-in-the-deceased/) for guidance on the precautions required and what is permitted for certain types of infections.
Staff should advise relatives of the appropriate precautions to be taken when viewing and/or having physical contact with the deceased, including when this should be avoided.

Read the **infection prevention and control during care of the deceased** (http://www.nipcm.hps.scot.nhs.uk/web-resources-container/transmission-based-precautions-literature-review-infection-prevention-and-control-during-care-of-the-deceased/) literature review to find out more about why we do things this way when dealing with the deceased.

Care home appendices

These appendices from the NIPCM can be used in care homes.
Appendix 1 - How to hand wash (/appendices/appendix-1-how-to-hand-wash/)
Appendix 2 - How to hand rub (/appendices/appendix-2-how-to-hand-rub/)
Appendix 5 - Glove use and selection (/appendices/appendix-5-gloves-use-and-selection/)
Appendix 6 - Putting on and removing PPE (/appendices/appendix-6-putting-on-and-removing-ppe/)
Appendix 7 - Decontamination of reusable non-invasive care equipment (/appendices/appendix-7-decontamination-of-reusable-non-invasive-care-equipment/)
Appendix 8 - Management of linen at care level (/appendices/appendix-8-management-of-linen-at-care-level/)

SCOTTISH HOSPITALS INQUIRY

Review of the Expert Report for the Scottish Hospitals Inquiry on the evidence of risk of infection from the water and ventilation systems at the Queen

Elizabeth University Hospital and Royal Hospital for Children,

Glasgow written by Professor PM Hawkey, Dr SG Agrawal and Dr LN Drumright ('HAD' Report)

Expert Report prepared for the Scottish Hospitals Inquiry

Date: 28 May 2025

Dr Shona Cairns, BSc (Hons), PGDip, MSc, ARHAI Scotland, NHS NSS

This document may contain Protected Material within the terms of Restriction Order 1 made by the Chair of the Scottish Hospitals Inquiry and dated 26 August 2021. Anyone in receipt of this document should familiarise themselves with the terms of that Restriction Order as regards the use that may be made of this material. The terms of that Restriction Order are published on the Inquiry website.

Table of Contents

1. Executive Summary 3

2. Introduction and Background 4

3. Review of Chapter 7: ‘Water - analysis of infection rates and data from QEUH & RHC’ 5

3.1 Inclusion criteria and definitions 5

3.2 Numerators and denominators 7

3.3 General analytical and statistical methods 11

3.4 Clustering analysis methods 12

3.5 Review of Paediatric incidence analyses 16

4. Review of Chapter 8: ‘Ventilation - analysis of infection rates and data from QEUH & RHC’ 18

1 Executive Summary

1.1 This review is based on the data made available to NSS and does not seek to replicate the analyses undertaken by Dr Drumright. The raw and final datasets and additional information (**A52617217 – Bundle 44, Vol 2, Document 1, page 12 - Prof Peter Hawkey, Dr Lydia Drumright & Dr Samir Agrawal - Draft Joint Response to HAD Questionnaire** and **A52609154 - Bundle 44, Vol 2, Document 46, page 706 - SHI Source Identification and Supporting Workings Request Dated April 11, 2025**) provided were helpful context in assessing the epidemiological aspects of the report. However, a number of the analytical methods and calculations are not clearly defined and there is not sufficient information to fully assess the analytical work undertaken.

1.2 The epidemiological analyses of bloodstream infections do not account for some of the nuances of environmental/water-related outbreak epidemiology including polymicrobial episodes of infection or poly-clonal and/or poly-strain outbreaks. Furthermore, the authors rely heavily on unvalidated outbreak definitions. This limits the ability to fully assess the potential for an environmental source for the infections.

1.3 In the paediatric population, the authors have not acknowledged a potentially important trend in bloodstream infection (BSI) infection rates after the move to Royal Hospital for Children (RHC) nor the impact of mitigations or controls implemented. In Section 7.2.10 (page 119), the authors note “policies and procedures for patient management over time could be decreasing incidence of bacteraemia attributable to environmentally relevant microorganisms” but have not considered whether this may have been related to the environmental controls implemented at the time.

1.4 The strength of the conclusion made by the authors in Section 8.1.5 (page 130) in relation to the *Aspergillus* spp. ventilation analyses that the “observed number of cases and variations over time do not show evidence of the built environment increasing infection rates” does not reflect the limitations of the data and the analyses undertaken. The limitations and caveats have not been fully acknowledged by the authors. There is also a period where there appears to be a potentially higher number of cases in the paediatric population following the move to RHC and, whilst the numbers are small to draw conclusions, this was not acknowledged by the authors in their commentary.

1.5 In conclusion, this review has identified significant epidemiological limitations and caveats that have not been fully acknowledged by the authors. In relation to whether there is evidence of “widespread contamination of the water system”, the authors conclude in Section 7.2.10 (page 119) that “taken together, these data provide little to no evidence for environment sources of bacteraemia in patients at QEUH”. The analysis

assessing whether there is evidence of an “increased rate of airborne infections in QEUH consistent with a failure of the ventilation system” concludes in Section 8.1.5 (page 130) “for both the paediatric and adult services, the observed number of cases and variations over time do not show evidence of the built environment increasing infection rates”. The strength of these conclusions has not been made in the context of the methodological issues, limitations and caveats of the data as described in this review. Furthermore, there are potentially signals in the paediatric population data that appear to have been overlooked by the authors, and in the absence of their consideration, their conclusions made cannot be regarded as fully supported by the evidence presented.

2 Introduction and Background

2.1 This review has been prepared to assist the Inquiry in its considerations of the NHS Greater Glasgow and Clyde (NHSGGC) commissioned ‘Expert Report for the Scottish Hospitals Inquiry on the evidence of risk of infection from the water and ventilation systems at the Queen Elizabeth University Hospital and Royal Hospital for Children, Glasgow’ (**A49396252 – Bundle 44, Volume 1 – Documents in respect of NHS GGC – Expert Report by Prof Peter Hawkey, Dr Samir Agrawal and Dr Lydia Drumright – The evidence of risk of infection from water and ventilation systems at QEUH and RHC – 24 July 2024 (“HAD Report”)**). The HAD report was admitted into evidence following a Procedural Hearing on 11 March 2025.

2.2 The preparation of this review has been supported by an expert statistician from the University of Strathclyde (Dr Kimberley Kavanagh) and the multi-disciplinary team within ARHAI Scotland. Dr Kavanagh did not have access to the data and supported this work by answering specific queries regarding the statistical methods described in the report.

2.3 The focus of this review is on the epidemiological aspects of the HAD report as described in Chapter 7 and 8. It does not seek to comment on content relating to the microbiological aspects (other than those associated with epidemiological interpretation) including water testing results and whole genome sequencing. The NHSGGC authored water testing reports and whole genome sequencing (WGS) reports were therefore out of scope of this review.

2.4 There were several issues that limited the scope of this review:

2.4.1 There was a significant delay in receiving the final Chapter 7 datasets from Dr Drumright. These were received on 7 May 2025 so there was limited time to consider these files in any detail.

2.4.2 There remained a lack of detail on the calculations undertaken by Dr Drumright. The details of the underlying arithmetic/working provided to the Inquiry were not comprehensive and appeared to be responses to questions posed by the Inquiry team. A plan of the analysis undertaken and, ideally, outputs from statistical packages including the code used would have improved the transparency of the report and greatly assisted the NSS review.

2.4.3 There is follow up information from Dr Drumright outstanding. Dr Drumright indicated that the clustering analysis was being reviewed and the supplementary data were pending. NSS has not had sight of any further supplementary information.

2.4.4 Chapter 8 was produced by Dr Agrawal and the final dataset and calculations for the *Aspergillus* spp. analysis have not been made available to NSS. This made a comprehensive assessment of Chapter 8 challenging and, therefore this review is high-level only. Review of Chapter 7: 'Water - analysis of infection rates and data from QEUH & RHC'

3 Review of Chapter 7: 'Water - analysis of infection rates and data from QEUH & RHC'

3.1 Inclusion criteria and definitions

3.1.1 There were some challenges in the interpretation of the report as no summary information relating to the included patients and infections was provided. The lack of descriptive information about the total number of admissions, bed days and patients make the report difficult to interpret. A high-level summary of the underlying data would have improved transparency and aided interpretation. Furthermore, there was no description of the demographics of cases e.g. age, sex, diagnosis. It is best practice to provide this important contextual information in any epidemiological report to aid those considering the findings.

3.1.2 The report lacks summary information in relation to the infections and microbiological data included in the report. The lack of detail regarding the number of episodes of infection, the distribution of the microorganisms identified and whether there were polymicrobial episodes of infection also limits the ability to interpret the report. The report predominantly provides data graphically or presented in line lists of cases of infection at patient level. Tables 5A to 8 (adult patients) and Tables 11A to 14 (paediatric patients) are essentially the underlying data for report. The authors have not provided a high-level summary of the distribution of microorganisms identified in the patient populations or in the sub-populations of interest e.g. Yorkhill Hospital/RHC and

QEUH/Other Hospitals. This makes it difficult to interpret the overall epidemiological picture within the populations. Such a distribution provides an opportunity to consider the variety of microorganisms causing infection and the presence of polymicrobial episodes of infection. These are useful indicators given the likely heterogeneity of the microorganisms isolated when there is an environmental source of infection.

3.1.3 A review of the microorganisms that were included across various reports previously considered by the Inquiry indicated that there were some minor differences in the microorganism lists. This may be explained in part by the differing time periods included in the reports as the lists of microorganisms are based on those identified during the period. In the additional information provided by Dr Drumright (**A52609154 – Bundle 44, Vol 2, Document 46, page 706 - SHI Source Identification and Supporting Workings Request Dated April 11, 2025**), it was noted that "organisms of environmental concern are not identified through calculation, these are based on biological knowledge and expertise and can be confirmed by thorough literature search and review of biology texts". Notably, the authors have included *Mycobacterium* spp. in the list of microorganisms that are not usually associated with an environmental source though no reference is provided to evidence this in the literature review undertaken by Professor Hawkey. Non-tuberculous Mycobacteria have been implicated in healthcare outbreaks related to water sources so justification for their exclusion from the environmental microorganism list is required.

3.1.4 The case definition includes microorganisms grown from blood culture (Section 7.2.1, page 65). However, Cryptococcus neoformans is often detected in blood using a serology/antigen test rather than by culturing the microorganism and this will have resulted in an under-estimate of the number of Cryptococcus neoformans cases included in the report.

3.1.5 The authors refer to microorganisms that have a potential environmental source in several ways when reporting their analyses. For the purpose of this review, we have assumed that the following all refer to the same microorganism group in the analysis: 'could be environmentally transmitted' (Figure 5-6), 'environmental concern' (Table 5A-C, Table 11A-F), 'environmental significance' (Figure 7-8), 'environmentally relevant' (Figure 9-10, 13-16, 19, 22), 'potential environmental concern' (Figure 18), 'relevance to environmental survival and transmission' (Figure 20).

3.1.6 The authors describe the episode case definition in Section 7.2.2 (page 67) as a "new case if the patient had not had a positive detection for that organism within the prior 14 days". This would suggest that the case definition is aligned with that used by ARHAI

Scotland where the 14-day episode period is applied to the last positive blood culture in any series of blood cultures **(A32938402 - Bundle 19, paper 9, page 53 – ARHAI Scotland - Protocol for National Enhanced Surveillance of Bacteraemia)**. However, a review of the data provided by Dr Drumright indicates that this was not the case and the 14-day period was applied to the first positive blood culture. The inconsistency between the description of the definition and the final datafile makes interpretation of the data challenging.

3.2 Numerators and denominators

3.2.1 The description of adult and paediatric populations described in the HAD report is not well defined. Some clarification was provided in the questionnaire where the authors noted the dataset requested was described as “paediatric oncology patients and adult haemato-oncology patients” **(A52617217 – Bundle 44, Vol 2, Document 1, page 14 - Prof Peter Hawkey, Dr Lydia Drumright & Dr Samir Agrawal - Draft Joint Response to HAD Questionnaire 1 Question 1Ae**). Further understanding was developed by review of the datafiles provided though there remain aspects that are not well defined. This prevents a clear understanding of the patient population and activity included in their analyses. Specific issues relating to this are described in paragraphs 17 to 22.

3.2.2 The choice of a bed days denominator is appropriate for both adult and paediatric populations due to the differential lengths of stay in these patients. The authors suggest in Section 7.2.1 (page 64) that bed days are deemed a better denominator for healthcare associated infection (HCAI) incidence as they also account for “percentage bed occupancy”. The authors suggest that higher bed days equate to higher person density on the ward. High person density is a recognised risk for transmission of HCAI however aggregated bed days do not provide a measure of this. This requires an understanding of the capacity, availability of single rooms and size/floor plate of the unit. Whilst bed days are a better denominator for this population, person density is not an appropriate justification for this choice.

3.2.3 Bed days provide a measure of time at risk and patients with longer lengths of stay contribute more to the denominator/time at risk. It is not defined in the report whether day case attendance activities have been accounted for in the denominator. However, additional information provided by the authors indicated that “the dataset consists of all inpatients and day case admissions with a length of stay greater than zero” for adult and paediatric patients (**A51838352 – Bundle 44, Volume 1, Document 1, page 5 – Documents in respect of NHS GGC – Expert Report by Prof Peter Hawkey, Dr**

Samir Agrawal and Dr Lydia Drumright – The evidence of risk of infection from water and ventilation systems at QEUH and RHC – 24 July 2024 ("HAD Report")). This would suggest that the denominator does not account for the contribution of day cases, where patients can spend time at risk in hospital receiving treatment. Such day cases are relevant and ideally should be included in the denominator. Where this has not been possible, this limitation should have been acknowledged by the authors as the denominator will underestimate the time at risk.

3.2.4 Review of adult population denominators:

3.2.4.1 The authors have stated in the additional information provided by Dr Drumright **(A52609154 - Bundle 44, Vol 2, Document 46, page 706 - SHI Source Identification and Supporting Workings Request Dated April 11, 2025**) that the adult denominator data was extracted by NHSGGC based on the consultant of the patient and mapped to the Sector in which the consultant is based.

3.2.4.2 The bed days include all admissions where the patient's consultant is a haemato-oncology consultant, irrespective of where the patient was admitted to and cared for. This means that the Sector bed days include bed days for care delivered outside of haemato-oncology specialty wards and across NHSGGC.

3.2.4.3 The allocation of bed days to QEUH and Other Hospitals used Sector and date ranges noted by the authors (Section 7.2.2, page 69) as "South sector became QEUH in May 2015 and remained part of QEUH through 2023 where data provided stops; BMT became part of QEUH for a period of approximately one and a half months across the months of June and July in 2015 and then from June 2018 onward". Review of the datafiles provided indicated that this method results in QEUH bed days including bed days from Other Hospitals and vice versa. Furthermore, the QEUH bed days include bed days for other specialties in the hospital.

3.2.4.4 The impact of this limitation cannot be determined as the bed days within an inpatient stay are calculated as a whole and do not take into account transfers within NHSGGC during a continuous stay. The NHSGGC raw datafile included admissions which did not start in a haemato-oncology ward and others that did not end a haemato-oncology ward. Bed days in haemato-oncology wards cannot be distinguished from those in other locations.

3.2.4.5 The choice of denominator, which does not define the patient cohort by location of care and includes locations within and outside of haemato-oncology services, may limit the conclusions that can be drawn about a water system that is located in the QEUH estate.

3.2.4.6 The inclusion of non-haemato-oncology bed days in the denominator is an important point of clarity as this increases the denominator and will result in a lower rate of infections than if only haemato-oncology bed days were included.

3.2.4.7 On review of the data provided by the authors for Figure 4 (Section 7.2.3, page 73), there appears to be some discrepancy with the Other Hospitals denominator. It is unclear why the North Sector and Bone Marrow Transplant (BMT) bed days were not included in the Other Hospital denominator for Quarter 1 2013 to Quarter 2 2014 and the North Sector bed days were not included in Quarter 3 2014. The authors do not provide an explanation for this change from the definition of Other Hospital bed days. This exclusion of bed days may result in an over-estimated rate of infections in the early part of the time period and may impact on any comparisons with other time periods or when fitting linear trend lines.

3.2.4.8 The authors note in the report that they had identified points during the time period when there were an "uncharacteristically low number of bed days" and noted it was not clear if the low number was an error or real (Section 7.2.3, page 69). The analyses were carried out using adjusted bed days for the months noted to be low. The authors did not appear to consider or adjust for months when the bed days were uncharacteristically high e.g. in South Sector during July 2019 when the bed days were more than double other months in the year. This may have resulted in a lower rate for some of the months with an uncharacteristically high number of bed day and may impact on the linear trend analyses.

3.2.5 Review of adult numerator data

3.2.5.1 The review of the adult BSI numerator data was more difficult with some inconsistencies between the report and the data provided. As with the bed days, the BSI have been assigned to Sector based on the consultant's Sector (rather than location of where the blood culture was obtained). The report states in Section 7.2.2 (page 69) that "for adult patients, data were examined both by consultant sector, BMT, North and South, and by months and years in which consultant section was assigned to either the QEUH or all other locations". This implies that the same method of attribution from Sector to the QEUH and Other Hospitals categories was applied to BSI. This does not appear to have universally been the case. For example, there are BSI categorised as BMT consultant Sector during 2016 and 2017 that have been assigned to QEUH. However, according to the methods in Section 7.2.2 (page 69) of the report, BMT consultant Sector BSI would be attributed to Other Hospitals as "BMT became part of QEUH for a period of approximately one and a half months across the months of June and July in 2015 and then from June 2018 onward".

3.2.5.2 On review of the data, the majority of BMT BSI in 2016 and 2017 had a location of 'General OP QEUH' recorded which may suggest that the authors have mapped the location of where the blood culture was taken to QEUH or Other Hospitals rather than using consultant Sector information.

3.2.5.3 This difference in the way the denominator (consultant Sector irrespective of location) and cases (based on location) have been defined at hospital level has implications for interpretation of the rates. Not all cases that could arise from the population (defined by the Sector denominator) will have been included in the BSI numerator (defined by location) and may artificially reduce the rate in some analyses.

3.2.6 Review of paediatric denominator data

3.2.6.1 Based on the review of the raw denominator datafile from NHSGGC, the admission data appears to have been extracted based on the patients' specialty. This was confirmed in follow up information provided by the authors (**A51838352 – Bundle 44, Volume 1 – Documents in respect of NHS GGC – Expert Report by Prof Peter Hawkey, Dr Samir Agrawal and Dr Lydia Drumright – The evidence of risk of infection from water and ventilation systems at QEUH and RHC – 24 July 2024 ("HAD Report")**). Similar to the adult denominator data, there are admissions that did not start in a haemato-oncology ward and some that did not end there when patients were transferred to other specialties. All of the admissions started and ended in RHC so bed days from other hospitals are not included.

3.2.6.2 As with the adult denominator, the inclusion of non-haemato-oncology bed days in the denominator is an important point of clarity. The rate described is the rate of BSI in patients under the care of a haemato-oncology specialty and is not based on the location of the patient. The inclusion of bed days from other locations will increase the denominator compared with e.g. the denominator used in the HPS report that used haemato-oncology bed days. This may potentially result in an increased denominator in the HAD report and therefore a reduced rate of infection than if only haemato-oncology bed days were included.

3.2.7 Review of paediatric numerator data

3.2.7.1 The criteria for extraction and identification of paediatric BSI is not clear and the raw dataset from NHSGGC indicates that several criteria were used to identify cases though this is not described fully by the authors in the report.

3.3 General analytical and statistical methods

3.3.1 The small number of cases included in many of these analyses, particularly at month level and in the BMT specific analysis (Section 7.2.6, page 92), limits the interpretation. Statistics such as p-values and confidence intervals are used routinely in epidemiology to account for the inherent randomness in data, the effects of which are greater the smaller the amount of data available. When small numbers are included in analyses, it is more difficult to determine whether the result has been obtained through chance.

3.3.2 The usefulness of statistics when the numbers are so small can be limited and it appears that the authors have in places, by necessity, described the data rather than undertaking any formal testing. This makes it challenging to draw conclusions about signals in data outside of normal variation. This applies to spikes in cases that have been identified from review of the graphs and appear to have been described rather than formally tested. However, language such as 'significant' has been used without evidence of statistical testing of significance (Section 7.2.3, page 74; Section 7.2.6, page 85). It would be helpful for the authors to acknowledge when their assessment is descriptive only.

3.3.3 For analyses where statistical testing has been undertaken, it would be best practice to include the outputs from the tests to support the statements being made about the data. Further reporting of p-values and confidence intervals would have made the analysis more transparent to readers and enabled an assessment on whether the results were significant.

3.3.4 The authors refer to rates being higher/lower over long periods of time where the conclusions drawn are unlikely to be true over the entire time period. As an example, the authors have noted the near equal distribution of *Acinetobacter* spp. across QEUH and Other Hospitals (Section 7.2.3, page 75). This is based on a small number of cases (n=28) over an extended period of time (July 2013 to August 2023). We would suggest that the number of cases is too small to draw any conclusions from this statement.

3.3.5 In Tables 10 (adults, page 85) and 16 (paediatrics, page 114), the authors have compared incidence rates of BSI in QEUH versus Other Hospitals and in QEUH/RHC versus Yorkhill Hospital, respectively. These comparisons are unadjusted and do not take account of differences between the comparators and any confounding that may result. This is a limitation that should have been acknowledged by the authors.

3.3.6 The authors have used regression models to fit linear trend lines to the incidence rates over time and compared the linear trends between QEUH and Other Hospitals (adults)

and QEUH/RHC versus Yorkhill Hospital (paediatrics). A number of methodological issues were identified:

3.3.7 Whilst fitting a line over a long period may be statistically acceptable, important points or signals in the data within the time period can be masked. In any linear trend analysis, clinical/epidemiological interpretation is required when deciding whether a longer-term linear trend describes the time period adequately.

3.3.8 If there is a need to assess shorter term trends, more than one line can be fitted and if there is a period of interest, fitting a line over a shorter period of time may be helpful to interpret the trend.

3.3.9 In the paediatric analyses, the linear trend line presented in Figure 22 (page 118) does not adequately describe the changing rates of infection during the overall time period and has possibly masked a signal in the data. The authors did not consider the patterns in the data immediately following the move to RHC and the period where the incidence of infection appeared to remain higher (untested) until later in 2019. These issues are discussed in paragraphs 38 to 41.

3.3.10 The authors have not provided any outputs or coefficients from the models to assist interpretation and enable full assessment of the results. We are unable to assess how well the line has fit the data.

3.3.11 Whilst no issues with the selection of the models or statistical regression modelling techniques used by the authors were identified, the other issues relating to the data underlying the models restrict the conclusions that can be drawn.

3.4 Clustering analysis methods

3.4.1 In Section 7.2.2 (page 67), the authors describe a method to identify “potential epidemiological” clusters of two or more cases of a single species of microorganism that had “potential to be environmentally transmitted” using four different categories of clusters based on location and time between cases. The authors have not provided a reference to support the use and validity of this method including the criteria for defining a cluster. This does not appear to be a recognised method for identifying outbreaks in healthcare particularly outbreaks with a potentially environmental source. Nor do the definitions align with the ARHAI Scotland National Infection Prevention and Control Manual (**A49799834 – Bundle 27, Volume 4 – Miscellaneous Documents - National Infection Prevention and Control Manual**). These guidance definitions are evidence based and recognised across the UK.

3.4.2 The cluster analysis undertaken in this report is based on a restrictive definition of a cluster that does not reflect the often polymicrobial and/or poly-strain epidemiology of outbreaks with an environmental source. The analysis is based on a single species cluster and the authors have not acknowledged the limitations of a definition restricted to one species. Evidence provided by Professor Mark Wilcox (**A50851931 - Transcript – Professor Mark Wilcox – 29.10.2024 – transcript column 125**) during the Glasgow III Hearings described the complexity of microbiological aspects of outbreaks with an environmental source. Traditional epidemiological methods and definitions require to be tailored to ensure that this complexity is reflected in analyses. Clusters of any microorganism in the environmental microorganism group and a description of heterogeneity of the clusters would have provided additional information to assess the possibility of an environmental source. The responses provided in the questionnaire response (**A52617217 – Bundle 44, Vol 2, Document 1, page 30 - Prof Peter Hawkey, Dr Lydia Drumright & Dr Samir Agrawal - Draft Joint Response to HAD Questionnaire 1 Question H17**) noted that Professor Hawkey would provide further evidence from the literature though NSS have not been sighted in this.

3.4.3 The cluster analysis presented in the report is based on a single ward location where the sample was taken. This does not take account of whether the patient had been exposed to a different location prior to the sample being taken. Outbreak/cluster investigations in healthcare require a wider approach due to movement of patients within the healthcare system. To fully assess location as a risk for developing a BSI with a potentially environmental source, an epidemiological timeline is required for each patient to describe their admission history and identify links in time and place. This review should also consider recent discharges and re-admissions. HCAI epidemiological case definitions, including the ARHAI Scotland Protocol for National Enhanced Surveillance of Bacteraemia, often include criteria to account for recent discharge from hospital (**A32938402 - Bundle 19, paper 9, page 53 – ARHAI Scotland - Protocol for National Enhanced Surveillance of Bacteraemia**). This is a time-consuming exercise and likely not possible for the authors of this report. However, an acknowledgement of this limitation is necessary, and the strength of any conclusions should have been drawn in this context. As Professor Mike Stevens described in his evidence (**A50866602 - Transcript – Professor Mike Stevens – 30.10.2024 – transcript column 59**), the Case Note Review developed detailed timelines for each patient enabling them to undertake a fuller assessment of each patient's journey in the healthcare system.

3.4.4 The authors have selected to use the incidence of clusters of two or more cases to assess the likelihood of environmental contamination. A single case of some of the unusual microorganisms identified may give an indication of an environmental source and would require investigation. A focus on clusters without consideration for single cases of some of the rarer microorganisms alongside a lack of information about how many of the patients had polymicrobial episodes of infection limits the interpretation in the context of environmental source outbreak epidemiology.

3.4.5 The methods for the cluster analysis are not described in the report nor were they provided in the follow up information from Dr Drumright. It is not clear how the date parameters in the definitions described in Table 3 (page 68) have been applied to identify clusters. There are outstanding questions: was the exact date of the blood culture used or was this based solely on the calendar month? If so, was the first blood culture in an episode used or all subsequent? What is the specific definition of a month e.g. 28 days or calendar month? In addition, there is a possible error with an overlapping time period in the 'possibly cluster' and 'unlikely to cluster' categories. It is not clear how cases in different wards 2 months apart would be categorised as both definitions include 2 months ('unlikely to cluster' if >= 2 months, 'possibly cluster' if <=2 months).

3.4.6 The follow up information from Dr Drumright indicated that the clustering analysis was being reviewed and the supplementary data were pending. NSS has not had sight of any follow up information. This makes assessing the results from the cluster analysis difficult.

3.4.7 The authors have not provided evidence for the methodology used for the development of a weighted summary score described in Section 7.2.2 (page 68). It is unclear if this is a validated method for assessing the impact of clustering. The authors have not provided justification for the weighting of scores and they seem to be arbitrary which limits the interpretation. Furthermore, the denominator issues noted previously will impact on the summary score rates that have been calculated and compared across QEUH/Other Hospitals and RHC/Yorkhill Hospital.

3.4.8 None of the datafiles provided by Dr Drumright include a variable that identifies the cluster status of the cases (and note that the supplementary data table is yet to be provided). It was possible to create a datafile from the tables included in the report (Tables 5A-8 for adults and Table 11A-14 for paediatrics). There is limited utility in using this datafile to assess the cluster analysis as there were several inconsistencies

between the data in the report and the final datafile provided by Dr Drumright as noted below:

3.4.9 For the adult population, the report includes 278 BSI cases of “environmental concern” listed in Tables 5A-8. The final dataset provided includes 446 BSI cases. A number of reasons for the discrepancies have been identified though there remain outstanding inconsistencies (that may have been explainable with additional information on methods from the authors).

3.4.10 The datafile from Dr Drumright includes 43 *Rothia* spp. categorised as environmental BSI. These are not included in the environmental list in Table 1 (page 65) of the report so it is assumed these were categorised as environmental in error and were excluded from the tables in the report.

3.4.11 There are 108 *Klebsiella pneumoniae* in the final datafile from Dr Drumright. These are not included in Tables 5A-8 and no explanation is given by the authors regarding their exclusion. It is also not possible to determine if these BSI were excluded from the weighted cluster summary measure.

3.4.12 There is an error in the calculation of the summary score in Table 10 (page 85). Application of the weighting as described in the methods should have resulted in a score of 175 for QEUH but it appears that a weighting of 2 has been applied to the 22 probable clustering BSI rather than 3 resulting in an underestimate of the score by 22.

3.4.13 For the paediatric population, the report includes 479 cases of BSI whereas the datafile includes 499 environmental BSI.

3.4.14 The datafile includes 7 Rothia mucilaginosa, which are not included in the environmental list in Table 1 (page 65), presumably in error.

3.4.15 Unlike the adult population, 85 Klebsiella pneumoniae cases have been included in the report and are described in Table 13 (page 108).

3.4.16 There are multiple minor differences between the tables presented in the report and the final datafile provided by Dr Drumright. The raw datafile from NHSGGC was not cross checked with Dr Drumright’s final datafile so it is not possible to describe if there are any discrepancies between the files.

3.4.17 On Page 114, the authors discuss the higher number of cases and number of cases that cluster in Table 16. It is not appropriate to compare the absolute number of cases as the time periods included are different (125 months in Yorkhill Hospital and 91 months in QEUH).

3.5 Review of Paediatric incidence analyses

3.5.1 The incidence of environmental BSI in the paediatric population is described in Section 7.2.8 (page 95) where the authors note that “incidence starts off at QEUH similar to that observed for the prior 10 years at Yorkhill, but then steadily declines from ~2018 onward”. They do not acknowledge the immediate decrease in rate for 6 months following the move to RHC. A decrease in infections with a potential environmental source may be expected when moving from an older estate to a newly built hospital. The rate of BSI with microorganisms with “no environmental relevance” did not decrease following the move providing further evidence that there may have initially been an effect on the rate of environmental BSI. This also supports that the decrease observed in the environmental microorganisms is not a result of a data artefact as it is assumed this would have occurred across all of BSI data. These observations are based on visual inspection of the data rather than formal statistical testing.

3.5.2 The authors do not consider or describe what appears to be a period of increased incidence from approximately June 2016 to November 2019. Before and after this time, the rates had fluctuated with multiple months with a rate of zero. During the period of increased incidence, there were no months where the rate returned to zero.

3.5.3 The authors note a decline in the environmental microorganism BSI rate from 2018 onwards though do not refer to any of the environmental controls or mitigations e.g. installation of filters, cleaning of drains and decanting of patients from affected wards as a hypothesis for this decrease.

3.5.4 As previously noted, the duration of time over which the linear trend lines are fitted can mask important trends within the time period. The linear trend line reported in Figure 22 (page 118) describes a significant reduction in environmentally relevant BSI though does not account for variation in rate over time or the implementation of mitigations and controls in the intervening period. A time series analysis that considers the rates of BSI in two segments after the move to RHC may have assisted in interpretation of differing trends including the period where the incidence of BSI appears to be higher. The rates post-move to RHC could have been segmented following the implementation of mitigations/controls. This would have provided some evidence of the effect of these on the rates and better described the changing trend over the time period.

3.5.5 An important caveat that must be acknowledged when making any comparisons between the rates of BSI in Yorkhill Hospital and RHC is that the built environments in the estates will be different. It cannot be assumed that the environment and the risk of

infection from an environmental source therein, will be equivalent in an old estate versus a state of the art new build hospital.

3.5.6 As HPS previously produced the Review of NHSGGC paediatric haemato-oncology data, there is an opportunity to consider some of the signals in the HPS data (**A43940545 - Bundle 7 – Written Reports Prepared by Health Protection Scotland (HPS), Health Facilities Scotland (HFS) and Antimicrobial Resistance and Healthcare Associated Infection (ARHAI)**). There are some considerations in relation to the different methods applied:

3.5.7 There are differences in the case definitions applied. The "environmental-enteric" group in the HPS report is better aligned with the environmental microorganism list in the HAD report as it includes *Citrobacter* spp., *Enterobacter* spp., *Klebsiella* spp., *Pantoea* spp., *Serratia* spp. though there remain some differences in the microorganisms included.

3.5.8 There are differences in the denominator used in the HPS report which includes haemato-oncology admissions and the HAD report which includes some bed days out with haemato-oncology specialties and wards.

3.5.9 The HPS report included a statistical process control (SPC) chart (Figure 6) describing the incidence of a the environmental-enteric group of microorganisms deduplicated at group level rather than at single species level (**A43940545 - Bundle 7 – Written Reports Prepared by Health Protection Scotland (HPS), Health Facilities Scotland (HFS) and Antimicrobial Resistance and Healthcare Associated Infection (ARHAI)**). This definition was applied to account for patients with polymicrobial infections being repeatedly counted in the case numbers. Of interest to the Inquiry is the higher rate of infections reported in the HAD report in May 2018 (Figure 18, page 95). On review, the HAD data and HPS data have the same number of single species BSI (n=10) but the HPS graph reports the number of episodes of BSI from any environmental-enteric microorganism. This reduced the number of episodes to 5 as there was one patient with a polymicrobial episode of BSI with 5 different microorganisms isolated.

3.5.10 Figure 6 in the HPS report describes the rate of environmental-enteric BSI and the rates, whilst noting the above differences, follow a similar pattern to that of the HAD report (Figure 22, page 118). There is an initial decline in the rate of infection followed by an increase. This period of increased incidence was not identified as outside of normal variation though caution is required due to the aforementioned issues regarding

small numbers and the limitations of a baseline calculated using Yorkhill Hospital infection rates.

4 Review of Chapter 8: 'Ventilation - analysis of infection rates and data from QEUH & RHC

4.1 The final data and the underlying arithmetic/workings for the *Aspergillus* spp. analysis were not available to NSS therefore a fully comprehensive review has not been possible.

4.2 The definition of an episode of infection is described by the de-deduplication section in 8.1: (page 124) "where the same patient had multiple positive tests for the same admission episode, this was classified as one case". As the final datafile was not available, it was not possible to assess how the de-duplication was applied nor how the laboratory results were linked to admission data. Case definition de-duplication criteria would usually have a date parameter e.g. 14 days for repeat blood cultures. This definition implies that a patient can have an episode of infection on each admission (if tested) irrespective of the time between samples. A description of the total number of patients and cases/episodes of infection would have assisted with interpretation to understand whether there were patients with multiple episodes and the impact this may have on the conclusion.

4.3 Section 8.1 (page 123) describes that cases were identified based on "either a haematology/haemato-oncology consultant or location". There is no further detail on how the location criterion has been applied and whether cases identified by samples obtained outside of haemato-oncology wards are included. This would present a similar issue to that identified in the review of Chapter 7 and may impact on the conclusions that can be drawn about a ventilation system located in the QEUH estate. Additionally, the location information is based on where the sample was taken and does not account for any prior admissions or exposure to the hospital environment. Prior exposure history is particularly important when considering the links between *Aspergillus* spp. infections and the environment due to the long incubation period which can vary widely from days to months.

4.4 The *Aspergillus* spp. analyses do not include a denominator that accounts for activity. This is likely to be important particularly during the period where services were moving between locations and where data are presented at ward level. The authors have not provided any justification for the lack of denominator in the analysis. Based on the earlier review of bed days data for Chapter 7, ward level bed days were not available to the authors as the total bed days for each continuous inpatient stay was provided

irrespective of whether a patient was transferred between wards. Therefore, bed days could not be allocated to individual wards. The lack of denominator in the analyses should have been acknowledged by the authors as a limitation.

4.5 The number of *Aspergillus* spp. cases are small in these analyses. As discussed previously, a small number of cases and the effects of random variation can impact on the ability to draw strong conclusions about the data. The authors do attempt to describe whether the number of cases has changed over time and have made some descriptive comparisons (Sections 8.1.1-8.1.4, pages 124-130). Whilst a small number of cases can make epidemiological analyses more challenging, there are other methods that can be used to assess potential links to the environment. Root cause analyses can be used to assess each patient and explore the possibility of links. An important aspect of such an exercise would be consideration of a timeline that describes location information over a longer period rather than a point in time where a sample was taken. This was the approach taken in the Case Note Review (A50866602 - Transcript – Professor Mike Stevens – 30.10.2024 – transcript column 23).

4.6 Review of adult data

4.6.1 The authors include a comparison of data from the adult Haemato-Oncology Unit at St Bartholomew's Hospital, London in Section 8.1.2 (page 126). There is insufficient information about the populations, *Aspergillus* spp. testing and case definitions to determine whether this is an appropriate comparison.

4.6.2 In Section 8.1.2 (page 126), the authors conclude "there is no indication of increased cases" in the "Adult BMT service" and the "Adult Haematology South service" including after the permanent move of these services to QEUH and that the case numbers in the "Adult Haematology North" service indicate "expected variation over time". The limitations of the analyses and caveats have not been fully acknowledged in the strength of this conclusion.

4.7 Review of paediatric data

4.7.1 The authors describe Figure 24 in Section 8.1.3 (page 128) and note "the number of cases with evidence of infection with A. spp. in the paediatric haematology and oncology service following the move to RHC in 2015 varied from 1 to 7 per annum from 2016- 2022, as compared to 0 to 5 from 2005-2014". Whilst not possible to do a formal statistical test and no denominator has been used, there is period with a potentially higher number of cases that is not acknowledged by the authors. The authors have focused on the range of case numbers pre- and post-move to RHC but do not note

that following the move there were 5 months between 2016 and 2020 where there were 4 or more cases identified. This is in contrast to before the move when there was only one month with 4 or more cases. Whilst it is not possible to draw a strong conclusion based on this data, it is worth acknowledging whilst considering the question relating to the ventilation system.

4.7.2 In Section 8.1.4 (page 130), the authors conclude that the analyses show low level variation that is expected over time. The limitations of the analyses and caveats have not been fully acknowledged in drawing this conclusion nor has the potential period where there was a higher number of cases.

Dear [redacted],

This will take a lot more time than I could devote so far. I will be working on it over the weekend and will update you again on Sunday.

I am aware of the need to work rapidly, but at the same time these are very big requests with little notice.

Following up on our discussion regarding individual level data. I am not comfortable assuming that the novation agreement covers this. I would kindly request that you or someone from your firm contact the CLO so that they can give me authorization to release individual level data in a documented and transparent communication.

Thank you so much.

Kind regards,

Dr Lydia N Drumright, PhD MPH

Subject: Request for Calculations/Workings - Re HAD Report

Dear Dr Drumright,

I hope this message finds you well.

Following a detailed review of Chapter 7 of the HAD report, our expert, Mr Sid Mookerjee, has compiled a set of queries and clarifications regarding the data sources, tables, and methodologies referenced throughout the chapter. The Inquiry seeks clarity on several key points, including the exact underlying data tables used in many of the figures, the spreadsheet sources, and the methodologies for deriving specific findings.

While we appreciate that you may not be best placed to respond to every query, please feel free to indicate where another expert (Dr Agrawal or Prof Hawkey) would be better positioned to answer, and kindly name the expert where appropriate.

In order to assist us in fully understanding and evaluating the findings, we would be grateful if you could review the questions below and provide the relevant documentation by **Wednesday 16 April**, if at all possible, and by **Friday 18 April** at the latest:

Source Identification and Supporting Workings

For the following pages, could you please confirm the exact spreadsheet or data source used (including the period the dataset covers), and provide the working spreadsheets, tables, and any relevant methodological details:

1. **Page 60** - Data mentioned in relation to QEUH and comparable hospitals.
2. **Page 62** –
    - Organism detection data differentiated by patient ID.
    - Data used to calculate Bed Days per month (including the period that it covers).
    - Working spreadsheet(s) that demonstrate the process used to define a new case (14-day rule), monthly case counts, environmental organism classification, and calculation of incidence rates per 1,000 bed days.
3. **Page 64 -**
    - Historical (2005 – May 2015) vs. current paediatric hospital data (June 2015 – 2022) - (Yorkhill vs. RHC).
    - Data used in Figures 1 and 2.
4. **Page 68 –** Data used in Figure 4, please also clarify if it is fair to assume that references to ‘other hospitals’ prior to page 69, do indeed refer, and always refer to the combined data from Beatson and SGH?

5. **Page 65 –**If available, please also provide the tables and workings for Figures 4–22.

6. **Pages 64–69**
    - Data source(s) for references to “other hospitals in NHS GGC” and related figures.

Terminology Clarifications

- Page 60: Please provide an explanation of what the 'ticks' and 'crosses' along the Adult and Paediatric columns in Table 1 and 2, in order to clarify the intent.
- Pages 64–69: Please confirm whether "other hospitals in NHS GGC" consistently refers to Beatson and SGH across the report.

Figure Labels and Consistency

- Page 65: Could you confirm whether Figures 1 through 22 represent *incidence rates* (cases per activity/time point) as opposed to *incidence* (cases per time point)?
- As many figures currently lack data labels, the provision of numerical tables would significantly aid in replicating and verifying your findings.

If the data you have drawn upon appears in the documents contained within **Bundle 44 Vol 1**, please refer to them as **Bundle X and Page Y**. If the sources are different or are not clearly identifiable within that bundle, we would be grateful if you could supply the specific spreadsheet(s), workings, and documentation as requested.

We understand this is a substantial request and appreciate your time. As noted above, please feel free to direct any specific queries to the relevant expert where appropriate. Additionally, we may seek to arrange a short **Teams consultation** in around two weeks' time, if needed, to follow up on any points arising from your response.

Please let us know your availability in advance and also if you would like to discuss any of the above further.

We also look forward to receiving your completed questionnaires tomorrow.

Many thanks & regards,

[redacted]

APPENDIX 3. ARHAI SCOTLAND ENVIRONMENTAL PATHOGENS SURVEILLANCE SURVEY 2024 26

Introduction

The National Infection Prevention and Control Manual (NIPCM) - Appendix 13 specifies a nationally agreed minimum (non-exhaustive) list of environmental bacteria alert organisms for high-risk units and patient cohorts to enable timely and adequate alert response and investigation.[1] In a September 2024 update, additional organisms were added to this list, along with signposting to the water section of NIPCM Chapter 4, which was launched in July 2024. However, there is currently no national advice to support boards to develop systems to pro-actively detect and monitor for infections caused by environmental bacteria in high-risk units in NHS Scotland hospitals.

ARHAI Scotland were tasked with scoping the feasibility of a surveillance system for environmental pathogens, to assist NHS boards with identification and monitoring of organisms which may have an environmental source. A scoping exercise, using Electronic Communication of Surveillance in Scotland (ECOSS) data, concluded that it would be feasible to use the positive microbiology results data from ECOSS to undertake surveillance of environmental pathogens isolated from clinical samples at the ward/unit level, acknowledging a number of limitations (**Appendix 1.** Data Limitations and Caveats). This activity was completed in FY 2023/24 and recommended that the proof-of-concept surveillance system be piloted in real-time with NHS board(s) to evaluate the attributes of the system and further refine suitable triggers for early investigation in high-risk settings.

Aims and Objectives of Pilot

The aim of the pilot was to further scope the feasibility of an environmental pathogen surveillance system for use in NHS Scotland high-risk units.

Objectives of pilot:

- To identify suitable triggers for further investigation, for high-risk units and patient cohorts.
- To assess the environmental pathogens surveillance system against the key attributes of a surveillance system.

- To further refine the environmental pathogens surveillance system as required.

Development of Methodology

Proposed surveillance system

Data processing

R scripts were developed for all data extraction and processing (version 4.0.2; R Core Team 2020). Data were extracted from ECOSS using an Open Database Connectivity (ODBC) connection to the ECOSS live database. All available final positive microbiology results (Status 50) were extracted from ECOSS, from December 2016 to date of report generation. Unidentified organisms, viruses, and those from veterinary and agricultural laboratories, were excluded. Organisms were categorised as either ‘environmental’ (those considered to be exogenous and not typically part of normal human flora, and may be acquired from an environmental reservoir), ‘environmental enteric’ (those considered to be endogenous and part of the normal human gut flora but may also be acquired from an environmental reservoir) or ‘non-environmental’, according to a reference list compiled by ARHAI Scotland. The reference list classifies and groups organisms in a number of ways, including by genus, type, Gram stain category, environmental source/habitat, and with tags for key antimicrobial resistance markers. Any novel organisms in an extract were flagged during data processing and investigated and added to the reference list. The reference list was maintained by ARHAI and validated by consultant microbiologist for the duration of the pilot.

All environmental and environmental enteric bacteria were included in the surveillance and predominantly focused on bacteria associated with water sources. A summary table of the bacteria included in these categories is provide in **Appendix 2.** Organism categories Fungi were excluded from surveillance due to issues with the reliability of reporting of these results into ECOSS.

Results may be submitted to ECOSS from both NHS board diagnostic laboratories and national reference laboratories. Therefore, where possible, results were matched to allow details of the specimen type and location from the diagnostic laboratory result to be combined with details

of the organism species and antimicrobial resistance from the national reference laboratory result.

ECOSS specimen type groupings were used to identify clinical microbiology results for inclusion in analysis, and include: Normally Sterile Site; Lower Respiratory; Upper Respiratory; Wound; Urine; Faeces; Alimentary (excl. Faeces); Genital; Superficial; Unspecified non-viral (re-categorised as Other/Not Known). Blood cultures were distinguished from the other normally sterile sites to allow identification of bacteraemia episodes. Sputum and cough swab results were distinguished from the other lower respiratory tract specimens such as bronchoalveolar lavage and endotracheal aspirates for analysis since sputum and cough swabs will be more likely to include contaminants. The Other/Not known category were results where no specimen site was stated, or the specimen site was unclear.

Results were deduplicated at the 'patient', 'patient-species', and 'patient-species-specimen type' level, according to the episode definitions below.

- ***Patient level episodes:*** a patient with any environmental or environmental enteric bacteria isolated from any specimen type, who has not had any environmental or environmental enteric bacteria isolated from any specimen type within the previous 30 days.
    - Additional patient level episode definitions, including only environmental or environmental enteric bacteria, or only specific specimen types were also used, to allow for maximum flexibility in the data visualisation dashboards.

- ***'Patient-species' level episodes:***
    - Episode of bacteraemia: a patient with any specified bacteria species isolated from a blood culture, who has not had the same bacterial species isolated from a blood culture within the previous 14 days.
    - Episode of infection or colonisation: a patient with any specified bacteria species isolated from any specimen type, who has not had the same bacterial species isolated from any specimen type within the previous 30 days.

- ***'Patient-species-specimen type' level episodes:*** a patient with any specified bacteria species isolated from a specified specimen type group, who has not had the same

bacterial species isolated from the same specimen type group within the set specimen group deduplication period:

- Alimentary (excl. Faeces): 30 days
- Blood: 14 days
- Faeces: 30 days
- Genital: 30 days
- Lower Respiratory (excl. Sputum and Cough Swab): 30 days
- Normally Sterile Site (excl. Blood): 14 days
- Other/Not Known: 30 days
- Other Respiratory: 30 days
- Sputum and Cough Swab: 30 days
- Superficial: 30 days
- Upper Respiratory: 30 days
- Urine: 30 days
- Wound: 30 days

Note: when using ‘patient-species’ level episodes or ‘patient-species-specimen type’ level episodes, a patient may have results for different bacterial species or isolated from different specimen types during the same time period, therefore an individual patient may contribute more than one episode.

The hospital and unit of each episode was determined by the location of the patient at the time of specimen collection for the first result of the episode. The location code in ECOSS, as provided by the laboratory submitting the result to ECOSS, was used to identify the specific wards/units involved in the pilot. Any episodes where the first positive result was not recorded as taken in pilot unit were excluded from analysis since the episode started before the patient was exposed to that environment.

Triggers Reports

Triggers reports were developed in R markdown with the aim of providing early triggers for local investigation of a potential issue in the built environment. The candidate triggers were adapted from those proposed by Anthony *et al* (2013).[2] Environmental incidents can be complex given the environmental source may contain multiple different organisms.[3,4,5,6,7] For

example, environmental organisms can form biofilms in hospital water systems, which support the existence of a diverse range of environmental organisms.[8] This can lead to polymicrobial infections in patients and polymicrobial outbreaks.[3,9] Triggers to identify multiple episodes of different organism species were therefore included, rather than only identifying multiple episodes of the same organism species. Additionally, the majority of triggers include episodes of both infection and colonisation, as opposed to focusing on only sterile site isolates, in order to provide more sensitivity in detection to allow earlier opportunity for intervention. Finally, to align with Appendix 13 of the NIPCM, a trigger to identify any of the listed environmental alert bacteria was included.[1]

Note: At the time of the pilot, Appendix 13 listed *Pseudomonas aeruginosa*, *Acinetobacter* species, *Stenotrophomonas maltophilia* or *Serratia marcescens*, as minimum alert organisms, and these were incorporated into an Appendix 13 specific trigger. However, in September 2024, this list was updated to also include *Chryseomonas indologenes*, *Cupriavidus pauculus*, all *Serratia* spp., and *Sphingomonas spp.,* and to link to NIPCM Chapter 4, which was launched in July 2024.

Candidate triggers are listed below.

A. Environmental Bacteria:

1. A single episode of bacteraemia with an environmental bacterial species.
2. A single episode of infection or colonisation with *Pseudomonas aeruginosa*, *Acinetobacter* species, *Stenotrophomonas maltophilia* or *Serratia marcescens* (environmental alert bacteria as per Appendix 13 of the NIPCM before September 2024 update).[1]
3. Two or more episodes of infection or colonisation in a two-week period with the same environmental bacteria.
4. Three or more episodes of infection or colonisation in a two-week period with any environmental bacteria.

B. Environmental Enteric Bacteria:

5. A single episode of infection or colonisation with an extended-spectrum beta-lactamase (ESBL) producer, carbapenemase-producing Enterobacterales (CPE) or vancomycin-resistant Enterococcus (VRE).
6. Two or more episodes of bacteraemia in a two-week period with any environmental enteric bacteria excluding *Escherichia coli*.

C. Environmental and Environmental Enteric Bacteria:

7. Three or more episodes of infection or colonisation in a two-week period with any environmental or environmental enteric bacteria excluding *Escherichia coli*, unspeciated Coliform species, vancomycin-sensitive *Enterococcus faecalis* and vancomycin-sensitive *Enterococcus* species.

Results are deduplicated at the 'patient-species' level according to the episode definitions for an episode of bacteraemia and an episode of infection or colonisation described in the definitions above. It is important to note that an individual patient may have results for different bacterial species during the same time-period, and therefore may contribute more than one episode. Consequently, a trigger may be met due to multiple episodes from the same patient. An anonymised patient ID is included in trigger data so that the number of unique patients contributing to a trigger can be identified. It should also be noted that the same patient episode may contribute to more than one trigger.

Triggers reports included all triggers identified from the unit in the past year, with any triggers identified in the past month highlighted.

Data Visualisation Dashboards

Data visualisation dashboards for each pilot unit were developed in Tableau (version 2023.1) to enable further exploration of the available clinical microbiology data from ECOSS at the 'patient', 'patient-species' and 'patient-species-specimen type' level. Dashboards included epidemic curves and T-charts, displaying data from January 2020. Data filters could be applied to select subsets of the data, for example particular species or specimen types. Epidemic curves plot the number of episodes per month and allow the identification and tracking of outbreaks over time. T-charts are a type of statistical process control (SPC) chart most appropriate for rare events. T-charts plot each episode along the x-axis and the time between

episodes along the y-axis, meaning changes in the frequency of episodes can be visualised. T-charts and epidemic curves do not adjust for changes in underlying patient population or activity on the unit but provide a visual measure of the frequency and distribution of events occurring over time. These dashboards were demonstrated to the pilot sites alongside the triggers reports to further support interpretation of the underlying data in the triggers.

The methodology needs to be considered along with the caveats and limitations outlined in **Appendix 1.** Data Limitations and Caveats.

Recruitment to pilot

ARHAI Scotland aimed to recruit three pilot wards/units treating high-risk patient cohorts. A call for volunteers was communicated through the Data & Intelligence Oversight & Advisory Group. Three NHS boards were offered the opportunity to participate in the pilot. Two of the NHS boards (Board A and Board B) had asked for ARHAI Scotland support with potential environmental linked incidents and the pilot was agreed as provision of epidemiological support.

The three pilot sites from these two NHS boards consisted of two neonatal units (NNU) and one adult intensive care unit (ICU), as shown in **Table** 1**Table 1**.

Table *1:* Participating units and pilot periods

NHS Board	Unit type	Pilot period
Board A	Neonatal Unit	February to June 2024
Board B	Adult Intensive Care Unit	February to August 2024
Board B	Neonatal Unit	April to August 2024
Board C	Neonatal Unit	NA – system demonstration received but declined to take part in pilot

A third NHS board (Board C) received a demonstration of the system but declined to take part in the pilot as they did not feel that the methods proposed would enhance their existing surveillance systems and noted reservations about the methods being piloted. ARHAI provided the board with a written response highlighting that the purpose of the pilot was to take their feedback in a structured way to support refinement of the methods. As ARHAI were not able

to further explore their feedback in the pilot, the information provided when Board C declined to participate has not been included in this pilot report.

Pilot process

Throughout the pilot, ARHAI Scotland met monthly with key stakeholders from the infection prevention and control teams (IPCTs) for each pilot unit from Board A and Board B to review and discuss outputs from the surveillance system. Monthly meetings were agreed with key stakeholders to be the most appropriate frequency to balance timely sharing of data against resource requirements.

During meetings, ARHAI Scotland shared surveillance system data on the pilot using the triggers reports and dashboards, including interactive epidemic curves, timelines and T-charts. Monthly triggers reports, developed and generated by ARHAI Scotland, were emailed to the agreed key stakeholders, in the form of HTML files so that they could review these further and consider any triggers identified. Given the level of complexity in the dashboards, these were only shared during meetings with ARHAI Scotland, to minimise the risk of misinterpretation of the data included. Feedback on the surveillance system received during meetings was used to further develop and refine the data processing, triggers reports and dashboards.

Participating sites were asked to continue to report as per Chapter 3 of the NIPCM.

Feedback and evaluation

Following the pilot, ARHAI Scotland sent a feedback questionnaire (**Appendix 3**Appendix 3. ARHAI Scotland Environmental Pathogens Surveillance Survey 2024) to the key stakeholders from the IPCTs who had been involved in the pilot for each pilot unit. The questionnaire was intended to assess the usefulness of the triggers reports and the appropriateness of the candidate triggers included. ARHAI Scotland further evaluated the surveillance system against the priority attributes of a surveillance system.

A comparison was undertaken between the triggers reports and incidents including potential environmental bacteria submitted to the Outbreak Reporting Tool (ORT) from the pilot units between January and August 2024. January to August 2024 was chosen to cover the full pilot

periods of both Board A and Board B, plus one month prior, to reflect the focus in the triggers reports on data from the past month.

Assessment and Evaluation

Summary of questionnaire responses

A total of three responses were received from Board A and Board B, with at least one response from each. Responses provided additional information on usefulness, efficiency and acceptability of the triggers in identifying potential environmental incidents for further investigation.

Surveillance system attributes

This section summarises the evaluation of the proposed surveillance system against the priority attributes of a surveillance system.

Usefulness

The triggers reports were broadly accepted by representatives from Boards A and B as useful for detecting trends and areas of concern for action, with one respondent highlighting the appeal of the visual nature of the trigger reports in combination with the dashboard. In contrast, one respondent indicated that although reports were interesting from an academic perspective, they were not providing any new information that the current incident management team (IMT) monitoring environmental incidents in the high risk-unit were not already aware of. This likely reflects the already heightened awareness due to an ongoing incident.

Where respondents were asked about the relevance of each individual trigger when applied to either an ICU or NNU, all triggers were deemed appropriate for both scenarios. The trigger concerning a single episode of bacteraemia with an environmental bacterial species merited further comment, with one respondent indicating that although notification of these incidents was of benefit for monitoring, a rating system to identify the more serious environmental bacteria species could help separate the triggers into more and less urgent.

It was additionally noted that although the trigger concerning a single episode of infection or colonisation with *Pseudomonas aeruginosa*, *Acinetobacter* species, *Stenotrophomonas*

maltophilia or *Serratia marcescens* was relevant for both high-risk settings, it may not always be easy to determine whether triggers for *Pseudomonas aeruginosa* in adults were arising due to infections, or colonisations. Due to the difficulty in defining colonisations in adults, a filter was added to remove all *Pseudomonas aeruginosa* specimens from the dashboard so these could be excluded to aid in interpretation.

Efficiency

The proposed environmental pathogens surveillance system employs passive surveillance using existing clinical specimens captured in ECOSS, compared to more resource-intense active data collection. Positive clinical microbiology results are obtained from ECOSS and a preprepared script is run to output triggers reports and dashboard. The process is currently adapted to the unit level and suited for use in the limited number of units participating in the pilot. As location data in ECOSS is not consistently recorded, detailed mapping of unit level data in ECOSS was required. When asked whether any existing local infection prevention and control (IPC) surveillance systems available in their NHS board could be used to identify the triggers included in the report, all respondents from Boards A and B indicated that it would be possible. However, two respondents indicated that this would require additional time and resource for implementation and continuous monitoring. As the triggers reports need to be manually updated and checked by ARHAI, this process would not be efficient if scaled up to include more units and is not a solution for providing all high-risk units in Scotland with timely triggers reports.

Sensitivity

Between January and August 2024, a total of 60 triggers were identified across the three pilot units, including a total of 77 unique patients. During this time period, 14 ORT incidents with potential environmental bacteria were submitted across the pilot units, with a total of 32 patient cases.

Although a one-to-one match with triggers and outbreak reports in the ORT was not expected due to differences in reporting criteria, the majority of ORT incidents could be matched to at least one trigger. There were 13 incidents that could be associated with triggers, with only one ORT incident involving a single patient infection with an enteric environmental organism in a NNU that did not meet the criteria for any of the triggers but met ORT (NIPCM Chapter 3) reporting criteria. As patients included in triggers reports are anonymised and no patient

identifiable information is submitted with the ORT, it was not possible to definitively match specific episodes to incidents reported within the ORT.

There were several triggers which did not result in an ORT submission. The ORT is designed for the reporting of healthcare infection incidents and outbreaks in line with Chapter 3 of the NIPCM, and the minimum list of alert organisms in Appendix 13. There may be reasons why triggers identified in this pilot were not reported via the ORT, including that they did not meet the requirements for reporting as described in Chapter 3 of the NIPCM. For example, where investigation by local IPCTs has determined that an incident is not healthcare-associated to the unit/hospital e.g. identified within 48 hours of admission or mother-to-neonate transmission. In addition, the organism list included in Appendix 13 and Chapter 4 is not exhaustive, and many potentially environmental bacteria, such as *Paenibacillus* spp. and *Roseomonas* spp., are not named though were included in the environmental organism list in this pilot (**Appendix 2**). Incidents involving organisms included in Appendix 13 are more likely to be reported than those that are not. The retrospective matching of the 60 triggers to ORT incidents was complex due to patients featuring across multiple triggers (not mutually exclusive); organisms featuring across multiple triggers (not mutually exclusive); and multiple/mixed organism ORT incidents that were open for extended periods of time and where the dates the organisms were isolated were not available to match (this information is not required or consistently provided in the ORT submission).

Overall, the proposed environmental pathogens surveillance system was sensitive in detecting potential environmental organism related incidents as reported via the ORT. However, further work is required to understand the links between the triggers and Chapter 3 reporting.

Timeliness

For data included in the pilot wards/units there was a median of five days lag between specimen collection and data being received in ECOSS. This lag in availability of confirmed results impacts on the timeliness of identification of and response to triggers.

On discussion with the pilot wards/units, monthly sharing of data was considered the most appropriate frequency for the pilot. This balanced the resource demands of producing and reviewing the pilot data and meeting ARHAI to discuss the results.

For triggers to be useful to identify potential areas for investigation, they must be timely. A lag of 4-5 weeks does not support timely investigation though this could be reduced if triggers could be reproduced using NHS boards' local surveillance systems rather than the use of national datasets.

Representativeness

All episodes of environmental and environmental enteric bacteria reported to ECOSS from the pilot wards/units were included in the surveillance system, and so it can be considered to be representative for these wards/units. However, as detailed in **Appendix 1.** Data Limitations and Caveats, there are a number of data considerations that limit representativeness. Reference laboratory specimens do not always include details of the original ward/unit location of the specimen; if these could not be matched with diagnostic laboratory specimens which detailed the location, they were excluded. Furthermore, due to limitations of ECOSS data, the pilot did not include fungi. Specimens taken from patients while they were not in the unit will not be included. As this is a laboratory-based surveillance system, no additional clinical information was collected including length of time of the patient in the unit prior to the sample being taken. It is also not possible to distinguish infection from colonisation or contamination, nor to distinguish community-associated from healthcare-associated episodes. The surveillance data is therefore not comparable with nosocomial data from other surveillance systems.

The environmental pathogens surveillance system is designed to be highly localised and for high-risk settings/patient cohorts, and is not intended to be representative of any wider patient population or higher level surveillance (i.e. board level). Triggers data cannot be used for benchmarking or comparisons with other high-risk units. No denominator data has been included in this surveillance, so no rates can be calculated, which further restricts comparisons. Variation in unit size, screening and testing practices, patient population, and unit environment (for example layout and staffing), all affect the data and comparability. In particular, triggers would likely need to be adapted if different patient cohorts were being investigated, even within the scope of high-risk units. Additionally, the boards included in the pilot may have altered their practice and vigilance during the pilot (e.g. by increasing swabbing in pilot high-risk units) due to perceived risk of environmental hazards.

Data quality

Environmental pathogen surveillance uses unvalidated ECOSS data as submitted by Scottish NHS laboratories and processed by the ECOSS Team. Between 2019 and 2020, five NHS boards went through the ECOSS Development Rollout Improvement Programme (EDRIP), aimed at improving the quality and completeness of data held within ECOSS. Activities related to this, along with the removal of filters in ECOSS between 2019 and 2022, have resulted in an increase in the number of reports recorded for organisms and specimen sites that have not historically been subject to national reporting (e.g. wound, sputum and cough swabs). This must be taken into consideration when interpreting results over time. Blood culture data in ECOSS are considered to be reliable, however reporting from other specimen types may be less complete, particularly from NHS boards that have not been through EDRIP. Some NHS boards are affected by issues with tagging of key antimicrobial resistance markers in ECOSS, which may affect the completeness of data captured by triggers 5 and 7 for these areas. Additionally, confirmation of carbapenemase-producers (included in trigger 5) is carried out by the reference laboratory, and therefore may be excluded from reports where location data cannot be obtained from a matched diagnostic laboratory specimen.

Positive results in ECOSS indicate the presence of the bacteria in the specimen, but it is not possible to differentiate colonisation or contamination from infection when using these data.

Differences in screening and testing practices over time and between wards/units will impact on the number of cases and organism species identified. Improvements in methods used to detect and identify organisms may contribute to apparent increases of particular species over time requiring specialist microbiological testing expertise to interpret. Therefore, data may not be comparable over longer time periods or between wards/units.

Reference laboratory reports do not always include unit location data, or specimen type details. Where possible, these reports were matched with original diagnostic laboratory reports to obtain this data. Where this was not possible, unmatched reports may result in unspeciated results being included in unit data, or reports being excluded from analyses focussing on specific specimen types.

Whilst ECOSS data can be used to effectively highlight triggers for further investigation, local interpretation and investigation is required to ascertain whether these triggers are incidents/outbreaks of concern and for artefactual changes to be ruled out e.g. changes to speciation or testing.

Further details regarding these data quality limitations can be found in **Appendix 1.** Data Limitations and Caveats

Acceptability

Key stakeholders from the IPCTs from both NHS boards involved in the pilot were willing to participate in the surveillance of environmental pathogens, with regards to reviewing the triggers reports shared with them and considering the triggers highlighted. Although overall positive feedback on the usefulness and sensitivity of the triggers reports was received from both Board A and Board B, two respondents raised concerns around the local surveillance resource required if considering identifying triggers using existing local IPC surveillance systems.

Limitations of Pilot

- The two NHS boards that took part in the pilot were approached to be part of the pilot after asking ARHAI Scotland for support with potential environmental linked incidents. As such, these NHS boards may not be representative of all NHS boards in their feedback to the pilot. Due to perceived risk of environmental hazards, these boards may have altered their practices resulting in a higher number of samples in ECOSS i.e. increased swabbing in high-risk units and changes to screening.
- An environmental pathogen isolated from a patient who is being treated within a unit does not necessarily indicate that this unit is the source of the organism and should only be used as a prompt for further investigation.
- The trigger definitions used have been adapted from those proposed by Anthony *et al* (2013) .[2] These triggers were developed for neonatal units, and so further adaptations may be required to ensure they are relevant to other high-risk settings.

- Changes in screening/testing practices and ward activity may impact on the types of organisms seen and number of episodes. This must be considered when comparing triggers data over time.
- This was a pilot at the local level and the triggers reports and dashboard are not suitable for larger scale surveillance including national surveillance. The current triggers are specific to the unit level, and T-charts used in the dashboard are designed for rare events.

Conclusion and Recommendations

The pilot included three units across two NHS boards, and seven candidate triggers for further investigation were developed. Feedback from boards was positive and suggested triggers were useful for detecting trends and areas of concern for action. The ORT incidents reported during the pilot were successfully identified in the triggers reports, with the exception of one incident. The links between the candidate triggers and Chapter 3 NIPCM reporting was more difficult to define in the pilot. Further work is required to describe the links and would support the review of Chapter 3 of the NIPCM. The triggers were designed for NNU and ITU settings and while sensitivity was suitable for the NNU it was suggested some of the triggers may be too sensitive for adult ITUs. Further work to refine the triggers is necessary including consideration for other types of high-risk units.

This phase of the pilot identified that there are some limitations with the availability of data in ECOSS and manual mapping is required to identify unit locations for reference laboratory results. Resource requirements of manual updates and checking required by ARHAI Scotland has indicated that this surveillance system could not be scaled up to include all high-risk units in Scotland. Furthermore, ARHAI provision of monthly trigger reports using ECOSS data is not timely enough to prompt local investigations. Theoretically, the triggers could be incorporated into existing IPC surveillance systems, however, concerns were raised around the local surveillance resource required to do this. The development of a future national IPC surveillance solution may support this in future if alert organism lists can be managed nationally.

The system developed has successfully been used to support boards with ongoing incidents with potential environmental source. This does limit the interpretation of the pilot as these areas already had heightened vigilance to these types of organisms. Future work to include units without ongoing incidents in the pilot is required to determine the feasibility of the system as a routine environmental organism surveillance system.

Finally, this surveillance system was designed to be highly localised, and the triggers reports and dashboards developed are not suitable as a national surveillance system or for benchmarking. National surveillance of priority environmental pathogens could be considered with stakeholder input as part of the national surveillance review. However, national surveillance would not be available to unit level.

In conclusion, further work is necessary to refine the triggers ensuring there is a balance between the resource implications of multiple triggers and associated investigations alongside identifying potential risk to patients in high-risk units.

ARHAI Scotland recommend the following:

- Continue with the pilot in 2025/26 to further refine the triggers ensuring setting-specific consideration.
- Recruit sites without ongoing incidents that are potentially linked to the environment to ensure triggers are developed in the context of ongoing surveillance.
- Consider the expansion of the pilot to include a wider range of high-risk settings (following completion of the development of ICU and NNU triggers).
- Further describe how the triggers identified are linked to Chapter 3 reporting, informing both the refinement of triggers and the development of Chapter 3.
- Work with NHS boards to explore how triggers could be reproduced using local surveillance systems such as ICNet.
- Ensure that flexible alert organism surveillance and Chapter 3 reporting requirements are included in the outline business case for the national IPC system.
- Consider national surveillance of environmental Gram-negative bacteraemia as part of the national surveillance review inclusive of board stakeholder engagement.
- Continue to make the triggers reports and dashboards available for outbreak support if required.

Appendix 1. Data Limitations and Caveats

- Data are derived from the ECOSS database and as such are based on the data submitted by Scottish NHS laboratories. Not all results held within ECOSS are validated. Additionally, we are aware that data submissions are incomplete for some NHS boards and therefore cannot be certain that all relevant isolates have been captured in ECOSS.
- Improvements in methods used to detect and identify bacteria may contribute to apparent increases in incidence or prevalence of particular species over time. Laboratory diagnostic methods (e.g. MALDI-TOF, VITEK®) and subsequent reporting to ECOSS have changed over the years which may affect the numbers and types of organisms reported.
- Changes in screening practices in wards/units over time may affect the numbers and types of organisms reported into ECOSS. This is particularly relevant for results reported from specimen types commonly used for screening, such as rectal swabs.
- Activities related to the ECOSS Development Rollout Improvement Programme (EDRIP) and the removal of filters within ECOSS, which took place at different times between 2019 and 2022 for different NHS boards, have resulted in an increase in the number of reports recorded for organisms and specimen sites that have not historically been subject to national reporting (e.g. wound, sputum and cough swabs). This must be taken into consideration when interpreting results over time. Additionally, when interpreting results for NHS boards that have not been through EDRIP (AA, BR, FF, GJ, GGC, HG, LO and WI), it should be noted that reporting for specimen sites other than bloods may be incomplete. Reporting of blood specimens into ECOSS has not been significantly impacted by EDRIP or filter changes and is considered to be reliably reported for environmental bacteria for all NHS boards across time.
- Environmental fungi are not captured in this surveillance system as there are limitations around the reliability of fungal isolate reporting within ECOSS, with fewer results than expected received into ECOSS due to electronic data transfer issues between UK mycology reference laboratories and ECOSS.
- Positive results in ECOSS indicate the presence of bacteria in the specimen only. It is not possible to differentiate colonisation or contamination from infection when using

these data. Certain specimen types, for example sputum and faeces samples, are more likely to represent colonisation than other specimen types such as blood specimens.

- Ward location, where the patient was at time of specimen collection, has been determined from the requesting location or unit location raw fields in ECOSS. There may be inconsistencies in how wards are named, or changes in naming over time. Local knowledge of ward names may be needed to accurately identify ward locations.
- It is not possible to accurately identify the specialty of ward locations from the ECOSS data. ARHAI Scotland would need to work with NHS boards to reliably identify high-risk locations such as intensive care units and haemato-oncology wards.
- Reports from reference laboratories do not always include details of the original ward/unit location that the specimen was taken in, and instead may use the location details of the diagnostic laboratory submitting the specimen to the reference laboratory. Therefore reference laboratory reports cannot always be included in ward/unit data, or may be included in data for the incorrect ward/unit. Where possible, reference laboratory reports have been matched with the original diagnostic laboratory report to retain location information, however this is not possible for all reference laboratory reports. Consequently, ward/unit data may include unspeciated results, even where a subsequent reference laboratory result has identified the species of organism. This is particularly relevant to mycobacterium species.
- Results from reference laboratories do not always include specimen type details. Where possible, reference laboratory results have been matched with the original diagnostic laboratory result retain specimen type information, however this is not possible for all reference laboratory reports. Therefore, unmatched reference laboratory reports may be excluded from analyses focussing on specific specimen types such as blood cultures.
- ‘Patient – species’ level deduplication may count the same patient as an episode more than once if they have isolated multiple different species within the same time-period. Consequently, a trigger may be met due to multiple episodes from the same patient. Likewise, ‘patient – species – specimen type’ level episodes may count the same patient more than once if they have isolated multiple different species or have isolates from multiple different specimen type groups within the same time period. To estimate the

number of individual patients infected or colonised with environmental bacteria, the patient level episode data in the dashboards should be used.

Appendix 2. Organism categories

High-level classification of environmental and environmental enteric bacteria used for pilot.

Note that this list is not exhaustive. Unless species are listed individually, all species within the genus are included in the classification.

Environmental bacteria	Environmental enteric bacteria
Environmental bacteria are those considered to be exogenous and not typically part of normal human flora and may be acquired from an environmental reservoir. This includes, but is not limited to, organisms such as *Stenotrophomonas maltophilia*, *Serratia marsescens* and *Acinetobacter bauminii*.	**Environmental enteric bacteria** are those considered to be endogenous and part of the normal human gut flora, however, they may also be acquired from an environmental reservoir. This includes, but is not limited to, organisms such as *Klebsiella pneumoniae*, *Enterobacter cloacae* and *Enterococcus faecium*.
Gram-negative *Achromobacter* species; *Acidovorax* species; *Acinetobacter* species; *Aeromonas* species; *Alcaligenes* species; *Anaeroarcus* species; *Aureimonas* species; *Brevundimonas* species; *Burkholderia* species; *Buttiauxella* species; *Cedecea* species; *Chromobacterium* species; *Chryseobacterium* species; *Chryseomonas* species; *Comamonas* species; *Cronobacter* species; *Cupriavidus* species; *Delftia* species; *Edwardsiella* species; *Elizabethkingia* species; *Erwinia* species; *Ewingella* species; *Flavobacterium* species; *Herbaspirillum* species; *Kalamiella* species; *Kosakonia* species; *Legionella* species; *Luteibacter* species; *Luteimonas* species; *Methylobacterium* species; *Myroides* species; *Ochrobactrum* species; *Olivibacter* species; *Pandoraea* species; *Photobacterium* species; *Providencia* species; *Pseudocitrobacter* species; *Pseudomonas* species;	***Gram-negative*** *Citrobacter* species; *Cloacibacillus* species; *Coliform* species; *Enterobacter* species; *Enterobacteriaceae* species; *Escherichia* species; *Hafnia* species; *Klebsiella* species; *Kluyvera* species; *Leclercia* species; *Lelliottia* species; *Morganella* species; *Pantoea* species; *Plesiomonas* species; *Proteus* species; *Shigella* species. ***Gram-positive*** *Enterococcus* species; *Eubacterium* species; *Levilactobacillus* species.

Pseudoxanthomonas species; *Psychrobacter* species; *Rahnella* species; *Ralstonia* species; *Raoultella* species; *Rhizobium* species; *Roseomonas* species; *Serratia* species; *Shewanella* species; *Sphingobacterium* species; *Sphingomonas* species; *Stenotrophomonas* species; *Variovorax* species; *Vibrio* species. ***Gram-positive*** *Alicyclobacillus* species; *Aneurinibacillus* species; *Arthrobacter* species; *Brachybacterium* species; *Brevibacillus* species; *Brevibacterium* species; *Carnobacterium* species; *Cellulosimicrobium* species; *Clavibacter* species; *Deinococcus* species; *Dietzia* species; *Erysipelothrix* species; *Exiguobacterium* species; *Gordonia* species; *Janibacter* species; *Leifsonia* species; *Lysinibacillus* species; *Microbacterium* species; *Niallia* species; *Nocardia* species; *Paenibacillus* species; *Patulibacter* species; *Priestia megaterium*; *Pseudoclavibacter* species; *Pseudoglutamicibacter* species; *Rhodococcus* species; *Solibacillus* species; *Sporosarcina* species; *Streptomyces* species; *Terrisporobacter* species; *Tsukamurella* species; *Vagococcus* species; *Virgibacillus* species. ***Gram-variable*** Non-Tuberculosis *Mycobacterium* species (NTM).	

Appendix 3. ARHAI Scotland Environmental Pathogens Surveillance Survey 2024

ARHAI Scotland have been tasked with scoping the feasibility of a surveillance system for environmental pathogens, to assist NHS boards with identification and monitoring of incidents/outbreaks which may have an environmental source. As part of this ask, ARHAI Scotland have undertaken a proof-of-concept pilot to test potential triggers using patients' clinical/screening results from laboratory data at unit level. Environmental pathogen trigger reports have been developed to identify and monitor key environmental pathogens in selected high-risk units in NHS Scotland hospitals.

As a pilot site, we would be grateful if you could please take the time to complete this short questionnaire to provide feedback on the usefulness of the environmental pathogen trigger reports and how they were used by your NHS board during this pilot.

NHS board: ……

Pilot unit: ……

Job role: ……..

1. **How useful have you found the triggers reports?**

2. **How have you used the triggers reports and who did you share them with?**

3. **In your opinion, are the environmental pathogen trigger criteria (as outlined in the table below) appropriate for the patient population in this high-risk unit?** *Please provide detail in the table below:*

Trigger criteria for further investigation	**Appropriate for NNU**	**Appropriate for ITU**	**Comments**
A single episode of bacteraemia with an environmental bacterial species.	Yes/No	Yes/No	
A single episode of infection or colonisation with *Pseudomonas aeruginosa*, *Acinetobacter* species, *Stenotrophomonas maltophilia* or *Serratia*	Yes/No	Yes/No	

marcescens (environmental alert bacteria as per Appendix 13 of the National Infection Prevention and Control Manual).			
Two or more episodes of infection or colonisation in a two-week period with the same environmental bacteria.	Yes/No	Yes/No	
Three or more episodes of infection or colonisation in a two-week period with any environmental bacteria.	Yes/No	Yes/No	
A single episode of infection or colonisation with an ESBL producer, CPE or VRE.	Yes/No	Yes/No	
Two or more episodes of bacteraemia in a two-week period with any environmental enteric bacteria excluding *Escherichia coli*.	Yes/No	Yes/No	
Three or more episodes of infection or colonisation in a two-week period with any environmental or environmental enteric bacteria excluding *Escherichia coli*, unspeciated *Coliform* species, vancomycin-sensitive *Enterococcus faecalis* and vancomycin-sensitive *Enterococcus* species.	Yes/No	Yes/No	

4. **Are there any additional environmental pathogen trigger criteria that you would consider appropriate to initiate an investigation?**

   Please provide detail in box below:

5. **Could any existing local IPC surveillance systems you have in your NHS board (e.g. ICNet) be used to identify the triggers included in the report?** *Please provide detail in box below:*

6. **Is there anything that could further improve the triggers reports?**

   Please provide detail in box below:

SCOTTISH HOSPITALS INQUIRY

Review of the Expert Report for the Scottish Hospitals Inquiry on the evidence of risk of infection from the water and ventilation systems at the Queen

Elizabeth University Hospital and Royal Hospital for Children,

Glasgow written by Professor PM Hawkey, Dr SG Agrawal and Dr LN Drumright ('HAD' Report)

Expert Report prepared for the Scottish Hospitals Inquiry

Date: 16 May 2025

Dr Sara Mumford, MB. BS., MSc., FRCPath., SFFMLM.

This document may contain Protected Material within the terms of Restriction Order 1 made by the Chair of the Scottish Hospitals Inquiry and dated 26 August 2021. Anyone in receipt of this document should familiarise themselves with the terms of that Restriction Order as regards the use that may be made of this material. The terms of that Restriction Order are published on the Inquiry website.

1. Summary

1.1. This report has been prepared at the request of the Scottish Hospitals Inquiry and reviews the report of Professor Hawkey and colleagues (herein referred to as the HAD Report), on its methodology and conclusions from a Microbiology and IPC perspective.

1.2. The Inquiry has asked a series of questions in order to assist in this review and has asked that two further documents, *Initial bullet point thoughts on executive summary for report.docx* and *Glasgow Hospitals Case Note Review D3 - notes and commentary on environmental bacteria.docx* are also considered.

1.3. This report does not address the aspergillus infections seen at QEUH and RHC. This subject is dealt with separately through a joint report with Sid Mookerjee.

2. Executive summary and Introduction

2.1. The issues in the water system at QEUH/RHC which would cause the system to become microbiologically unsafe have been well documented[1] [2]. From the time of occupation in 2015, *Legionella sp* counts in the water were out of specification and microbial contamination was able to spread through the system and form biofilms due to poor temperature control. The first recognised infection with an environmental gram-negative, *Cupriavidus pauculus* BSI in a paediatric haemato-oncology patient, which had a confirmed link to the water system occurred in 2016. By 2018/19 it was known that there was extensive microbial contamination and biofilm formation in water tanks, expansion vessels, tap fillings, showerheads and drain components. The extensive biofilm meant that where remedial works were undertaken at the outlets (replacement of taps and pipework, silver hydrogen peroxide dosing to pipes and drains, etc), recontamination occurred within a month.

2.2. Biofilms are complex structures in which microorganisms (single or multiple species) are encased in extracellular polymeric substances. As they develop they become more difficult to remove and the bacteria within them are protected from the action of antimicrobials. Physical interactions, co-adhesion and metabolic cooperation amongst bacterial cells promote multispecies biofilms. As the biofilms mature they release the bacteria held within, into the surrounding environment, which can then spread through the water system and settle elsewhere creating new biofilm. On reaching a certain thickness, parts of a biofilm may break off and settle in other parts of the system.

[1] Bundle 21, Volume 1, Paper 5, page 180.
[2] Bundle 21, Volume 1, Paper 6, page 354.

2.3. The risk that this level of contamination presented to the Schiehallion cohort of patients is complex to quantify. In relative terms, the paediatric haemato-oncology patients are the most vulnerable patients in a hospital, by the severity of their disease, the profound nature of their immunosuppression, their length of stay in hospital and the frequent courses of antimicrobials which may destroy the natural defences of their microbiota. The additional avoidable risk associated with a contaminated water and drainage system which could contaminate the environment through aerosol and droplet/splash spread combined with insufficient ventilation with low air changes, lack of filtration and potential recirculation of contaminated air through the use of thermal wheels has contributed in great part to the high number of blood stream infections with environmental organisms seen in this cohort of patients. Therefore, I would assess the risk of infection prior to the extensive remedial work on 2A/2B in individual patients as a high probability of occurring combined with a potentially catastrophic outcome.

2.4. The HAD Report fails to consider any of the earlier reports in relation to the environmental infection risk or other available information and reports based on the Case Note Review only.

2.5. The outbreak definition proposed in the paper is at odds with established IPC practice in the UK. The primary approach of any potential outbreak investigation is to protect patients in a timely manner.

2.6. The conclusions drawn by the authors do not consider the environmental challenges, preferring to speculate based on experience elsewhere such as the assumption that only 20% of cases are related to the environment in any way.

2.7. The authors also take a view on carbapenem usage which is at odds with the data presented to them.

2.8. The statistical analysis will be reviewed in detail in a separate paper by Sid Mookerjee. However, I do not agree with the approach taken, particularly the comparison of heterogenous patient groups and to conclude that there is no increase in infection at QEUH and not considering the remedial work undertaken to avoid an increased environmental infection rate.

2.9. For the Schiehallion cohort the authors have failed to follow their own stated recommendation of comparing rates of infection with external peer groups to ensure that an accurate comparison is made.

2.10. Overall, the HAD Report does not take into account available data which would enable the authors to come to a more accurate conclusion on the infection risk at QEUH/RHC and its underlying causes.

3. Chapter 2

3.1. Section 2.1 of the HAD Report attempts to describe the manner, or family tree, in which bacteria are grouped. This is difficult to describe in a few paragraphs as entire textbooks have been devoted to the subject and it is unclear therefore why this section has been included.

3.2. One comment is included that suggests that *Escherichia coli 0157* is more likely to cause infection than other strains in 'normal people'. I presume that this is in reference to the low infectious dose (around 100 bacteria) of *E. coli 0157* required to cause infection which results in a higher virulence. *E. coli* 0157 is an unusual finding, which prompts public health and outbreak investigation due to the danger posed by its ability to produce a shiga-like toxin resulting in severe infection and sequelae, one of which (haemolytic uraemic syndrome) is a notifiable disease in both England and Scotland. In 2021 there were 365 cases, 0.65/100 000 population seen in England[3] and 137 cases in Scotland[4]. *E. coli* in general is very commonly seen causing infections such as urinary tract infection (most often in otherwise fit and well individuals) and blood stream infections. In England the incidence of *E. coli* blood stream infection was 68.5 cases per 100 000 population in 2022-2023[5] and in Scotland, 79.1 per 100 000 population in 2023[6] . I would disagree with the impression given here that it is seen more frequently than other strains which is misleading, and the correct context would have been helpful.

3.3. In section 2.2 the authors discuss what is meant by an outbreak. For all practical purposes when managing healthcare associated outbreaks, the definition of an outbreak is that which is found in the Scottish Infection Prevention and Control Manual section on healthcare associated incidents[7] and includes:

[3] Shiga toxin-producing *Escherichia coli* (STEC) data :2021 UKHSA - https://www.gov.uk/government/publications/escherichia-coli-e-coli-o157-annual-totals/shiga-toxin-producing-escherichia-coli-stec-data-2021.

[6] ARHAI Scotland 2023 report https://www.nss.nhs.scot/media/5564/arhai-annual-report-2023.pdf

[7] Bundle 27, Volume 4, Document 16, page 176 - National Infection Prevention and Control Manual: Chapter 3 - Healthcare Infection Incidents, Outbreaks and Data Exceedance (scot.nhs.uk) accessed 10.04.2025.

- *An exceptional infection episode* - A single case of any serious illness which has major implications for others (patients, staff and/or visitors), the organisation or wider public health.

- *A healthcare associated infection outbreak* - Two or more linked cases with the same infectious agent associated with the same healthcare setting over a specified time period; or a higher-than-expected number of cases of HAI in a given healthcare area over a specified time period.

- *A healthcare infection exposure incident* - Exposure of patients, staff, public to a possible infectious agent as a result of a healthcare system failure or a near miss e.g., ventilation, water or decontamination incidents.

- *A healthcare infection data exceedance* - A greater than expected rate of infection compared with the usual background rate for that healthcare location.
- *A healthcare infection near miss incident* **–** an incident which had the potential to expose patients to an infectious agent but did not e.g. decontamination failure
- *A healthcare infection incident should be suspected if there is* – a single case of an infection for which there have previously been no cases in the facility (e.g. infection with a multidrug-resistant organism (MDRO) with unusual resistance patterns or a post-procedure infection with an unusual organism

3.4. The English national IPC manual is not as mature as the Scottish version, being first published in 2022 and does not yet have a section on outbreaks and incidents, however the definitions above would be widely accepted by IPC professionals in the rest of the UK.

3.5. In order to identify a potential outbreak all that is needed is the identification of two infections by the same organism which are related in time and place. The authors of the HAD Report suggest that identifying the source of the organism, the route of transmission and the portal of entry into the patient are needed in order to define an outbreak. In practice this information will often be identified during the investigation, not prior to, but is sometimes difficult to identify and should not be a barrier to identifying an IPC incident. The portal of entry and exact transmission route may not be identified and the experience, training and expertise of the IPC professionals leading the

investigation will enable them to make educated assumptions on how transmission has occurred.

3.6. Chapter 3 of the NIPCM discusses the importance of making an early and effective response to an actual or potential healthcare incident, outbreak, or data exceedance. In practice, surveillance systems are used to aid detection of incidents and outbreaks. Risk based approaches are utilised for particularly vulnerable groups such as those we are immunosuppressed, cystic fibrosis patients and renal dialysis patients.

3.7. Tools for the initial assessment of incidents (HIIAT) are available within the manual and these were widely used during the incidents seen at QEUH/RHC since its opening in 2015[8] and reporting to Antimicrobial Resistance and Healthcare Associated Infection Scotland (ARHAI) is expected as part of this process.

3.8. The NIPCM describes a three-pronged investigation looking at epidemiology, microbiology and the potential exposure to the infectious agent (environmental investigation). Review of IPC practice is also recommended and, in my experience, would be a routine part of any incident investigation involving infection.

3.9. The epidemiological investigation includes establishing a case definition and a working hypothesis regarding source and transmission. This approach allows investigation and preventative measures to be put in place simultaneously without waiting for confirmation of a definitive match of infections with potential primary sources.

3.10. In many circumstances, the identification of the primary source of infection can also be difficult to identify. If environmental surface contamination with the organism in question is found, for example, the original source of that contamination may no longer be available for testing. It is very unusual for contemporaneous (to the time of transmission) environmental samples to be available and interventions such as cleaning may have happened before the outbreak is recognised. If the source is another patient who is colonised and not recognised (eg with MRSA) then that patient may have been discharged prior to the recognition of the outbreak.

3.11. Whilst having the ability to perform WGS on isolates from an outbreak will be helpful to link cases, it is not a technique that is widely available to all hospitals except as a retrospective test and is therefore an unrealistic expectation for many outbreak investigations. The HAD Report refers to sub-species typing by whatever method (including WGS) as strain level typing.

3.12. The author's proscriptive approach to outbreak identification is not compatible with widely recognised infection prevention and control practice which is to control and

[8] For example, Problem Assessment Group Minutes - Bundle 2, Document 17, page 44-45.

prevent without waiting for results of further tests, in order to maintain patient safety and prevent further harm.

3.13. The authors suggest that infection in neutropenic patients commonly arises as a result of translocation of the gut by commensal bacteria in the patient's intestines. This is well recognised by all clinicians who care for this group of patients. It is also well recognised that for organisms such as *Pseudomonas aeruginosa* the level of gut colonisation of hospitalised patients, particularly those who are neutropenic, is higher than for the general population rising from 3-17% in the general population to 20-60% of neutropenic patients [9]. This rise in colonisation/carriage suggests that organisms are acquired from the hospital environment for instance through ingestion, contact with water or other contamination of surfaces[10]. Also see para 4.2.

3.14. This increase in colonisation by contact with the hospital environment could potentially be extrapolated to other, less pathogenic, environmental organisms, however little research has been carried out on these rarer organisms and the body of evidence to support this theory or that there is evidence of any level of gut colonisation with the rarer environmental organisms in this patient population does not exist. Whilst the authors of the HAD Report argue that the gut is the source for BSI in neutropenic patients, the published evidence of gut colonisation by the rarer of the organisms which caused BSI at QEUH/RHC is weak and other sources must therefore be considered.

3.15. The single roomed environment at QEUH/RHC would make it unlikely that direct patient to patient spread occurred, assuming that staff were observing standard IPC precautions. The reduction of infections through the use of single rooms is by the reduction of person to person spread and also by limiting the spread of infection by reducing person-surface-person contacts[11]. Studies have also shown that combining single room accommodation with good ventilation can reduce infection risk and mortality[12] [13].

3.16. On reviewing the published literature, Ulrich et al[14] found that the design of the physical environment impacts healthcare associated infection rates by affecting the three main transmission routes: air, contact and water. They found that the literature supports various design measures for controlling and preventing infection including single patient rooms in order to enable separation or isolation of patients from the time of admission, allowing patients to be tested for infection and reduce airborne transmission.

3.17. A further advantage of single-bedded patient rooms is the ability to clean with newer methods of cleaning such as hydrogen peroxide vapour (HPV) or UV-C light decontamination. French et al[15] found that the conventional methods of cleaning such as disinfectant and steam did not effectively decontaminate surfaces with 66% of surface swabs remaining positive for MRSA post-cleaning, whereas following the use of HPV, only 1.2% of swabs remained positive. As noted in my previous report for the inquiry[16], HPV was not in routine use at QEUH/RHC and the potential contamination of surfaces by environmental organisms was not recognised adequately.

3.18. The authors do not appear to have taken into account the views of the clinical teams on the Schiehallion Unit who were concerned about the rapid and persistent rise in cases of blood stream infection (BSI) due to environmental organisms. These clinicians are highly experienced in the care of neutropenic patients and had also worked at Yorkhill previously, but the PAG and IMT minutes throughout 2017-2019 do not reflect that gut translocation was a concern or considered as an explanation for the majority of infections at the time.

3.19. Where gut translocation is recognised as the most likely cause of infection, a PAG may be held in order to discuss and confirm that this is the case (particularly if a more unusual organism is involved), but this would not proceed to IMT and a heightened level of concern.

3.20. In addition, Ms Harvey-Wood (clinical scientist in microbiology) who specialised in paediatric microbiology, for both Yorkhill and RHC, expressed concern about the increased number of unusual environmental organisms seen in blood cultures and also the fact that multiple organisms were being found in the same blood culture on a more frequent basis, which again was an unusual finding[17]. Polymicrobial BSI are associated

with increased mortality[18] [19] and are often more complex to treat due to the different antimicrobial sensitivities of the organisms[20].

3.21. The HAD Report note at the end of section 2.2, that *Cupriavidus spp*. and *Burkholderia spp*. can be found at low levels in Glasgow tap water, perhaps suggesting that contamination of the hospital system was inevitable. An explanation of wholesome water and why it is acceptable to have low levels of bacteria in tap water is found in Dr Walker's expert report for the Inquiry[21]. The finding of low levels of these two bacteria would not prevent the water being classed as wholesome and compliant with the Public Water Supplies (Scotland) Regulations 2014 SSI 2014/364 regulation 4(2)(a) "water intended for human consumption purposes must not contain any microorganism …at a concentration or value which would …constitute a potential danger to human health".

3.22. On entry into QEUH, mains water is put through an ultrafiltration plant, which removes organisms and fungi, and then to filtered water storage tanks. This is done to protect vulnerable patients and means that bacteria should not be able to enter the system through the mains water, however, it is known that there was a period of time in 2015 when the ultrafiltration plant was bypassed inappropriately[22], allowing bacteria and debris to enter, proliferate and colonise the hospital water system[23], creating a risk for neutropenic and immunocompromised patients coming into contact with the water.

4. Chapter 3

4.1. Chapter 3 is, in part, a textbook-style review of the bacteria causing infections included in the Case Note Review[24]. It appears to be attempting to make the case for the infections to be caused by commensal gut organisms which are then selected out by antimicrobial treatment, rather than a direct environmental source of infection.

4.2. However, it is known that many of these organisms including *Pseudomonas aeruginosa*[25] and others have higher carriage rates in hospitalised patients and evidence suggests that they may be acquiring them from the hospital environment and

is not only dependent on antimicrobial use[26] [27] [28]. Bacteria can be carried on the skin or in the naso-pharynx and acquisition does not always result in intestinal carriage. However, colonisation of the patient by organisms from the hospital environment may be a precursor to what may appear to be endogenous infection. In the context of infection prevention and control is important to understand the full aetiology of an infection so that environmental risks can be recognised and mitigated as early as possible. The HAD Report does not appear to take this into account.

4.3. The HAD Report places emphasis on antimicrobial resistance amongst these organisms. However, no concerns were raised through IMTs for blood stream infections on the Schiehallion Unit at RHC regarding spread of multi-resistant organisms, suggesting that this was not a factor in these infections, save for those where the bacteria are inherently resistant such as *Stenotrophomonas maltophilia.* This is discussed further at paragraph 5.9.

4.4. In my experience it is widely accepted that colonisation by bacteria often precedes infection[29] [30] [31] [32] and strategies may be employed in individual patients to reduce risk of infection. For example, where patients are colonised with Meticillin resistant *Staphylococcus aureus* (MRSA), efforts are made to decontaminate the patient using antibacterial washes and nasal antimicrobial ointment prior to surgical procedures in order to protect them from surgical site infection with MRSA. Whilst skin carriage alone is not harmful to the patient, as soon as a surgical wound of other breach of the skin's integrity is present, the risk of infection is increased.

4.5. Alternatively, some infections arise without prior colonisation, for example wound infections where a traumatic wound becomes contaminated (as opposed to colonised) with the infectious agent immediately it occurs.

4.6. An example where both mechanisms may occur is infection of a central venous cannula where bacteria are transferred to the cannula through poor hygiene/infection prevention techniques, contact with contaminated water or surfaces, or from the bacteria colonising the patient's skin.

4.7. Mechanisms of transmission from the environment to individuals is described in my previous report[33].

4.8. The colonisation stage allows the number of bacteria (bacterial load) to increase to the point that it can cause infection by whatever mechanism is involved. So, whilst it could be argued that the infection is secondary to colonisation, the colonising organisms have to be first acquired whether from food, the environment, from other individuals or another source. The intermediate step of colonisation does not preclude an environmental source for the infection and hence Key Question 4 for the Inquiry remains valid.

5. Chapter 4

5.1. In this and previous chapters the authors place a lot of importance on colonisation of the patients in the home environment which, they opine, subsequently led to blood stream infections caused by translocation from the gut.

5.2. It should be remembered that the Schiehallion cohort of patients had not significantly changed and nor had the senior medical team caring for them, but nevertheless concerns were raised that there were an increased number of blood stream infections occurring which the clinical team identified as unusual following the move to RHC.

5.3. It is notable that Mookerjee, in his expert report to the Inquiry[34] found that the rate of BSI with environmental organisms was higher (for certain years) of that of comparator units in the UK. Given that the children concerned had frequent day and inpatient admissions to the Schiehallion Unit, the likelihood of the hospital environment being implicated in the infections cannot be dismissed as easily as the authors appear to wish to do. If the home environment was the issue then the infections would not be seen as unusual as this would have been a constant. The Case Note Review included only infections, with environmental gram negatives, which arose after attendance or admission to QEUH/RHC. Therefore, it does not seem reasonable that the authors make an assumption that only 20% or less of BSI are related to the hospital environment without any knowledge of the specific cases.

[33] Bundle 21, Volume 1, Document 4 para 9.21-9.32.
[34] Bundle 21, Volume 1, Document 1, page 3.

5.4. It was notable (and to an extent expected[35]) that the number of BSI temporarily reduced on the initial transfer of the Schiehallion Unit to RHC. This would be the hoped-for outcome of moving to a brand-new facility. This is noted and shown in the analysis by HPS and NSS[36] using SPC charts to compare the rate of infections with the expected rate and demonstrating a change in the trend in blood culture incidence for environmental organisms, which reduced around the time of the move to RHC in 2015, but increased above the centreline with 9 of 12 data points for 2017 above the centreline, including one point above the upper warning limit, and in 2018 the data points indicated two exceedances of the upper confidence limit. These are significant findings and reflect a real and sustained increase in the rate of blood stream infections due to environmental bacteria in the Schiehallion cohort of patients when compared with the equivalent patient cohort at Yorkhill prior to the move.

5.5. A further HPS analysis[37] reviewed data from 2013 to 2019 and showed the same step change in incidence of BSI caused by environmental organisms, followed by a significant reduction in cases from October 2018 to February 2019 when the Schiehallion Unit moved to wards 6A and 4B, followed by another significant increase in incidence with 6 of 7 data points above the centreline for the remainder of 2019.

5.6. The authors insist that a route of transmission and portal of entry of infection must be identified in order to support the probability of any site acting as the source. In my experience this is often challenging to do. The water system has been identified as a key source but that does not necessarily mean that direct water to patient transmission has taken place. Various other indirect routes of transmission are also identifiable and most Schiehallion patients will have central venous cannulas, breaching the skin defences, which give additional patient portals of entry. This is explained in my earlier report to the Inquiry[38].

5.7. A great deal of reliance is placed in the HAD Report on the lack of finding indistinguishable isolates of BSI causing organisms and the environment. The environmental sampling of the water system was not consistent, nor were all samples cultured for environmental organisms other than *Legionella spp* and *Pseudomonas*[39]. Nor were there water samples contemporaneous or from the patient's own room environment for BSI cases in the vast majority of cases. Where samples were cultured

[36] Bundle 7, Document 5, page 205.
[37] Bundle 7, Document 6, page 214.
[38] Bundle 21, Volume 1, Document 4, paragraph 9.27-9.32.
[39] This is not surprising as routine water samples are not examined for other organisms unless specifically requested.

for environmental organisms, multiple strains of the same organism were often identified. It is not clear how many of the different strains were followed up and stored. Not all of the clinical isolates were subjected to WGS. For these reasons it cannot be argued that because the WGS evidence does not exist, that cases of BSI were not related to the hospital environment.

5.8. The authors criticise the exclusion of *E. coli* from the CNR. Whilst it is understood that the organism can, on occasion, contaminate surfaces in healthcare facilities and patient to patient transmission can occur via this mechanism, it is not a recognised environmental organism and is a constant in the human gut flora. The Terms of Reference for the CNR inclusion criteria were such that *E. coli* would be excluded as it is not an environmental organism.

5.9. In the paper, the number of *Stenotrophomonas spp* infections is, in part, attributed to the shortage of Piperacillin-tazobactam between May and September 2017. The authors suggest that this shortage resulted in an increase in meropenem usage which selects out resistant organisms such as *Stenotrophomonas spp.* However, the data supplied by NHSGGC[40] clearly shows that the use of Piperacillin-tazobactam increased during this period in paediatric haemato-oncology patients, peaking in August 2017 and the usage of Meropenem remained reasonably stable, dipping from June to November. Usage was no lower than the preceding 6-12 months in adult patients in BMT, North Sector or South Sector (sectors as defined in the paper).

5.10. Documents provided by NHS GGC[41] [42] examine the prescribing data for three antibiotics/antibiotic group: Carbapenems (including Meropenem), Piperacillin/Tazobactam and aminoglycosides. We know from other reviews [43] [44] [45] that the highest numbers of environmental gram-negative infections seen in the Schiehallion cohort occurred in 2017 and up to October 2018. The antimicrobial data shows that there was a clear upward step change in piperacillin/tazobactam prescribing in 2017 with Carbapenem prescribing remaining constant, as shown by mean prescribing and change point analysis, but in 2018 the opposite is seen, with an upward step change in Meropenem usage and a reduction in Piperacillin/tazobactam.

[40] Public Inquiry Data v11 (20240126) - This document contains datasets relied upon by the HAD group, spanning January 2010 to December 2022, and was provided to the Inquiry by NHS Greater Glasgow & Clyde on 18 February 2025. As it contains patient-identifiable data, it has not been included in a Hearing Bundle.
[41] Bundle 44, Volume 1, Document 7, page 248.
[42] Bundle 44, Volume 1, Document 8, page 297.
[43] Bundle 21, Volume 1, Document 1, page 3.
[44] Bundle 7, Document 5, page 205.
[45] Bundle 7, Document 6, page 214.

5.11. In my opinion, the increase in Meropenem usage would not have been seen if there had been a concern that a high number of Meropenem resistant infections with environmental gram negatives was being seen, as the Meropenem would have been ineffective against these organisms.

5.12. In addition, it is worth noting that although the authors put great emphasis on *Stenotrophomonas maltophilia*, the maximum number of blood stream infections in any quarter was three and this was not the main driver of the overall environmental gram-negative blood stream infections.

5.13. The authors dismiss the concept of an outbreak of infection at QEUH/RHC on the basis of a lack of WGS evidence, despite the environmental specimen collection being inconsistent and mostly non-contemporaneous to the clinical infections. However, there is no doubt that there was a significant increase in the number of infections seen[46] (a data exceedance) due to a number of different environmental organisms, some in clusters, over a prolonged period of time and the investigation of the built environment uncovered issues in the water system including poor management, contamination, taps with flow straighteners, extensive biofilm etc, and ventilation issues such as the lack of particulate (HEPA) filtration, lack of positive pressure and 2.5 air changes per hour compared with the national guidance of 10 ach [47]. All of these factors significantly increased the risk associated with the built environment for immunosuppressed patients such as those on the Schiehallion Unit.

5.14. The newly refurbished Schiehallion Unit, which has had the built environment faults corrected, has seen a reduction in blood stream infections caused by environmental organisms[48] to levels similar to peer Units in England. This is further evidence that the environment was contributing to the infections seen.

6. Chapter 5

6.1. In my experience, it is widely accepted that no water system can be sterile but that water supply and management of the water system must be managed on the basis of risk.

6.2. For example, much emphasis in water management is placed on *Legionella spp* and in particular *Legionella pneumophilia* serogroup1 due to its ability to infect previously healthy individuals by droplet spread from contaminated water. This affects all patients and potentially some staff in the hospital environment.

[46] Bundle 21, volume 1, Document 15.
[47] Bundle 13, Volume 3, Document 32, page 951.
[48] Bundle 21, Document 10, page 767.

6.3. For other organisms, such as *Pseudomonas aeruginosa* and other environmental organisms, the risk is much greater for certain groups of patients who are susceptible to opportunistic infections. Immunosuppressed children (particularly those undergoing haemopoietic stem cell transplant (HSCT)) are at greatest risk together with children with ineffective defence against infection such as those with cystic fibrosis[49] [50], neonates and ITU patients. The same groups apply for adults with BMT patients having the greatest risk but the risk for each group is lower than that for children.

6.4. Acquisition of environmental bacteria will often result in skin or mucosal (naso-pharynx) rather than enteric carriage. This is especially observed in cystic fibrosis patients but is also the case in others due to the body's natural defences of mucosal cilia, gastric acid and the enteric defence of the gut microbiota resulting in colonisation resistance.

6.5. Patients who have indwelling vascular access lines, abdominal feeding tubes, urinary catheters etc are all at higher risk of infection as their medical devices breach the skin and/or mucosal barriers.

6.6. Not all haematological conditions confer the same risk, for example hereditary spherocytosis which does not require immunosuppressive treatment but can result in splenectomy which then confers an increased risk of some vaccine-preventable diseases. These patients are cared for by haematologists who also care for patients with haematological malignancies.

6.7. The authors of the HAD Report do not appear to consider these differences in vulnerability in their approach. Not all patients are at equal risk and it must be remembered that the adult BMT patients moved back to the Beatson in July 2015 and did not return until July 2018 by which time a number of changes had been made including all water outlets on the ward had point of use filters, the ventilation in the BMT rooms had been upgraded to include HEPA filtration and the chlorine dioxide dosing system was installed soon after, in November 2018.

6.8. This group were the most vulnerable of the adult patients, but infections did arise in adults associated with environmental organisms and Problem Assessment Group meetings were held for suspected outbreaks in adults including *Mycobacterial*

[49] Mainz JG et al. Cystic Fibrosis Upper Airways Primary Colonization with Pseudomonas aeruginosa: Eradicated by Sinonasal Antibiotic Inhalation. American Journal of Respiratory and Critical Medicine; 2011. Vol 184, Issue 9 pages 1089-90.

abscessus in adult cystic fibrosis patients[51], Aspergillus in adult ITU[52], *Acinetobacter* infections in adults on neurosurgical ITU[53] and *Pseudomonas* on 10D[54].

6.9. Children are most vulnerable to environmental infections in hospitals because they have a comparatively immature immune system. Risk increases with severity of underlying illness, young age, nutritional status and extrinsic factors such as use of invasive devices (central venous catheter, urinary catheter, mechanical ventilation) and length of stay. Whilst adults can and do acquire environmental infections, their vulnerability is less than that seen in children.

6.10. The authors of the HAD report cite a paper by Couchoud et al[55] to conclude that endogenous infection is a more significant source of BSI than environmental sources or cross infection from another patient. As discussed at paras 3.13 and 4.2, environmental acquisition in hospital leading to increased incidence of gut colonisation/carriage is well recognised and the root cause of the source of an infection is much more complex than this might suggest. Environmental acquisition of colonisation of the oro-pharynx may also result in significant infection and blood stream infection.

6.11. The authors identify that 'when a water system is a source of environmental contamination and when there is spread to vulnerable patients it is generally not the whole system that has a high bacterial load'.

6.12. Evidence suggests that the water system at QEUH/RHC was indeed contaminated throughout and the authors conclusion at 5.3.2 is incorrect in this case.

6.13. There is evidence submitted to the Inquiry such as Dr Walker's expert report[56] and the draft Storrar and Rankin[57] HPS report which demonstrate widespread contamination with a wide range of gram-negative waterborne pathogens and biofilm throughout the water system during the first 6 months of occupation and again during the 'water incident' in 2018 when more extensive testing was carried out.

6.14. Dr Walker's view is that 'the microbiological data provide a pictorial and temporal evidential data-base that the entire domestic hot and cold-water system was

[56] Bundle 21, Volume 1, Document 5, page 180.
[57] Bundle 19, Document 21, page 174.

contaminated with a wide range of waterborne pathogens that would have presented a HAI risk to patients from the day of occupation'.

6.15. There is evidence from pre- and post-flush samples carried out in PICU as early as 2016[58], that *Cupriavidus sp* was detected in both indicating that both the outlet and the pipework further back in the system were contaminated.

6.16. Health Protection Scotland and NHS NSS reported[59] in December 2018 that following a decision to decant wards 2A/2B to allow for further investigation of the environment in these wards, 4B was being prepared for the transfer of adult BMT patients from the Beatson. As a precaution, water testing was undertaken and revealed the presence of *Cupriavidus pauculus* and other gram-negative bacteria in water outlets in the ward. This prompted the suggestion that there may be widespread contamination of the water system across QEUH/RHC and further testing was undertaken.

6.17. Test results provided confirmation of widespread contamination with positive samples in multiple areas including ward outlets as well as basement risers. The working hypothesis of the investigators was that a combination of regressional contamination and contamination at installation/commissioning was the cause.

6.18. Dr Peters reported on environmental sampling on ward 2A/2B in March 2018 done in response to two cases of *Cupriavidus pauculus* BSI. Showers and taps from the ward and from ward 4B, dismantled and cultured. A diverse population of environmental organisms including *Cupriavidus pauculus, Burkholderia sp, sphingomonas paucimobilis, Delftia acidovorans, Serratia fonticola, Brevundimonas sp, Rhodotorula mucilaginosa, Bordetella bronchisepticum and candida guillermondii* was found.

6.19. At the Water Technical Group on 20 April 2018[60] it was confirmed that every floor in QEUH/RHC had positive and negative results and attendees agreed that this indicated widespread water infection (sic).

6.20. Susanne Lee reviewed the system on-site following a request from the WTG. Her report[61] identified that the system was likely contaminated prior to handover, with a 12-month lag between the system being filled and occupation, allowing biofilm to develop. She reported that temperature fluctuations were a likely contributory factor as they had been inconsistent. The high number of little used outlets, particularly the en-suite bathrooms was also a risk factor. She made recommendations around improvements

[58] Bundle 21 Volume 1, Document 5, page 180.
[59] Bundle 18, volume 1, Document 11, page 819.
[60] Bundle 10, Document 3, page 14.
[61] Bundle 8, Document 32 page 134.

to the safety management of the water system, the correct use of point of use filters and the reduction of the number of outlets in patient rooms.

6.21. In July 2019, Intertek[62] reported on an expansion tank from QEUH which showed areas of corrosion and contaminated and found widespread biofilm on the holding plate, the expansion bladder and debris from the expansion vessel, together with multiple bacterial strains found on culture.

6.22. Whilst individual outlets undoubtedly played a role in the contamination of water, in part due to the use of plastic flow straighteners which have been shown to become contaminated with biofilm[63] and have also been the source of outbreaks of infection elsewhere[64], there is evidence of poor management of the water system as a whole[65] and contamination of water tanks with debris and bypassing of the ultrafiltration units allowing micro-organisms and debris to enter the water system.[66]

6.23. In May 2018, black grime was seen coming out of the drains in wash hand basins[67] in ward 2A/2B suggesting that biofilm was not only prevalent in the water supply but also in the waste-water system. This was observed again in September 2018[68].

6.24. This widespread contamination with biofilm formation at QEUH/RHC has not been addressed by the HAD Report. Instead it concentrates on the part played by biofilm in the spread of multi-resistant organisms. It is well recognised that biofilm can protect bacteria from chemical (biocide) destruction, and extreme environments such as heat. When they occur on a medical device such as the lumen of central venous cannulas, they can enable bacteria to resist destruction by antimicrobials. Mature biofilms allow dispersal of bacteria from the biofilm[69]. This can be the mechanism of infection in central line associated blood stream infections (CLABSI) or the release of bacteria into water systems.

6.25. The issue of multi-resistant organisms, save for those which are inherently resistant, has only appeared once in IMT minutes, in November 2018 and related to a multi-resistant pseudomonas isolate which was found in at least two sinks and caused a BSI in one patient and was confirmed by typing[70].

[70] Bundle 1, Document 54, page 241.

6.26. At 5.4.3 the authors of the HAD Report remark on the time period between September 2018 and April 2019 when there were no cases of *Stenotrophomonas maltophilia* seen in the Schiehallion cohort. In October 2018 wards 2A/2B were decanted to Wards 6A and 4B in the adult hospital and interventions in the water system were implemented on 2A/2B including removing and replacing all of the wash hand basin and associated pipework and taps. In addition, dosing of the water supply with Chlorine dioxide commenced. The episodes of BSI due to *Stenotrophomonas maltophilia* in April 2019 were on ward 6A QEUH. This could be seen as confirmation that the Stenotrophomonas BSI were not related to intrinsic patient factors such as GI colonisation and translocation as the patient cohort did not change and the only factor which did change was the location of the ward.

6.27. The QEUH/RHC water contamination incident appears to be unique in the extent of contamination and the range of micro-organisms implicated in infections. I have not been able to find a directly comparable incident in the published literature. There are many incidents related to *Legionella* contamination in the literature[71], some with contaminated cooling towers and whole cold-water systems suggesting widespread contamination but none with the diversity of organisms examined.

6.28. Water testing has been variable in range, volume and organisms tested across the QEUH/RHC campus[72]. Although some isolates have been stored and tested by WGS it is not possible to be confident that these are either contemporaneous with infections caused by environmental organisms or comprehensive enough to rule out, as the authors seem to do, an environmental link based on the limited WGS testing undertaken[73],[74],[75].

6.29. If comprehensive water testing looking for organisms relevant to the infections seen, had been undertaken earlier in the course of the investigations into all of the unusual infections seen at QEUH/RHC, it may have been possible to relate the water contamination to the infections more definitively. However, because of the lack of this comprehensive testing it is impossible to rule out a link as the authors appear to wish to do.

6.30. I would also argue that by the time WGS results would be available in an outbreak investigation, the IPC team would usually have implemented the necessary control

[71] CA Hart et al. *Legionella* in hospitals: a review. Journal of Hospital Infection (1991) 18 (Supplement A), 481-489.
[72] Bundle 21, Volume 1, Document 1, page 3.
[73] Bundle 8, Document 44, page 223.
[74] Bundle 8, Document 45, page 230.
[75] Bundle 8, document 46, page 239.

measures. Most NHS hospitals do not have direct, immediate access to WGS and in-house water testing, meaning that an investigation team would have to wait for external contractors to test the water, produce results and then return any significant isolates so that they could be paired with clinical isolates and sent away to a reference facility for further typing and WGS as necessary. This would take weeks rather than days to achieve which would be too long to wait to implement control measures. There are of course, more extensive outbreaks which are assisted by WGS in identifying epidemiological links between cases and may in turn, identify additional control measures, however initial IPC measures would have to be implemented at pace to control the outbreak.

6.31. As noted at paragraph 5.4 in this report, it would be expected that moving to a brand-new facility from a much older facility there would be a reduction in infections with environmental organisms[76]. From Sid Mookerjee's work[77] it is clear that this was the case for the Schiehallion Unit patients but the numbers of environmental infections rapidly increased to a peak in 2017 and a decline from 2018 due to multiple interventions including, but not limited to, point of use filters on taps, bottled water for washing and teeth cleaning, enhanced cleaning including silver hydrogen peroxide vapour (HPV) decontamination, mobile HEPA filters in patient's rooms and decant away from ward 2A/2B.

6.32. This is also seen in Dr Kennedy's paper[78] which shows by a rolling case count that the number of cases of BSI reduced at the time of the move to RHC but then steadily increased from May 2016 onwards to peak in June 2018. The nuance of the polymicrobial episodes is not visible in this graph (p 109) but is clearly seen on the preceding page.

6.33. HPS also showed this in their SPC analysis[79] discussed at 5.4.

6.34. As part of the works on ward 2A/2B, the ventilation system was significantly upgraded. In their proposal for changes required, Innovated Design Solutions noted that '*the original design philosophy was not intended for use by patients with immune response impairment/deficiency'* and that the existing ventilation was likely to increase the risks associated with ingress of infectious aerosols and would require a new dedicated air handling unit plant and installation of new distribution, as modification of the existing system was not thought to be feasible to create the desired outcome.

[76] Bundle 18, Volume 2, Document 130, page 1566.
[77] Bundle 21, Volume 1, Document 1, page 3.
[78] Bundle 6, Document 28, page 104.
[79] Bundle 7, Document 5, page 194.

6.35. It was only after the move back to the refurbished ward 2A/2B which had the environmental issues resolved and now met the SHTM guidance[80] [81], and the correct level of maintenance was being undertaken, that the rates of infection decreased to a similar level to comparator units elsewhere in the UK.

6.36. Comparing infection rates at RHC with those at Yorkhill gives false reassurance that there is no problem, as accepting a baseline without comparing it to a number of other units caring for a similar cohort of patients is misleading.

7. Chapter 6

7.1. Airborne pathogens such as aspergillus were not included in the CNR as they were not included in the Terms of Reference. One case where the child had a gram-negative BSI and aspergillus was included but not specifically commented on with reference to the aspergillus. Details of each case were, again, specifically excluded from the report by the Terms of Reference.

7.2. In my earlier joint report[82] with Ms Dempster, aspergillus was mentioned briefly but was not included in detail as we had no laboratory results for aspergillus infections from NHS GGC as the data set we worked from was specifically blood culture results.

7.3. In chapter 6 the authors again give a general review of ventilation requirements. They appear to pit the SHTM against NICE guidance and the JACIE requirements. Clearly the NICE and JACIE guidelines have to be suitable for existing buildings as well as new, hence the comparative lack of detailed standards and mandating of standards of ventilation but SHTM 03-01[83] is for new builds and should be followed without derogation wherever possible but particularly for vulnerable patients such as the Schiehallion cohort. As can be seen, in the case of QEUH/RHC the derogation away from the SHTM standards (reduction of air changes to 2.5ach/hr, not providing positive pressure and not providing sufficiently filtered air (H12) as described in Appendix 1, table A1) appears to have contributed to the increase in infection rates secondary to the built environment with three probable cases of aspergillus infection seen on ward 2A between July 2016 and March 2017.

8. Chapter 7

Analysis of data

8.1. When comparing cohorts of patients, it is important to ensure that they match in profile, for example the same diseases are seen in both groups, the hospital environments are similar and that the comparison is like for like. As discussed at 6.35, using Yorkhill as a comparison to RHC, gave false reassurance that infection rates were acceptable whereas using peer comparators from other areas of the UK provides a more accurate view of achievable infection rates.

8.2. The choice of splitting the data by consultant sector appears to be an arbitrary designation in that on review of the data provided, both the North sector and BMT admit patients to many wards in the Beatson and also to other hospitals including QEUH providing no standardisation to the patient cohort thus exposing them to the same hospital environments. There are also patients on the South list admitted to the Beatson. This means that a true comparison in the context of examining environmentally relevant infections cannot be made due to conflicts in the data.

8.3. The paediatric data set provided[84] contains data only for paediatric haemato-oncology patients. From this data 26 cases of *Burkholderia cepacia* blood stream infections can be identified from 16 patients. 24 of the cases were patients at Yorkhill and two at RHC. There are no blood culture results for patients from other specialties at Yorkhill. The data shows that on average 2 cases were seen every year, but cases were not distributed evenly across all years and this trend did not continue when the Schiehallion Unit moved to RHC, with just two infections seen in six and a half years. This could suggest that there was a factor influencing the rate of infections at Yorkhill which was not present at RHC and was not patient-mediated. In table 11A of the HAD Report, the cases are grouped as possible or probable clusters. This does not bear scrutiny in all cases, for example, by examining CHI numbers it can be seen that all of the episodes in 2005 and January 2006 were the same patient but they are assigned as a probable cluster. Patient level data is important to include in such an analysis to avoid assigning clusters where they do not exist.

8.4. The three cases of *Elizabethkingia meningoseptica* in 2014 were three episodes in two patients. The two episodes in the same patient were less than 28 days apart

[84] Final Combined GGC Paeds Onc CHI only 01.01.05 – 31.12.22.xlsx – This document contains datasets relied upon by the HAD Expert group, spanning January 2005 to December 2022, and was provided to the Inquiry by NHS Greater Glasgow & Clyde on 18 February 2025. As it contains patient-identifiable data, it has not been included in a Hearing Bundle.

suggesting a relapsing infection. The two patients were cared for by different consultants.

8.5. There were a further two cases at Yorkhill which were identified as *Chryseomonas meningosepticum*. This organism was reclassified as *E. meningoseptica* in 2005 and the cases should be recognised under the correct heading. When a change in name is made, diagnostic laboratories can on occasion, take time to change their diagnostic and identification protocols to include the new names.

8.6. There were three cases of *E. meningoseptica* at QEUH in a relatively short period of time between September 2016 and February 2017 which likely represents a cluster as no cases have been seen in the Schiehallion cohort at any other time in the data.

8.7. There were three episodes of blood stream infection with *Pantoea agglomerans* in two patients at Yorkhill. The two episodes in the same patient occurred 35 days apart and would be classed as recurrent infection. There is nothing to suggest a link between the two patients and their infections although they were cared for by the same consultant.

8.8. It is unclear from the HAD Report how the adult bed day data has been derived. One would expect that a highly specialised service such as BMT would have fewer bed days than non-BMT haemato-oncology, however, that is not the case here and the South sector appears to have fewer bed days than BMT and the North. It is also not clear whether this data is specific to a patient group or to the service or to individual consultants. Yet the patients involved in the data were admitted to 98 different wards, in at least 10 hospitals, across all sectors when their blood cultures were taken and there is no confirmation that any data cleansing or validation of the link between consultant and patient has been done. In addition, the authors appear to compare patients who have admissions to multiple sites and wards to patients using a single site. This makes direct comparison between patient cohorts and hospital sites impossible with any confidence that a like-for-like comparison is being made.

8.9. It is particularly important to ensure that there is a like-for-like comparison when one is investigating a link to the environment. Trying to compare so many wards and hospital sites in aggregated data with any accuracy is not feasible. The patient groups are said to all be haemato-oncology but there are patients within the list[85] who have benign conditions such as sickle cell anaemia, disorders of iron metabolism, etc which will skew the data.

[85] IP Haem Onc selected consultants from 2013 by sector.xlsx - This document contains datasets relied upon by the HAD Expert Group, covering the period from 2013 to 2023, and was provided to the Inquiry by NHS Greater Glasgow & Clyde on 18 February 2025. As it includes patient-identifiable data, it has not been included in a Hearing Bundle.

8.10. Therefore, in my opinion and for the reasons set out above, comparing North, South and BMT sector data based on consultant affiliation rather than defined geographical location is a flawed approach to comparing infection rates.

8.11. The BMT patients returned to the Beatson in July 2015 after a month in QEUH and did not return to 4B until remedial works had been completed in June 2018. Other haematology patients were housed in 4C in a bed base of 10 beds.

Relevant infections

8.12. PAGs were held on three occasions for infection concerns on 4B and 4C.

- In August 2018 a PAG was held following 4 cases of Vancomycin resistant enterococci (VRE) on 4C. No IMT was required.

- In September 2020 four cases of VRE were seen in BMT patients on 4B. A second PAG was held but no IMT was required.

- In October 2020 two cases of *Stenotrophomonas maltophilia* bacteraemia were seen in haematology patients on 4C. No IMT was required.

8.13. I am not aware of any further concerns raised about infection rates in these patients whilst on 4C and 4B.

8.14. To date there has not been a detailed analysis of infection rates in QEUH 4B and 4C based on the ward patients and activity and comparing them with infection rates in comparable units that I am aware of.

8.15. Following remedial work 4B has a higher level of ventilation protection than many wards in QEUH (although still falls short of full compliance with SHTM 03-01 (2013)) with 5.8-8.9 air changes per hour (ach), HEPA filtration (rooms only, not corridor), no chilled beams and 6.6-13.9 Pa of positive pressure to the corridor. By comparison, 4C has the same ventilation as standard wards in the hospital with 2.8-3.3 ach, no HEPA filtration (mobile HEPA units in use), chilled beams and neutral to +1 Pa positive pressure[86] [87]. The ventilation on ward 4C does not meet the standards in SHTM 03-01 and therefore represents a risk of infection for neutropenic and immunocompromised patients.

[86] Bundle 21, Volume 1, Document 8, page 611.
[87] Bundle 21, Volume 1, Document 7, page 468.

8.16. There has been extensive reporting of infection rates in the Schiehallion unit at the RHC. All of the reports[88] [89] [90] [91] [92] show that the rates of bacteraemia with gram negative environmental organisms increased following the move of the Schiehallion Unit to RHC, peaking in 2017-18. Sid Mookerjee showed that the rates of infection decreased to rates similar to comparator units in the rest of the UK following the extensive environmental remedial works undertaken on 2A/2B and other remedial strategies such as system-wide chlorine dioxide dosing, which strongly indicates an environmental link between infections and the water and ventilation systems.

8.17. The final report of the Oversight Board noted that environmental data was not well organised with inconsistent labelling of samples and their locations together with the format in which they were recorded. The report also comments on the inconsistent recording of reference laboratory results and that there was no database recording al typing results for cases. This makes retrospective reviews difficult and potentially incomplete due to missing data.

8.18. The impression gained from the Executive Summary and Chapter 7 is that the authors of the HAD Report consider that if it could be shown that the incidence of bacteraemia caused by 'environmentally relevant' microorganisms in a particular hospital or patient population is in a pattern largely the same as the incidence of bacteraemia caused by microorganisms that are 'not environmentally relevant' then that would indicate that the environment did not play a significant role in harbouring and transmitting pathogens. This theory does not take into account the complete history of infections at QEUH/RHC.

Water

8.19. The water incident occurred in 2017-2018 and it is notable that this coincided with the peaks in incidence of environmental BSI in adult haem-onc patients in QEUH as shown on Figs 5 and 6. These peaks are evident even when the 'adjusted' bed day data is used as the denominator.

8.20. The remedial interventions undertaken by the Health Board including the implementation of point of use filters, chlorine dioxide dosing of the water system, remedial work on 4B and 4C have impacted on the rate of infections and were

[88] Bundle 21, Volume 1, Document 1, page 3.
[89] Bundle 7, Document 2, page 32.
[90] Bundle 7, Document 7, page 250.
[91] Bundle 6, Document 36, page 795.
[92] Bundle 6, Document 38, page 975.

implemented in response to the peaks in paediatric infection rates in 2017 and 2018 which were also seen in the adult data.

8.21. The authors have analysed the data using clustering of cases as a method of counting which is confusing and given the errors made in assessing the presence of clusters described earlier, due to not considering multiple infections/relapses in the same patient, are unlikely to reflect the true picture.

8.22. Chaput[93] reported the data on pseudomonas contamination in QEUH/RHC and showed that the percentage of out of specification samples was 1.8% for the period 2015-2020. This would be reassuring if a larger number of samples had been taken. From early 2016 until late 2018, in the vast majority of months less than 50 samples were taken for the entire new build site. This level of testing is not reassuring and is below what would be expected for the size of the QEUH/RHC building.

8.23. The authors comment on the more intensive water testing undertaken from November 2018 which commenced after the implementation of continuous Chlorine dioxide dosing which would inevitably have an impact on the bacterial counts.

8.24. The Coppry study[94] examined 10 intensive care units over a five-month period and found variable initial levels of tap water positivity varying from no contamination to 76% contaminated with Pseudomonas aeruginosa. All taps on the unit were tested on a weekly basis throughout the study. This study cannot be compared directly with the rate of contamination in QEUH/RHC as the level of water testing is not comparable either in volume or in frequency – to ascertain the contamination rate of 1.8% Chaput looked at 8 years of data with very small levels of testing for several years including when the infection rates in the haemato-oncology patients was at its height. The lack of data from water testing at QEUH/RHC does not allow a conclusion to be drawn on the extent of water contamination in the same manner as in this study.

8.25. Making a comparison with the Halstead study[95] has similar problems. In the Halstead study all outlets (881) in four augmented care units were tested on three occasions over a period of 16 weeks. This gave a picture of the level of contamination of water over the course of the study. At QEUH/RHC from 2016 to 2018, for most months less than 50 samples were taken for the whole site. For the Schiehallion unit where there were three outlets per room plus other outlets on the ward, this would not allow all

[93] Bundle 19, Document 18, page 107.
[94] M Coppry et al. Exogenous acquisition of *Pseudomonas aeruginosa* in intensive care units: a prospective multi-centre study (DYNAPYO study). JHI 104 (2020) 40-45.
[95] FD Halstead. *Pseudomonas aeruginosa* infection in augmented care: the molecular ecology and transmission dynamics in four large UK hospitals. JHI (2021) 162-168.

outlets to be tested once. It is not possible to use this comparison to conclude that there was no widespread contamination at QEUH/RHC as the data is not comparable.

8.26. It is well known that the taps fitted to the wash hand basins in QEUH/RHC were manufactured by Horne and had plastic flow straighteners[96]. These have been shown to be a high risk for biofilm formation[97] and therefore present a risk of HCAI for neutropenic and immunosuppressed patients. These taps are also fitted with thermostatic mixer taps which deliver water at around 41°C, creating a favourable environment for *Pseudomonas aeruginosa* to grow. This high risk combined with very low levels of water testing also brings into question whether the conclusion that the water system did not have widespread contamination can be made with any confidence.

Susceptibility to infection

8.27. In general, in any population, susceptibility to infectious diseases change with age. The general approach is that the extremes of age, neonatal and very elderly have the highest risk of infection, this drops during childhood and then increases gradually from early-twenties onwards[98].

8.28. Hospitalised patients, due to underlying illness and treatment, are more susceptible to infection. Those who have diseases of the immune system or who are treated with immunosuppressive drugs are at greatest risk.

8.29. In any scientific analysis of infection rates, it is important to compare like with like. As discussed earlier, the comparison of mixed sets of patients does not stand up to scrutiny. The data used in this analysis, split by consultant sector results in a patient mix where not all of the patients have the same vulnerability to infection. The BMT patients will be more vulnerable than other haemato-oncology patients due to their profound neutropenia during transplant and ongoing immunosuppressive drugs. The patients with benign haematological conditions will be less vulnerable than the haemato-oncology patients depending on treatment.

8.30. This type of comparison is helpful when a problem is suspected and assurance is needed as to the correct baseline to be comparing with. If there is confidence that the ‘usual’ rate of infection is within acceptable levels compared to peer units, then

[96] Bundle 21, Document 75, page 188.

[98] Glynn, J.R., Moss, P.A.H. Systematic analysis of infectious disease outcomes by age shows lowest severity in school-age children. Sci Data 7, 329 (2020).

prospective monitoring of rates of infection is likely to detect ongoing infection issues in a more timely manner.

8.31. Children with haematological or solid tumours are more susceptible to infection than adults with the same diseases.

8.32. Overall paediatric haemato-oncology patients are more vulnerable to infection than children with solid tumours. In general, children with AML have a higher risk of infection than those with ALL[99].

8.33. It is also known that infection risk persists into adulthood for child survivors of cancer[100].

Blood stream infections

8.34. The statement at 7.2.1 of the HAD Report that '*growth of pathogens in blood samples, i.e., bacteraemia, is not always a true indicator of a bloodstream infection (BSI), as contamination of the blood culture can occur when collecting or processing samples. Therefore, retrospective analyses of blood cultures are not confirmatory of a BSI, and may overestimate true numbers of infections, which is most often true for microorganisms commonly found on human skin'* is largely true, however, cultures which grow skin colonising organisms can also reflect significant infection in a relevant clinical scenario. Features in the clinical history (e.g. extensive immunosuppressive therapy, prolonged fever, embolic events) may aid clinical differentiation between infection and contamination[101]. Dismissing organisms as contaminants without the clinical context is inaccurate at best.

8.35. Bloodstream infections may result from a more localised infection, for example and urinary tract infection may result in bacteraemia and blood stream infection known as urosepsis. Alternatively, a primary BSI may result in localised infection, for example in a prosthetic joint may become infected due to seeding of bacteria from the blood.

8.36. Bacteraemia can be transient and not result in a symptomatic BSI; for example, where there is a source of infection such as an abscess or infected joint, bacteria can enter the blood in low numbers and be cleared quickly by the body's immune system. In these circumstances the blood culture may not be positive. In subacute endocarditis, several blood cultures are recommended to be taken as the bacteria causing the infection are intermittently released into the blood stream. It is usually recommended

[99] F Carlesse, et al. Infections in children and adolescents with Acute Leukaemia, EJC Paediatric Oncology, Volume 3, 2024.

[101] RM Martinez and DM Wolk. Bloodstream Infections. Microbiology Spectrum, Vol 4, No 4, August 2016.

where this diagnosis is suspected that cultures are taken when the patient's temperature is rising to have the best chance of isolating the causative organism.

8.37. The taking of blood cultures is usually subject to protocols which include the patients displaying signs of infection such as fever (or very low temperature), increased heart rate, low blood pressure, raised serum lactate, or specific infection related clinical signs, etc. This is in order to maximise the yield from the test and ensure that there is a valid clinical reason for taking the test.

8.38. Taking more than one set of blood cultures from the same patient, ideally from a different site such as both arms, or sequentially from a single site such as a central line, can increase both the sensitivity yield from 65-91% of cases to 80-99%[102] and aid in the differentiation between a skin contaminant and a true pathogen (when taken from different sites). In addition, a skin contaminant will likely only grow in one bottle.

8.39. Skin organisms tend to be gram positive with those grouped as coagulase negative staphylococci being the commonest contaminant of blood cultures. The analysis around gram negative environmental organisms should not be affected by these contaminants.

8.40. The lists of environmental and non-environmental micro-organisms broadly match lists used in other reports. *Proteus spp* are considered normal human gut flora[103] and I would argue that they should not be included in this list. A notable absentee from the list is environmental mycobacteria.

8.41. Several environmental organisms have not been considered before in earlier reports including *Cellulosimicrobium cellulans* and *Psychrobacter phenylpyruvicus* which have been seen in adult and not paediatric blood cultures, and *Leclercia adecarboxylata, Ochrobactrum anthropi* and *Scopulariopsis brevicaulis* (a fungal pathogen) which have only been seen in paediatric, not adult, blood cultures from Yorkhill in one patient each and prior to the date of the data set used in the HPS report[104].

8.42. *Cellulosimicrobium cellulans* is a gram-positive bacterium and would therefore have been excluded from other data sets.

8.43. In table 16, the authors compare a 10-year period of BSI at Yorkhill with a 6-year period at RHC and make a finding based on the number of clusters which is erroneous as the time scales are not equivalent.

[102] ML Towns and LB Reller. Diagnostic methods current best practices and guidelines for isolation of bacteria and fungi in infective endocarditis. Inf Dis Clin North Am. 2002 Jun;16(2):363-76.
[103] AL Hamilton et al. Proteus spp as putative gastrointestinal pathogens. Clinical Microbiology Reviews 2018 vol 31 Issue 3 pages 1-19.
[104] Bundle 7, Document 6, page 214.

8.44. The examination of potential clusters of infection is useful but has limitations as described at 8.2.2.

8.45. Although the same patient cohort is followed throughout, there has not been any comparison of infection levels at Yorkhill with other comparable sites in the UK. This lack of assurance questions the validity of its use as a baseline. As discussed earlier, the expectation of moving to a brand-new facility should be that infection rates, particularly in relation to environmental organisms, will decrease.

8.46. In figure 18 it is clearly shown that immediately after the move from Yorkhill to the RHC, environmental BSIs reduced until early 2016. Thereafter rates began to rise again with the mean rate increasing above the baseline with no months returning to zero.

8.47. The authors comment that the rate of all bacteraemias reduced following the peak of early 2018 and conclude that the same interventions that had an impact on the environmental BSI also impacted on the non-environmental infections. In May 2017, two years of retrospective data were analysed, showing an increase in line infections from 3.25 per 1000 line days to 6.33 per 1000 line days. This resulted in the establishment of a Quality Improvement central line associated blood stream infection (CLABSI) working group. The full impact of this working group was not seen until 2019 and the rate of CLABSI fell. This contributed to the fall in BSI seen in figure 17 of the HAD Report.

8.48. Figure 18 demonstrates the reduction of environmental BSI happened concurrently with the implementation of Chlorine dioxide dosing of the water system, the decant of the Schiehallion unit to ward 6A/4B and implementation of mobile HEPA filtration together with the impact of the CLABSI reduction actions.

8.49. The move back to 2A/2B, following a full refurbishment, installation of an upgraded ventilation system including full HEPA filtration and improvements to the water system and outlets, in March 2022 shows the environmental infection rates fall even further. This strongly suggests that rectifying the environmental issues such as contaminated water supply and inadequate, non-compliant ventilation have decreased the risk of environmental infection in this highly vulnerable cohort of patients.

8.50. As stated at paragraph 6.26, I have been unable to identify any publications based on similar situations to that which has arisen at QEUH/RHC. This suggests that the events, their persistence and the widespread nature of the contamination are extremely unusual.

8.51. The lack of comprehensive water testing contemporaneous to the height of the infection episodes cannot exclude an environmental source for the infections with

unusual organisms which were seen in the Schiehallion cohort of patients and to some extent the adult haemato-oncology patients.

8.52. Whole genome sequencing is a useful tool if used in the manner described in many published works on outbreak investigation or prospective monitoring where it has been used. However, that has not been the case here. The water testing was of a very low level, there were issues with recording of results, and identification of stored clinical isolates, and therefore as mentioned at paragraph 5.7 the results reported by Prof Leanord and Dr Brown[105] and those reported by Prof Evans[106] [107] [108] cannot be used to exclude a link.

9. Other papers by the authors

9.1. I have been provided with two further documents [109] [110]. The '*Initial bullet point thoughts on executive summary for report'* from Prof Hawkey is repeated in the executive summary of the final HAD Report. The document '*Glasgow Hospitals Case Note Review D3 - notes and commentary on environmental bacteria'* is largely repeated in Chapters 3 and 4 regarding the Case Note Review.

9.2. I note that the comparison of infection rates with peer units which Prof Hawkey identifies as important in his final paragraph of Chapter 4 (page 40) and *Glasgow Hospitals Case Note Review D3 - notes and commentary on environmental bacteria'* has been completed by Sid Mookerjee[111] and confirms the high rates of infection in the Schiehallion cohort of patients.

Bacterial biofilms are complex microbial communities encased in extracellular polymeric substances. Their formation is a multi-step process. Biofilms are a significant problem in treating bacterial infections and are one of the main reasons for the persistence of infections. They can exhibit increased resistance to classical antibiotics and cause disease through device-related and non-device (tissue) -associated infections, posing a severe threat to global health issues. Therefore, early detection and search for new and alternative treatments are essential for treating and suppressing biofilm-associated infections. In this paper, we systematically reviewed the formation of bacterial biofilms, associated infections, detection methods, and potential treatment strategies, aiming to provide researchers with the latest progress in the detection and treatment of bacterial biofilms.

KEYWORDS

bacterial biofilms, infection, antibiotic resistance, biofilm detection, treatment

1 Introduction

Bacterial biofilms have become an essential contributor to global health problems due to antibiotic resistance, the host's immune defense system, and other external pressures. Biofilms are commonly found on the surface of hospital instruments and body tissue, in industry, food processing units, and natural environments (Schulze et al., 2021). Almost all bacteria can form biofilms.

Bacterial biofilms are usually defined as fixed microbial communities encased in extracellular polymeric substances (EPS). It is characterized by changes in the irreversible adhesion of microbial cells to surfaces or substrates or each other, embedded in EPS, and exhibiting specific phenotypes in terms of gene transcription and growth rates. A bacterial biofilm is composed of a single microorganism or a mixture of bacteria, fungi, archaea, protozoa, and yeasts. It has a channel structure that controls the release of gases, nutrients, and antimicrobials.

Free-floating bacterial cells can also aggregate to form biofilms, which exhibit similar characteristics to medical device-related biofilms (Hall-Stoodley et al., 2012). With the improvement of medical technology, the widespread use of medical devices, and the

A53210128

pursuit of high quality of life for patients, medical device-associated biofilms pose a severe threat to the life and health of patients. Microorganisms can adhere to almost all medical devices and cause medical device-associated biofilm infections. Device-associated infections usually occur during treatment, where some microorganisms originate from the host. When these microorganisms attach and colonize the surface of a medical device, they can form a biological container. The pathogenesis of medical device-associated infections is related to microorganisms in complex communities that adhere to and grow on device surfaces. Medical device-related biofilms can consist of single or multiple species, depending primarily on the type of device and the time it is left in the patient's body. In most cases, device-associated infections are associated with biofilm formation on device surfaces. When floating bacteria come into contact with the surface of a medical device, they secrete polymers that create a three-dimensional matrix, which eventually sticks to the surface of the device, forming a biofilm structure. When the biofilm on the surface of implanted medical devices reaches a critical level, it can induce an inflammatory response in the host and may even cause implant failure. The most common microorganisms for medical device-associated infections are *Staphylococcus aureus* and *Staphylococcus epidermidis*. Multi-resistant gram-negative bacteria (e.g., *Escherichia coli*, *Klebsiella pneumoniae*, *Pseudomonas aeruginosa*, and *Acinetobacter baumannii*) can also cause medical device-associated infections in complex hospital settings (Niveditha et al., 2012). In addition, microorganisms can adhere to various tissue surfaces in the body (e.g., skin, connective tissue, intestinal mucosa, vascular endothelium, oral cavity, airway, bone tissue, and vagina), which in turn can cause non-device (tissue) -associated biofilm infections and lead to various diseases (Wi and Patel, 2018). When microorganisms in the oral cavity attach to enamel, dentin, and mucosal epithelial tissues, they can form a dental plaque, which is influenced by the nature of the attachment surface, the intraoral environment, and the state of oral health.

When stimulated by the harsh environment, the exopolysaccharides, fibrins and lipoproteins secreted by bacteria adhere to the surface of inert objects and form microbial substances. EPS is conducive to bacterial adhesion and promotes the formation of a biofilm matrix composed of extracellular polysaccharides, exogenous DNA, proteins, and lipids (Schilcher and Horswill, 2020; Chiba et al., 2022). The EPS matrix reduces the effect of antibiotics by neutralizing antimicrobial agents or limiting diffusion using extracellular polysaccharides. EPS facilitates intercellular communication, protects cells from chemical damage, provides oxygen diffusion, releases extracellular enzymes for nutrition and, in turn, stimulates the spread of bacteria within the biofilm (Costa et al., 2018; Galdiero et al., 2019). Bacterial biofilms are highly structured, functional, specific and coordinated. Various substances in biofilms coordinate to complete several life activities, such as bacterial biofilms' morphological diversity, adhesion and protective barrier function. Taking *P. aeruginosa* as an example, Table 1 shows the main components and basic functions of biofilms.

Bacterial biofilms are communities of microorganisms derived from single or multiple bacterial strains. Compared with single-species biofilms, multi-species biofilms showed the following new characteristics through interspecies interactions: increased biofilm mass, increased community cell count, enhanced metabolic activity of community members, increased antimicrobial tolerance, and changes in spatial organization and structure (Sadiq et al., 2021). Multispecies biofilms exhibit new characteristics different from their floating state, resulting from competition or cooperation. The interactions among bacteria of multiple species are synergy, mutual benefit, cooperation, utilization, antagonism, and competition (Liu et al., 2016). Among them, synergistic interactions play an important role in regulating bacterial microbial activity and constructing complex spatial structures of multispecies biofilms. The cooperation and competition between bacterial cells promote the formation of multispecies biofilms. Multispecies biofilms are found in many natural environments, such as the oral cavity, implantable medical devices, and mammalian intestines. The physical interactions, co-adhesion, and metabolic cooperation among bacterial cells promote the formation of multispecies biofilms in natural environments. Until now, research has focused on single-species biofilms. But now microbiologists are paying more attention to multispecies biofilms and cell interactions between communities. The early stage of multispecies biofilm formation is the adhesion and aggregation of microbial cells. Different biofilm-forming abilities and strategies of various bacteria and microorganisms lead to the formation of multiple types of biofilm (Yao et al., 2022). Multispecies biofilms are associated with developing various diseases, such as cystic fibrosis, diabetic foot ulcers, chronic wounds, and otitis media (Chan et al., 2017; Loera-Muro et al., 2021). The development and outcome of multispecies biofilm-associated diseases are related to the physiological organization and distribution of biofilms.

TABLE 1 Main components and basic functions of *P. aeruginosa* biofilm.

Components	Percentage (%)	Functions	Authors
Exopolysaccharides	1-2	Maintaining the structure and stability of biofilm matrix	Rather et al., 2021
Proteins (including enzymes)	<1-2	Maintaining the stability of biofilm matrix and surface colonization; Maintaining the structural integrity of biofilm	Fong and Yildiz, 2015
Extracellular DNA	<1-2	Promoting biofilm formation; Protecting the integrity of bacterial biofilms; Maintaining structural stability; Protecting the host immune system	Okshevsky and Meyer (2015)
Water	Up to 97	Keeping the biofilm hydrated to prevent it from drying out	Flemming and Wingender (2010)

Due to species diversity, the various stages of bacterial biofilm formation vary but are generally close. The formation of bacterial biofilms is a multi-step process, as shown in Figure 1, including molecular attachment to the surface of an object, bacterial adhesion and secretion of extracellular polymeric substances, maturation of the biofilm through the formation of colonies, and bacterial cell escape and dispersion and formation of a new biofilm structure (Kranjec et al., 2021). The process of bacterial biofilm formation is detailed below.

The attachment of bacterial microorganisms to a surface is the first stage of bacterial biofilm formation. The bacterial cells are transported to the object's surface by convection, Brownian motion, or sedimentation (Palmer et al., 2007). Chemotaxis is prevalent in bacterial microorganisms and refers to the ability of planktonic bacterial cells in fluids to move along a distribution of material concentrations towards chemically induced substances (i.e., sugars and amino acids) or nutrient sources. It promotes interaction between bacterial cells and the surface of an object, which in turn stimulates the colonization and growth of planktonic bacteria on the surface. When planktonic bacteria reach the surface of an object, the sum of the attractive or repulsive forces between the cell surface and the object's surface determines the interaction between the two characters. When the repulsive force is greater than the attractive force, bacteria cannot adhere to the surface; conversely, when the attractive force is greater than the repulsive force, bacteria can stick to the surface (Carniello et al., 2018). Planktonic bacteria adhere to the surface of objects by non-specific physical forces such as van der Waals forces, electrostatic forces, and hydrophobic interactions (Carniello et al., 2018), and planktonic microbial cells are transformed into stable cells. Still, the process is reversible, and the adhesion is weak. Reversible bacterial cells can maintain a two-dimensional structure Brownian motion and can separate from the surface of an object by their mobility and shear effects. The substrate required for bacterial biofilm growth refers to all substrates that come into contact with planktonic bacteria. Physico-chemical properties such as the substrate surface's roughness, hydrophobicity, film modulation, and surface charge can influence the efficiency of planktonic bacterial colonization and biofilm formation.

Hydrophobicity plays a vital role in the attachment of bacterial microorganisms to surfaces. A hydrophobic surface is more conducive to bacterial microbial colonization than a hydrophilic material, probably due to the hydrophobic effect, which reduces the repulsion between the bacterial cell surface and the substrate. Yu et al. (2016) suggest that *Streptococcus mutants*' attachment can influence the hydrophobicity and roughness of the substrate. Bacterial cell surface hydrophobicity is influenced by multiple factors such as bacterial species, growth rate, and culture medium. Hydrophobicity affects the attachment of bacterial microorganisms to surfaces, and when the surface of a bacteria or object is more hydrophobic, the stronger the adhesion between the two. The structural and physicochemical properties of bacterial cells and object surfaces determine whether bacteria attach to hydrophilic or hydrophobic surfaces. Another physical factor affecting bacterial microorganisms' attachment surface is the surface charge. Many amino, carboxyl, and phosphate groups in most bacterial cells give them a negative surface charge. A positively charged surface facilitates the attachment of planktonic bacteria, while a negative charge hinders the attachment of bacteria (Tuson and Weibel, 2013). The surface charge of bacterial cells is influenced by bacterial species, age, environmental pH, ionic strength, and culture medium. The regulatory film is an integral part of the bacterial adherent surface. Almost all planktonic bacteria come into contact with the regulatory film as they transit from the medium to the surface. It is formed as a nutrient adsorbed onto the surface of an object, resulting in a change in the physicochemical properties of the material surface, which in turn affects the attachment of bacterial cells.

The second phase is irreversible adhesion, where microbial cell surface components can recognize bacterial adhesion molecules and consolidate bacterial interconnections (Nourbakhsh and Namvar, 2016). This phase is accomplished through bacterial cell surface hydrophobicity, hydrogen bonding, covalent bonding, ionic bonding, and dipole-dipole interactions. As bacterial cell surface

A53210128

adhesion structures, flagella and fimbriae can form bacterial biofilms and contribute to the physical contact of planktonic bacteria with the substrate (Carniello et al., 2018). Flagella can swim in liquid substances and swarm on the surface of wet solid substances. Through these two forms of movement, various species of bacterioplankton direct cell adhesion to surfaces and transfer to favorable environments. Flagella initiate the adhesion of planktonic bacterial cells to surfaces, primarily because of the ability of flagella to overcome the resistance that prevents cell-surface interactions. Fimbriae also contribute to the early adhesion of bacterial cells to surfaces and each other. *P. aeruginosa* generates bacterial cell surface motility through fimbriae in a manner known as twitching motility. As an intercellular signaling mechanism, the Quorum sensing (QS) system also significantly facilitates the formation of bacterial biofilms in single cells (Abraham, 2016). Bacterial cells use means through QS to synthesize and release first messengers, such as chemical signals, to enable communication between bacterial flora. Both Gram-positive and Gram-negative bacilli affect the formation of bacterial biofilms. Gram-positive bacilli utilize oligopeptides, while Gram-negative bacilli utilize acyl homoserine lactones (Muhammad et al., 2020).

Bacterial cell synthesis and secretion of EPS is the third stage of bacterial biofilm formation. EPS substrate is hydrophobic and ion bridging, which can promote bacterial condensation and biofilm adhesion. EPS can affect surface adhesion, bacterial biofilm formation, biofilm internal structure, mutual recognition between cells, signal transduction system, nutrient acquisition, cell maintenance, and genetic information exchange, playing a crucial role in various aspects (Costa et al., 2018). The second messenger, c-di-GMP, can stimulate bacterial adhesion from a reversible to irreversible state, mainly due to its ability to produce the EPS matrix and form bacterial cell surface structures. As an essential component of the EPS matrix, extracellular polysaccharides are necessary for most bacteria to form biofilms and promote their development. EPS is also rich in proteins (i.e., enzymes)and protein structures (i.e., fimbriae). At the same time, eDNA and lipids are also components of the EPS matrix. The former can connect to bacterial cells, while the latter can affect the attachment of *Thiobacillus ferrooxidans* (Flemming et al., 2016).

The maturation of bacterial biofilms is the fourth stage of biofilm development. Bacterial biofilms mature as bacteria replicate and multiply in the EPS matrix, forming small microbial colonies and generating three-dimensional structures. As the EPS matrix accumulates and bacterial colonies form, this leads to altered gene expression, and the induction products of these genes can be used for EPS matrix generation. When the matrix is formed, water channels can be generated, which act by a mechanism similar to the body's circulatory system to deliver available nutrients to the cell community while rejecting extraneous products.

The process of dispersal of bacterial biofilms is the final stage of biofilm development. After a while, the mature bacterial biofilm may suffer damage, and the biofilm structure evolves. Still, the released bacterial microorganisms can infect other parts of the organism and form new biofilm structures. The mechanisms of dispersal are different due to the specificity of the bacteria. Still, all broadly involve the following three standard processes: detachment of bacterial cells from small colonies, transfer of bacterial cells to other substrates, and attachment of bacterial cells to new substrates (Shen et al., 2018). The process of detachment of bacterial biofilms can be either active or passive behavior. Active behavior refers to seeding dispersion, where bacterial cells in the biofilm undergo their detachment to adapt to environmental changes when the bacterial biofilm is subjected to matrix-degrading enzymes, antimicrobials, and nutrient deprivation. Passive behavior refers to shedding and erosion dispersion mediated by external forces (e.g., shear). Shedding dispersion refers to the abrupt shedding of a large proportion of the bacterial biofilm, and erosion dispersion refers to releasing a portion of bacterial cells in a bacterial biofilm. Low expression levels of c-di-GMP can inhibit the formation of bacterial biofilms and promote biofilm separation (Kaplan, 2010). Thus, inhibition of the c-di-GMP signaling pathway can effectively disperse bacterial biofilms. Changes in environmental factors such as temperature, pH, oxygen, and nutrient content can also affect the dispersion process of bacterial biofilms. For example, low-oxygen environments can facilitate bacterial biofilm dispersion by accelerating the rate of c-di-GMP degradation. Increased glucose levels can reduce the amount of c-di-GMP in the organism and promote flagellar synthesis, which slows down the progress of separation (Lee and Yoon, 2017).

The process of bacterial biofilm formation is influenced by temperature and blood pH changes, nutrient content, quorum sensing, Brownian motion, and surface properties. At the same time, different strains and signal transduction also affect the formation of bacterial biofilm. The structure of mature biofilm is a matrix layer, regulatory layer, connective layer and bacterial biofilm layer from inside to outside.

Microorganisms can form biofilms on the surface of the device, causing the development of infectious diseases in the organism. Medical implants have brought hope to the medical revolution and provided new opportunities for human life and health progress. Still, they also increase the risk of infections in the body tissues. Bacterial adhesion is the first step in forming biofilms for device-related infections and is divided into two stages: initial non-specific reversible adhesion and specific irreversible adhesion. *S. aureus* and *S. epidermidis* are the main strains (Pietrocola et al., 2022). These microorganisms can come from the patient's skin, the healthcare worker's skin, or the environment. *S. epidermidis* adheres to each other and medical devices by using adhesins. *S. aureus* relies on adhesin ligands (fibronectin, fibrinogen, and collagen) for its adhesion (Darouiche, 2001). The prerequisite for device-related biofilm formation is the coating of the medical device with plasma proteins (Arciola et al., 2018). The type and amount of plasma proteins adhered to the device surface are mainly determined by the surface's physicochemical properties and the plasma proteins' characteristics. When *S. aureus* sticks to the surface of a medical device, it can interact through adhesins. Adhesins specifically recognize plasma proteins coated on the surface of the device. *S. aureus* can then proliferate and produce EPS composed of extracellular polysaccharides, proteins, and eDNA. The final stage is when the *S. aureus* community disperses and spreads the infection (Pietrocola et al., 2022). Inhibition of EPS production, enzyme-promoted EPS degradation, and surfactants all

A53210128

contribute to the bacterial dispersion process (Solano et al., 2014). The characteristic change of biofilm dispersion in *S. aureus* is the formation of phenol-soluble modulins (PSM) and extracellular enzymes. PSM plays an essential role in the diffusion stage of biofilm. It disrupts the non-covalent binding forces that strengthen the biofilm matrix, helping to form channels for transporting nutrients to deeper biofilm layers (Peschel and Otto, 2013).

Biofilms are a persistent cause of infection in implanted medical devices. The formation of device-related biofilms is closely related to the interactions between microbial cells. The common microorganisms that can form biofilms on the surface of equipment include *S. aureus*, *S. epidermidis*, *E. coli*, *P. aeruginosa*, *K. pneumoniae*, and *Enterococcus faecalis*. When a medical device is contaminated with these microorganisms, the formation of biofilms depends on several factors. First, the microorganisms must adhere to the exposed surface of the implant long enough to reach the irreversible attachment stage. The adhesion speed of microbial cells on the surface of the device mainly depends on the content and types of bacterial cells in the liquid exposed by the equipment, the liquid's flow speed, and the physical and chemical properties of the surface. At the same time, the composition of the fluid can change the properties of the device's surface and affect the rate of cell attachment. When microbial cells irreversibly adhere to the surface of a medical device and produce EPS to form a biofilm, the rate of growth and development is influenced by the flow rate, nutrient content, antimicrobial concentration, ambient temperature, and pH (Donlan, 2001). In the absence of antimicrobial agents, when a medical device is implanted in a host, the surface of the device is immediately surrounded by multiple fluids (e.g., blood, saliva, urine, and other fluids). Mucopolysaccharides, glycoproteins, and metal ions then appear within minutes. These substances can penetrate and adhere to the surface of the device. The bacterial cells can use their surface-specific adhesion molecules to recognize the device surface receptors and thus undergo the adhesion process. Once the microorganism adheres to the device surface, the gene expression level is immediately affected. During the growth and reproduction phase, bacterial cells can synthesize EPS, form microbial communities, and then form biofilms (Huang et al., 2022).

Microorganisms colonize almost all central venous catheters implanted in patients. The most common microorganisms that form catheter biofilms are *S. aureus*, *S. epidermidis*, *P. aeruginosa*, and *K. pneumoniae* (Elliott et al., 1997). These microorganisms can move outward from the skin or inward from the port along the outer surface of the central venous catheter. Colonization of the catheter surface by microorganisms can occur within 24 hours. Biofilms can commonly form on the surface of central venous catheters, but the location and extent of bacterial biofilm formation are influenced by the time of catheter implantation. When the catheter is implanted <10 days, more biofilms can form on the external surface of the catheter. When implanted >30 days, biofilms are more likely to form in the catheter lumen (Raad et al., 1993). Common contaminating microorganisms on urinary catheters are *S. epidermidis*, *E. faecalis*, *E. coli*, *P. aeruginosa*, and *K. pneumoniae*. When the catheter is implanted in the body, these microorganisms tend to form biofilms on the internal and external surfaces. The longer the catheter is left in place, the greater the ability of these microorganisms to form biofilms and the greater the likelihood of causing urinary tract infections.

Microorganisms can form biofilms on non-device (tissue) surfaces. There are several stages of dental plaque biofilm formation. First, the tooth's surface is covered with an organic "membrane" composed of immunoglobulins, carbohydrates, and glycoproteins. These substances can adhere to the surface of hydroxyapatite through electrostatic interactions. This interaction is generated between Ca2+, phosphate, and molecular groups with opposite charges in saliva. Among other things, carbohydrates comprise intracellularly stored polysaccharides and other intracellularly present polysaccharides. Water-insoluble glucans and fructans promote the attachment of bacterial cells to the tooth surface (Jakubovics et al., 2021). Bacterial cells can bind to surface organic membranes, leading to interactions between adhesion factors and fimbriae, capsules, and complementary receptors. Subsequently, the bacterial cells adhering to the tooth surface can produce various exopolymers to synthesize biofilm EPS (Mirzaei et al., 2020). Maturation and dispersion of dental plaque biofilm is the final stage. During the initial process of dental plaque biofilm formation, the source of nutrition for microbial cells is through the breakdown of salivary substrates (e.g., mucins and other glycoproteins) (Jakubovics, 2015). *P. aeruginosa* is the leading cause of death in patients with cystic fibrosis combined with *P. aeruginosa* infection due to its high virulence factor, biofilm formation, and resistance to antimicrobials. High levels of c-di-GMP expression generally promote matrix production and biofilm formation. In contrast, low levels of c-di-GMP expression down-regulate matrix production and can lead to a bacterial planktonic lifestyle. Carbon starvation and nitric oxide signaling can affect phosphodiesterase activity in *P. aeruginosa* cells, reducing the intracellular expression of c-di-GMP in the cells (Bjarnsholt et al., 2010). *P. aeruginosa* can produce a small molecule that can induce the dispersion of mature biofilms (Davies and Marques, 2009).

Bacterial biofilms provide an excellent and stable homeostasis environment that prevents host immune cells and antibiotics from entering the bacterial biofilm community while protecting bacterial microorganisms from the effects of blood pH, osmotic pressure, and nutrient deficiency. Thus, by providing a physical barrier for bacteria and microorganisms, bacteria can communicate with each other and co-exist, even in harsh conditions. This communication mechanism, called the quorum sensing system, comprises extracellular chemical signals (known as autoinducers). The QS system can help bacteria and microorganisms sense population density and influence biofilm formation and maturation, antibiotic resistance, bacterial communities, and bacterial-host interactions (Whiteley et al., 2017; Paluch et al., 2020). At the same time, some signaling molecules in bacterial microorganisms, such as c-di-GMP, can affect bacterial behavior, including cell cycle, cell movement, pili synthesis, RNA regulation, stress response, and bacterial virulence (Loera-Muro et al., 2021). Bacterial biofilms have specific immune escape mechanisms, including inhibition of immune cell function, alteration of gene expression, obstruction of immune recognition, and mechanical protection (Campoccia et al., 2019; de Vor et al., 2020). When

A53210128

bacterial organisms accumulate on the surface and form biofilms, the clearance function of immune cells is impaired, a phenomenon known as impaired phagocytosis (Urwin et al., 2020).

To provide additional research on bacterial biofilms, we review bacterial biofilm-associated infections, describe current methods used to detect biofilms and effective strategies for treating bacterial biofilms, and give an outlook on the development and future of bacterial biofilms.

2 Biofilm-associated infection

Bacterial biofilms can cause serious infections, such as multidrug-resistant, broad-spectrum drug-resistant, and complete drug-resistant bacteria. Currently, more than 80% of bacterial infections are caused by the formation of bacterial biofilms (Fleming and Rumbaugh, 2017). Bacterial biofilms can cause disease in the body through device-related and non-device-related infections. The following will describe the biofilm infections in terms of both and the relationship of bacterial microorganisms to infectious diseases and adhesive surfaces.

2.1 Device-related infections

The use of medical devices improves the quality of life for patients. Still, suppose bacterial biofilms form on the surfaces of medical implants (e.g., dental devices, catheters, heart valves, ventricular shunts, joint prostheses). In that case, they may cause bloodstream and urinary tract infections, posing a severe threat to global health. Medical device-associated infections are closely linked to biofilm formation, and the bacterial biofilm on the surface of most devices is composed of a variety of bacteria. Bacterial organisms first attach to the surface of the medical device or the surrounding tissue of the breakage. Bacterial cells proliferate, develop, and form a bacterial biofilm, which is then encapsulated in the EPS. At the same time, the bacterial cells are released from the bacterial biofilm. They can be transmitted through the bloodstream leading to infection or recurrence of localized lesions elsewhere in the body.

Cardiac implants, including pacemakers, artificial heart valves, cardioverter-defibrillators, and cardiovascular implantable electronic devices, are associated with higher morbidity and mortality due to infections (Habib et al., 2013). Gastrointestinal devices are associated with a wide range of microorganisms. A study using scanning electron microscopy showed defects in percutaneous endoscopic gastrostomy cannulas (PEGs), which can provide suitable sites for the attachment of bacterial microorganisms and biofilm formation (Dautle et al., 2003). The study found that bacterial biofilms were present on the surfaces of all devices included in the examination and that PEGs are a risk factor for colonization of the gastrointestinal tract by drug-resistant bacterial microorganisms and the formation of bacterial biofilms. Orthopedic implant surgery is often a safe and efficient treatment modality that restores hip and knee function and enhances patient well-being. However, there are still postoperative complications, the most common of which is an artificial joint infection, on top of which the formation of a combined bacterial biofilm may lead to osteomyelitis.

Neurosurgical implants include cerebrospinal fluid shunts, extra-ventricular cerebrospinal fluid drains, and neurostimulators. The main microorganisms in cerebrospinal fluid shunts are *S. epidermidis* and *S. aureus* (Fux et al., 2006). The microorganisms capable of forming biofilms on extra-ventricular cerebrospinal fluid drains are mainly *S. aureus*, followed by *Propionibacterium acnes* (Strahm et al., 2018). In neurostimulator-associated infections, common pathogenic microorganisms include *S. aureus*, *P. aeruginosa*, and *P. acnes* (Conen et al., 2017). The incidence of infection with these devices is 3-15%, with a higher incidence of infection with extra-ventricular cerebrospinal fluid drains (Caldara et al., 2022). These infections can be fatal to patients and increase morbidity and mortality. Permanent or temporary urinary catheters, nephrostomy tubes, penile implants, and ureteral stents are the most commonly used devices in the genitourinary system. Bacterial biofilms can be found on the surfaces of all these devices. In most clinical situations, infections from implanted stents occur, with fever and urinary tract infections being the most common complications, and even bacteremia and death may occur (Kehinde et al., 2002). Endovascular devices commonly used in clinical practice include intravenous infusions, hemodialysis, haemodilution, and parenteral nutrition. The risk of infection is increased by irregular disinfection, environmental contamination, and incomplete biofilm removal from the surface of implanted devices. To reduce the risk of infection, we should improve disinfection protocols and procedures in the future and detect the propensity for contamination of all types of implanted devices. Breast implants can be used for breast reconstruction and cosmetic surgery, helping improve patients' quality of life. However, breast implants are susceptible to complications such as infection, hematoma, contracture of the envelope, and scar formation. Contracture can lead to the removal or revision of the implant, causing discomfort and swelling of the breast and affecting its appearance. The researchers detected bacteria in 85% of the breast implants that developed periosteal contracture. They examined them using scanning electron microscopy and found bacterial biofilms in over half of the implants (Pajkos et al., 2003). *P. acnes*, *Streptococcus* spp., *Lactobacillus* spp., *Bacillus* spp., and *Mycobacterium* spp. can survive in the environment around breast implants and form a bacterial biofilm.

Bacteria in the mouth are closely linked to diabetes, heart disease, lung inflammation, and systemic diseases. Prevention and treatment Kalamaraof oral diseases can help prevent these diseases. Oral implants can be used to restore the normal function of the mouth. When bacterial microorganisms colonize the surface of these materials, a solid bacterial biofilm usually forms, leading to inflammation around the implant, which may damage healthy gums. The microorganisms can degrade the composite resin, and the bacteria can invade the implant and tooth interface, leading to severe consequences. Clinicians can apply prophylactic antibiotic treatment to avoid this outcome. At the same time, proper treatment planning, proper implant placement, attention to changes in condition, medication history, and monitoring of

underlying health conditions (e.g., diabetes, hypertension, obesity, osteoporosis) are essential to prevent implant failure. Bacterial keratitis is a cornea infection characterized by forming a bacterial biofilm on the eye's surface. If patients do not receive timely and effective treatment, it will likely lead to vision loss or even loss of vision. Bacterial keratitis is associated with various risk factors, such as corneal trauma, contact lens wear, surgical treatment of the eye, and immunocompromised systemic disease (Ng et al., 2015). Corneal trauma is a significant risk factor for bacterial keratitis in developing countries. Contact lenses are the primary source of bacterial keratitis infection in more developed countries. It can alter the corneal epithelium and carry bacterial organisms to the eye's surface. Bacterial keratitis is associated with the formation of a variety of bacterial biofilms. The lens materials (e.g., water retention, hydrophobicity) and contact lenses' physical and chemical properties can influence the colonization of bacterial biofilms. We should follow up with a vigorous search for novel materials to prevent implantable device-related biofilm infections. The most common bacterial organisms on the surface of medical devices are described in detail in Supplementary Table 1. In conclusion, medical device implant-related biofilm infections increase morbidity and mortality in patients, especially hospitalized patients, and pose a severe threat to their quality of life. We should pay more attention to the composition of different bacterial microorganisms on the surface of specific medical devices, continue to study biofilms *in vivo*, and systematically describe the interrelationship between bacteria on device surfaces and the surrounding environment of implants.

2.2 Non-device-related infections

Non-device-related infections also have a significant impact on health problems. Dental plaque (Rabe et al., 2022), urinary tract infections (Singh et al., 2022), cystic fibrosis (Vandeplassche et al., 2020), otitis media (Bair et al., 2020), infective endocarditis (Han and Poma, 2022), tonsillitis (Klagisa et al., 2022), periodontitis (Prado et al., 2022), necrotizing fasciitis (Grier et al., 2021), osteomyelitis (Huang et al., 2022), infective kidney stones (Fayez Hassan et al., 2021), chronic inflammatory diseases (Wu et al., 2015), bacterial vaginitis (Arroyo-Moreno et al., 2022), and bladder infections (Mirzaei et al., 2020) are all examples of non-device-related bacterial biofilm infections.

The human oral environment, with its favorable temperature and humidity and rich in micro-nutrients, can provide adequate conditions for bacterial growth, survival, and the formation and maturation of dental plaque biofilms. The most common microbial cell grouping in the oral cavity is the bacterial cell, followed by various fungi, viruses, and protozoa. Oral microorganisms co-exist with each other, maintain mutually beneficial relationships with their hosts, and generally do not cause disease. If this community changes, the symbiotic and mutually beneficial balance will be disrupted, leading to various conditions, such as dental caries. Bacterial microorganisms in the mouth can enter the circulation, affect the heart's function, and bind fatty plaque in the coronary arteries. Dental biofilms can cause periodontitis and gingivitis and even lead to tooth decay. Chronic bacterial infections cause almost all periodontal diseases. Periodontal infections increase the incidence of inflammation, promote the formation of plaque, and lead to edema in the coronary arteries. During the maturation of bacterial biofilms, anaerobes are the main colonizing bacteria in the human mouth. Several studies have shown that dental biofilms can cause not only the development of periodontitis but also various systemic diseases such as diabetes mellitus, infective endocarditis, and rheumatoid arthritis (Larsen and Fiehn, 2017; Marsh and Zaura, 2017). The main bacteria that play a role include *Porphyromonas gingivalis*, *Bacteroides forsythus*, and *Aggregatibacter actinomycetemcomitans*.

Lactobacillus strains can be associated with health problems by producing lactic acid to maintain a low pH environment in the vagina, thereby protecting the female genitourinary tract from bacterial microorganisms not of its origin. *Lactobacillus* spp. can play a role in maintaining the homeostasis of the vaginal environment while preventing bacterial microbes from colonizing and infecting it. Women are more prone to urinary tract infections than men because of the proximity of the female urethra to the anus, vagina, and rectum. Disturbances in the body's vaginal bacterial microbiota also increase women's risk of urinary tract infections. Estrogen plays a role in maintaining a low pH environment in the vagina, and post-menopausal women are more likely to develop urinary tract infections than younger women due to a lack of estrogen. The most common pathogenic bacteria for urinary tract infections in adult women is *E. coli*. Uropathogenic *E. coli* (UPEC) strains may evade the body's immune response by stimulating a pro-inflammatory reaction or obscuring the immunogenic bacterial component. Bacterial biofilms may play a key role in maintaining the sustainability of UPEC strains in the bladder and vagina. The second most common pathogen of urinary tract infections is *Proteus* spp. When they first adhere to surfaces, *Proteus mirabilis* can proliferate, develop and form biofilms, enhancing the antimicrobial properties of bacterial microbes and protecting the bacteria from the body's immune function. Bacterial biofilms are an essential factor in the persistence and existence of bacterial infections, and their diversity can influence the viability and survival of bacterial microorganisms (Delcaru et al., 2016). In addition, bacterial biofilms play an important role in renal pathology and can affect renal stones and the dialysis system. Pathogenic bacteria invade renal tissue and can cause chronic pyelonephritis and bacterial prostatitis. Most of the *E. coli* strains isolated from bacterial prostatitis exhibit the potential to form bacterial biofilms.

Bacterial vaginitis is the most common vaginal infection worldwide and severely impacts the quality of life of women who suffer from it. It is characterized by increased vaginal discharge, usually accompanied by a specific irritating odor. Various bacterial biofilms are present on the surface of the vaginal epithelium. *Gardnerella vaginalis* is associated with bacterial vaginitis infections and has been shown in several studies to produce bacterial biofilms on vaginal tissue and enhance the expression of various virulence factors (Castro et al., 2015; Gaspar et al., 2021).

Cystic fibrosis responds poorly to medications and is one of the chronic inflammatory diseases. Several studies have shown that

A53210128

most people with cystic fibrosis are susceptible to *P. aeruginosa* infections (Harrison, 2007; Filkins and O'Toole, 2015). *P. aeruginosa* infections in combination with cystic fibrosis are challenging to cure, mainly due to the formation of bacterial biofilms in the lungs of patients with cystic fibrosis. *P. aeruginosa* can colonize, develop and form bacterial biofilms in the lungs of people with cystic fibrosis due to the excessive release of mucus in the airways, providing an environment with low oxygen levels. Chronic *P. aeruginosa* infection can lead to complications such as epithelial tissue damage, mucus obstruction of the airways, respiratory dysfunction, and even accelerated death.

Infective endocarditis is a refractory disease that severely threatens human life and health. Although medical technology has been refined, the mortality rate of patients with co-infected endocarditis during hospitalization is still higher than 20% (Beynon et al., 2006). The ability to generate bacterial biofilms is critical in the virulence of bacterial microbes associated with infective endocarditis. Studies (Elgharably et al., 2016; Polewczyk et al., 2017) have confirmed that many bacterial microorganisms can form infectious neoplasms on the surface of the heart, which can lead to the development of infectious endocarditis. These neoplasms are essentially large bacterial biofilms. Using immunofluorescence staining techniques and electron microscopy, Bosio et al. (2012) found *Mycobacterium fortuitum* biofilms on infected artificial biological heart valves. Bacterial microorganisms shed from biofilm structures and enter the blood circulation, and the body will develop bacteremia and sepsis manifestations. Of these, bacteremia is controlled by the collective immune defense system and antimicrobials. Although bacteremia can be effectively prevented or even eliminated with aggressive treatment, the deeper biofilm and neoplasm structures can provide a "hideout" for the ever-present bacterial biofilm cells. When bacterial cells in biofilm structures are repeatedly shed, it is easy to develop septic embolism in the distal limb (Mirzaei et al., 2020).

Otitis media is a complex inflammatory disease, and its complications are a major cause of hearing loss. Approximately 75% of infants under three years suffer from middle ear-associated infections. Bacteria capable of forming biofilm in the middle ear are the leading cause of chronic bacterial infections. Using molecular methods, researchers have demonstrated that the DNA of *Haemophilus influenzae*, *Moraxella catarrhalis*, and *Streptococcus pneumoniae* can be detected in up to 80% of infants with otitis media (Otsuka et al., 2013).

The formation of bacterial biofilms can lead to severe chronic inflammatory and autoimmune diseases in the body. L-type pathogens and chronic biofilm infections can cause the development of inflammatory diseases. The vitamin D receptor is an alkaline substance that regulates the activity of immune cells and is the primary defense against bacterial microbial infections. Specific L-type and biofilm-forming pathogens can produce a substance that adheres to and kills the vitamin D receptor. Thus, as chronic bacterial biofilms and L-type pathogens accumulate in the body, most bacterial microorganisms can produce substances that inactivate the vitamin D receptor and severely compromise the body's immune defenses. Supplementary Table 2 describes non-device-related biofilm infections.

2.3 Bacterial biofilm cause tissue related and device associated infections

S. aureus and *S. epidermidis* can form biofilms on the surfaces of central venous catheters, heart valves, suture devices, and prostheses, in turn, can cause nosocomial infections, endocarditis, mucus cysts, and otitis media (Qu et al., 2010; Arciola et al., 2012). *P. aeruginosa* forms biofilms on the surface of contact lenses, central venous catheter, middle ear, and prosthesis, which can cause nosocomial infection, cystic fibrosis, and otitis media (Wiley et al., 2012; Huse et al., 2013). Bacterial biofilms formed by *S. aureus*, *E. coli* and *Streptococcus agalactiae* can cause mastitis (Loera-Muro et al., 2021). *E. coli* can form biofilms on medical devices such as catheters (Zhang et al., 2019), ultrasonic instruments (Khatoon et al., 2018), and contact lenses (El-Ganiny et al., 2017). The relationship between bacterial microbes adhering to surfaces to form bacterial biofilms and thus causing disease is detailed in Supplementary Table 3. The formation of bacterial biofilms will increase mortality in hospitalized patients (Batoni et al., 2016; Evans and Bolz, 2019). Multiple biofilm infections may exhibit different antibiotic sensitivities. Although the specific details of bacterial interactions in numerous microorganisms are not yet precise, there are metabolic links and spatial organization among bacteria, which may result in quorum sensing and resistance gene transfer to produce more antibiotic-resistant biofilms (Røder et al., 2020; Sadiq et al., 2021).

The three-dimensional structure of bacterial biofilm can act as a natural barrier to antibiotics and reduce the sensitivity of biofilm to antibiotics. Bacterial biofilm resistance to antibiotics is known to be 10–1000 times higher than planktonic bacteria (Ning et al., 2014), which may be related to the different antibacterial mechanisms between them. Biofilm communities produce antibacterial target mutations, efflux pumps, higher transverse transfer frequency, reduced cell permeability, and drug-neutralizing proteins (Kumar et al., 2013; Lata et al., 2015; Sharma et al., 2015; Sharma et al., 2016). In addition, there is a particular type of bacterial cell phenotype in biofilms – persistent cells, which can survive under the action of a powerful immune defense system and powerful antibiotics. These cells have metabolic inertia, slow growth and replication, and can regulate virus-antitoxic systems and enhance antioxidant and DNA repair systems. They show an inability to respond to antibiotics (Rather et al., 2021). Anoxia, nutrient deficiencies, antibiotic modification enzymes, and oxidative stress can also lead to antibiotic resistance in bacterial biofilms (Hall and Mah, 2017). Due to the phenotypic diversity of bacterial biofilms, the content of antimicrobials entering the biofilms will be reduced, and the microenvironment within the biofilms will be changed, causing the biofilms' resistance mechanism to antibiotics (Sharma et al., 2019), making it difficult to eradicate. In addition, genetic mutations can also lead to antimicrobial resistance in bacterial biofilms. As a result, the effect of antibiotics commonly used in clinical practice on bacterial biofilms is insignificant.

In recent years, due to the increasing incidence of iatrogenic bacterial biofilm-associated infections, long-term infections are difficult to cure, which will pose a new challenge to preventing and controlling infectious diseases caused by biofilms. In addition,

A53210128

bacterial biofilms can avoid the scavenging action of conventional antibiotics and the killing effect of the body's immune system and become a possible source of infection. Currently, methods for detecting, inhibiting and treating biofilm-associated infections are inadequate, and managing bacterial biofilm-associated infections remains a significant challenge. In addition, due to the specific environment within the biofilm, we cannot treat biofilm-associated infections with traditional antibiotics, and researchers must propose new antimicrobial or anti-biofilm-associated treatment strategies.

3 Methods for detecting bacterial biofilms

3.1 Nuclear medical imaging technology

Nuclear medicine imaging remains the standard method for detecting infectious diseases (Salmanoglu et al., 2018). As radionuclides, technetium-99m, indium-111, and iodine-125 have been shown to be useful for radio-labelling compounds. Still, some drawbacks exist, such as low expression of target receptors on the bacteria studied, non-specific adsorption, and complex radiochemical synthesis (Eggleston and Panizzi, 2014). A recent study found that as a metabolic product of bacteria, the maltodextrin transport system can also radially label compounds and trace them to detect bacterial biofilm infection (Auletta et al., 2019). Nuclear medicine imaging technology also has certain disadvantages, such as the need for specialized equipment and instruments, operator training, and patient exposure to radiation (Cruz et al., 2021).To further improve the sensitivity of nuclear medicine imaging, relevant researchers have developed an MH18F nuclear imaging agent, which can participate in the metabolism of bacterial carbohydrates and be internalized by maltodextrin transporter specific to bacteria (Auletta et al., 2019), contributing to the early detection of bacterial biofilms.

3.2 Ultrasonic technology

Ultrasonic technology can monitor dirt on instrument surfaces in real-time and has been shown to monitor the formation and growth of some bacterial microbial colonies (Kujundzic et al., 2007). Combined with other methods, it can enhance the detection strategy of bacterial biofilms (Vaidya et al., 2014). Ultrasound echo enhancers and microbubble contrast agents have opened up new avenues in diagnostic ultrasound medicine (Calliada et al., 1998). Ultrasonic medical imaging technology has matured with the application of contrast media, which contributes to the accuracy of medical diagnosis. The application of targeted ultrasonic contrast media is conducive to determining the difference between healthy and infected tissues (Unnikrishnan and Klibanov, 2012). The acoustic impedance of bacterial biofilms is similar to that of human tissue, making detection and *in vivo* targeting of bacterial biofilm substrates difficult. The combination of ultrasound and targeted ultrasound contrast agents can aid in the early detection and identification of bacterial biofilms and can help to improve therapeutic efficacy. Ligand-targeted ultrasound contrast agents can be a non-invasive imaging method for detecting early and late-stage bacterial biofilms. These agents can target, image, and detect the formation of the *S. aureus* biofilm matrix *in vitro* (Anastasiadis et al., 2014).

3.3 Crystal violet staining method

Crystal violet (CV) is the most commonly used staining method for the quantitative determination of microtiters of biofilms grown *in vitro* in polystyrene pore plates (Hassan et al., 2011). After CV staining, the structure of the biofilm can be observed directly by scanning electron microscopy. However, this staining method also has certain limitations, as it can reduce the number of bacterial biofilms after multiple washing (Hou et al., 2022), and the incubation time is longer. It is unsuitable for the rapid detection of biofilms. Castro et al. (2022) found that CV staining was highly effective for single-species biofilm detection. Still, in bacterial vaginosis, there might be bias in evaluating the formation of multiple bacterial biofilms.

3.4 Other detection methods

Bioluminescence analysis, tissue culture plate method, and percentage transfer method are also used to detect bacterial biofilms. Certain imaging techniques, such as infrared spectroscopy, reflection spectroscopy, optical fluorescence imaging, confocal laser scanning microscopy, target fluorescence imaging, and fluorescence *in situ* hybridization of peptide nucleic acid, can also be used to detect the formation of biofilms and provide spatial information on the distribution of strains and biofilms (Roy et al., 2018; Cruz et al., 2021). However, these imaging techniques depend on clear samples and are unsuitable for *in situ* bacterial biofilm detection. Raman and surface-enhanced spectroscopy offer high sensitivity and are non-invasive molecular detection techniques (Xu Y. et al., 2020). Laser capture micro-cutting technology has a high resolution, which can help researchers quickly separate or sample the required cells from solid tissue by laser beam, which is helpful for the detection of living biofilms. Ultra-wide-spectrum imaging is a labeling-free detection method showing bacterial biofilms in natural and wound environments.

One of the components of bacterial biofilm is protein, which is related to the types of pathogens and the stages of biofilm development and virulence. Several different proteins are listed below for their role in forming and maintaining biofilm structures. *S. epidermidis* expresses a variety of cell wall-anchored surface proteins that promote the formation of biofilms on the surface of medical devices, aid in binding to the EPS, and are a significant determinant of the virulence of *S. epidermidis*. For example, SdrG/Fbe protein can promote adhesion to the surface of conditioned biomaterials. SdrF protein enhances the adhesion between bacteria and fixed collagen. Embp protein can promote bacterial adherence to fixed fibronectin. Sesl protein may promote adhesion between bacteria and non-living surfaces. Sbp protein can

A53210128

promote the formation of amyloid protein and maintain biofilm integrity (Foster, 2020). McCourt et al. (2014) found that surface-bound fibronectin FnBPA and FnBPB could mediate the formation of methicillin-resistant *S. aureus* (MRSA) biofilm, increase bacterial aggregation, promote initial microbial adhesion on the surface, and facilitate biofilm accumulation. Manfiolli et al. (2018) showed that MAP kinases (MpkA, MpkC, and SakA) and phosphatases could regulate the *Aspergillus fumigatus* cell wall composition and affect cell adhesion and EPS production, as well as have essential effects on signaling pathways during biofilm formation. Liang et al. (2011) identified a novel cell surface protein, BapA1, from *Streptococcus parasanguinis* FW213 and found that it can affect biofilm formation. The BapA1 protein contains multiple putative fimbriae isopeptide junction structural domains that promote the aggregation of bacterial fimbriae in Gram-positive bacteria and is a novel streptococcal adhesin. When the BapA1 protein is deficient, it can inhibit the auto-aggregation of bacterial cells. Ye et al. (2018) found that outer membrane protein W (OmpW) contributed to the survival of *Cronobacter sakazakii* cells in a planktonic mode under the stress of NaCl and that the ability of cells to survive and form biofilms increased with increasing OmpW concentration.

Quantitative proteomics technology based on iTRAQ is helpful for the detection of bacterial biofilms and the search for promising targets for biofilm elimination (Sauer, 2003). The meta-proteomic analysis is an important technique for showing the interactions and functional roles of individual members of bacterial microbial communities. The areas of proteomics include protein function, expression level, post-translational modification, localization, stability, and adequate genome sequencing. Proteomic patterns are responses to the physiological state of cells and can elucidate bacterial biofilm phenotypes (Khemiri et al., 2016). Through the proteomic analysis of *Burkholderia pseudomallei* in the floating state and biofilm state, Khan et al. (2019) found that the change of proteome contributed to the survival of the biofilm by increasing the abundance of pressure proteins and reducing the presence of metabolic proteins. Ali Mohammed et al. (2021) used proteomic analysis to determine the proteome of *Fusobacterium nucleatum* and *P. gingivalis* expressed in the planktonic or biofilm state. The results showed that *P. gingivalis* produces fewer proteins due to the presence of *F. nucleatum* in the mouth. Resolution and dynamic range limit the initial development of proteomics techniques based on electrophoresis. The addition of transcriptomic analysis has led to the rapid development of proteomics because of its ability to detect solid structures capable of detecting functional cells. Charlebois et al. (2016) confirmed that by RNA transcriptional sequencing technology, 25.7% of genes were different between *Clostridium perfringens* biofilms and planktonic cells. About 12.9% of genes in biofilm cells were down-regulated, and about 12.8% were up-regulated. After leptospira forms a mature biofilm, some fundamental biological processes, such as DNA replication and cell division, are down-regulated. Transcriptome-based sequencing techniques can focus on transcriptional changes associated with leptospirosis biofilm formation and maturation (Iraola et al., 2016). *Fusobacterium nucleatum* stain ATCC 25586 at the planktonic cell and biofilm stages by RNA sequencing. It was confirmed that 110 genes of the *F. nucleatum* biofilm state differed from those of planktonic cells. The 85 down-regulated genes in the biofilm state are mainly related to cell proliferation, division, and oxidative stress. The 25 up-regulated genes are primarily associated with amino acid and carbohydrate metabolism (Zhao et al., 2022).

Metabolites are generated in the presence of metabolic enzymes and are the end products of gene expression processes. Many of the life activities in microbial cells (e.g., energy release, cellular signal release, and intercellular communication) are regulated by metabolites. Metabolites can reflect the microenvironment in which a bacterial cell is located and are also closely related to the nutritional status of the cell, the effects of drugs, contaminants, and other external factors. Several metabolites are listed below for their functions in biofilms formed by bacterial pathogens. Glucose, as the primary carbon source and metabolite, can upregulate the expression of extracellular polysaccharide-related gene pslA, which is conducive to promoting the formation of *P. aeruginosa* biofilms and changing metabolic pathways. Glucose could lead to decreased expression of 18 metabolites (including inositol, glutamine, 4-acetyl butyrate, myristic acid, and β-alanine) and increased expression of 7 metabolites (including fructose, 3-hydroxy propionic acid, and glucose-6-phosphate) in *P. aeruginosa* biofilms (She et al., 2019). Guanosine 59-diphosphate 39-diphosphate is also a metabolite that regulates the expression of a large number of genes and plays a vital role in the formation of biofilms of *E. coli*, *E. faecalis*, and *S. mutans* (de la Fuente-Núñez et al., 2014). Short-chain fatty acids, including butyrate, are also strongly associated with the pathogenesis of the periodontal disease. In the initial stage of biofilm formation, butyrate can promote early *Actinomyces oris*-dependent colonization and stimulate biofilm formation (Barbour et al., 2022). *Bacillus subtilis* can produce a variety of specific metabolites. Most of these metabolites (e.g., bacteriolysin, subtilisin A, surfactin, spore-killing factors) are associated with antimicrobial properties (Kalamara and Stanley-Wall, 2021). Schoenborn et al. (2021) investigated the role of nine specific metabolites in biofilm formation. They found that most of them (surfactin A, ComX, subtilin A, spore delaying protein, spore killing factor) could promote biofilm formation.

Metabolomics analysis techniques can reveal the processes of bacterial cell metabolism and are the study of metabolites (e.g., carbohydrates, amino acids, and lipids), intermediate metabolites, and other signaling molecules. The technique emphasizes discrete altered metabolic pathways and highlights biological small molecule metabolites. The Metabolite group is a complete assemblage of all metabolites in the tissues, organs, and compartments of biological cells that are extracted from cells or expressed as bodily fluids (Zhang and Powers, 2012). Metabolomics techniques focus on the broad or total analysis of cellular metabolites through high-throughput detection methods rather than localized and targeted analysis of specific numbers of individual metabolites (Fiehn, 2002). Many metabolic pathways between planktonic bacterial cells and biofilms were changed. Through instrumental analysis, bioinformatics, stoichiometry, and cell biology, metabolomics analysis can show the status of the overall metabolites, simplify the process of metabolite detection, and cover almost all metabolic changes of major pathways. Metabolomics analysis provides a systematic method for characterizing complex bacterial

A53210128

communities, showing the behavior of bacterial cells in biofilms, and contributing to the understanding of biofilms. In addition, biofilms' strain type and antimicrobial resistance are phenotypic by their differences from the metabolome. Shen et al. (2020) showed that carnosol could inhibit the formation of *S. aureus* biofilm by metabonomics analysis technique.

The fiber optic biosensor is capable of monitoring the growth quality of bacterial biofilms, quantifying analytes, and displaying biofilm properties. It works by monitoring the environment around the sensing element through changes in the refractive index. The sensor offers the following advantages: lightweight construction, compact size, biocompatibility, low fabrication costs, and real-time monitoring. The spherical resonance sensor is highly sensitive and can detect changes in the surface of bacterial cells, such as planktonic cells attached to the surface of an object, and has great potential for early detection of the presence of bacterial biofilms (Rakhimbekova et al., 2022). SiNW-FET, as a new nanosensor, can be combined with microfluidic technology to realize real-time, rapid, and fully automated detection of bacterial biofilms. It can reveal the biological and metabolic processes occurring in bacterial biofilms and has the advantages of high sensitivity, low consumption, non-invasive and traceless (Yeor-Davidi et al., 2020). Dai et al. (2022) reported a PH-responsive branched polymer [poly(MBA-AEPZ)-AEPZ-NA] capable of reducing the dose of antibiotics and overcoming antimicrobial resistance. It can emit intense green light rays in the local bacterial biofilm microenvironment (pH 5.5) to detect biofilm formation in real time. AmyGreen, a water-soluble amino ketone fuel, is a stain that enables the visualization of the amyloid component of the extracellular polymeric substances of bacterial biofilms. It can detect pathological amyloid proteins *in vitro* as a potent fluorescent dye. The application of the AmyGreen stain effectively reduced the risk of false positives when measuring the amyloidogenic fibrils of biofilms. In combination with other stains can be used for confocal fluorescence microscopy (Moshynets et al., 2020). Pandit et al. (2021) have developed a simple sensor of raw, non-functional graphene that is simple to manufacture and can be powerful without the need for precise species identification. It can distinguish and detect different bacterial types according to different growth dynamics, adhesion density, adhesion pattern, and colony formation between bacterial cells, which is helpful for the early detection of bacterial microbial colonization and biofilm formation. A new diagnostic kit is the product of a combination of two reagents, one that relies on a substance that promotes hydrogen peroxide to produce oxygen through catalase and the other a mobile biosensor. The kit can detect *P. aeruginosa* infection in sputum with high sensitivity and specificity within 8 minutes (Clemente et al., 2020). Bacterial biofilms attached to the mucous membranes of the mouth are difficult to visualize with the naked eye. Quantitative light-induced fluorescence (QLF) can detect bacterial infections in the oral cavity and the formation of dental biofilms. Park et al. (2022) demonstrated using QLF to detect and remove pathological biofilms from oral mucosa in elderly patients during hospitalization. The test tube method and Congo red agar technique can help detect biofilm formation by obtaining isolates of bacterial biofilm formation from contact lenses, the conjunctiva of contact lens wearers, and decorative contact lens cases (Raksha et al., 2020). Kouijzer et al. (2021) demonstrated that microvesicles in vancomycin-modified bacteria could detect the formation of *S. aureus* biofilms and could potentially treat *S. aureus* biofilm-associated infections.

Artificial intelligence technologies have also been found to be beneficial for detecting bacterial biofilms due to their powerful computational and learning capabilities. For example, biosensors based on electrochemical impedance spectroscopy can be used to detect *E. coli* biofilms (Xu et al., 2022). Convolutional neural network (CNN) can be used to detect the presence of biofilms and the formation of multiple biofilms through deep learning, with a CNN accuracy of up to 90%. Oh et al. (2022) have developed a material capable of precisely guiding the diagnosis and removal of bacterial biofilms. The material is a magnetic field-directed assembly of nanomaterials into surface topography adaptive robotic superstructures (STARS). It can adapt to complex bacterial surface topography and use automatic motion patterns to target the complex three-dimensional structure of human teeth to detect dental biofilm content with high accuracy while the effect of removing formed biofilm.

Currently, non-invasive techniques used in clinical practice have yet to provide the best method for detecting biofilms. Low practicability, low resolution and low cost-effectiveness limit the development of biofilm detection tools. Therefore, there is an urgent need to develop more accurate and practical detection techniques and diagnostic tools.

4 Strategies against bacterial biofilm removal

Bacterial biofilm inhibition is mainly achieved by physical, chemical or biological methods. Supplementary Figure 1 shows the different therapeutic strategies that inhibit bacterial biofilm formation. Physical methods include ionizing and ultraviolet radiation, damaging instruments and affecting material quality (Galié et al., 2018). Ultrasonic treatment is also one of the physical methods. Its mechanism of action is mainly through chemical and mechanical energy, including pressure, vibration, shear stress, shock waves and agitation. Stable pressure and cavitation can produce multidirectional acoustic microjets, which can damage proximal bacterial microorganisms and their biofilms. Relevant studies have confirmed the effect of plasma technology on therapeutic biofilms (Govaert et al., 2019; Patange et al., 2019). The influence of plasma on bacterial biofilms is mediated by biological activators, such as charged particles, ions, electrons, electric fields, and ultraviolet rays (Lu et al., 2016). Cold plasma can kill bacterial microorganisms and destroy the biofilm matrix. Still, the specific mechanism remains unclear, which may be related to ROS/RNS penetrating bacterial cells, oxidizing and nitrosating lipids and proteins, and then lipid peroxidation, inhibiting enzyme function, and changing DNA structure (Van Impe et al., 2018). Patange et al. (2021) found that atmospheric plasma and acoustic ultrasonic treatment technology can destroy the integrity of bacterial biofilm

A53210128

structure and effectively inactivate *E.coli* and *Listeria innocua* biofilm. They also found that atmospheric plasma was more effective than aeroacoustic ultrasound in treating both early and mature biofilms. When applied in combination, the two technologies have the potential to enhance the inactivation effect. The main mechanisms of atmospheric plasma damage to bacterial biofilms include cell membrane damage, structural changes, and biological and genetic changes. Future studies are needed to understand further the distribution of active particles in atmospheric plasma and acoustic ultrasonic techniques and the detailed mechanism of inactivating bacterial biofilms.

Microneedles (MNs) are an effective and minimally invasive method for the treatment of bacterial biofilms. MNs can not only destroy the tight physical barrier of EPS and directly penetrate the antibacterial agent into the biofilm, but also provide a large specific surface area to promote the diffusion of antibiotics in the biofilm. Yi et al. (2021) combined chitosan and zinc nitrate with MNs structure to produce CS-Zn[II] MNs. This substance has good cytocompatibility, rich acicular design and a large specific surface area, and is conducive to eradicating *S. aureus* and *E.coli* biofilms.

Chemical methods are unstable, cannot play a role in mild conditions, and the price of chemistry is relatively high, prone to producing toxic byproducts. Therefore, it is not usually the preferred method for eradicating bacterial biofilms.

Biological methods have higher inhibition efficiency, which is a relatively new method against biofilm, including the application of bacteriophage, bacteriocin and enzyme treatment of bacterial biofilm. In recent years, emerging anti-biofilm preparations have been developed to limit the adhesion of bacteria on the surface to eliminate the biofilm grown or replace cells from the established biofilm (Batoni et al., 2016). The EPS matrix in biofilms plays a crucial role in evaluating the drug resistance mechanism of biofilms. The ideal anti-biofilm preparation is characterized by its unique structure, antibacterial activity, restriction of EPS accumulation, facilitation of EPS penetration into cells, interference with communication mechanisms between cells, and synergistic action with other antibacterial agents (Wiens et al., 2014).

4.1 Antimicrobial peptide

Novel antimicrobial peptides (AMPs), as a kind of cation, can down-regulate biofilm formation genes, prevent bacteria from adhering to the cell-matrix surface, down-regulate QS system signals, and produce a wide range of antibacterial activities against bacterial microorganisms (Yazici et al., 2018). When used alone or in combination with antibiotics, AMPs can effectively inhibit the formation of biofilms or even destroy mature biofilms (Mulani et al., 2019) and can be used to treat biofilm-associated infections. AMPs bind rapidly to cell membranes, reducing bacterial load while circumventing the development of resistance, and it has strong antibacterial, fungal, and viral properties (Pontes et al., 2022). One of the mechanisms of action of AMPs against bacterial biofilms is the down-regulation of gene expression and inhibition of the biological behavior of bacterial cells (e.g., synthesis of DNA, RNA, proteins, and cell walls) (Graf and Wilson, 2019). At the same time, AMPs can interact with signaling molecules, which can control the maturation process of bacterial biofilm and cooperate with antibiotics to resist bacterial microorganisms.

Heinonen et al. (2021) proposed that AMP TAT-RasGAP 317-326 could effectively inhibit the formation and development of biofilms of *P. aeruginosa* and *A. baumannii*, and had little anti-biofilm activity against *S. aureus*. In the human oral environment, AMPs are widely present in the oral mucosa and salivary glands of the epidermal cells and neutrophils (Dale and Fredericks, 2005). AMPs are small in shape and have a positively charged amphiphilic structure, which can enter bacterial microbial cells through transmembrane pores and cause their cracking. AMPs are a potentially effective treatment for bacterial biofilm-associated oral infections due to their extensive antibacterial activity, low drug resistance, and ubiquity in the oral cavity. LL-37 is one of the most widely studied AMPs, which can modulate the immune response, regulate the inflammatory response, accelerate angiogenesis, promote wound healing, and help in oral defense against bacterial biofilms (Wuersching et al., 2021b). Levels of LL-37 are associated with various chronic inflammatory diseases, such as periodontal disease, gingivitis, systemic lupus erythematosus, and psoriasis (Pahar et al., 2020). Lactoferrin peptides are functional AMPs hydrolyzed by pepsin and are an effective anti-biofilm preparation. Wuersching et al. (2021a) demonstrated that LL-37 and human lactoferrin could interfere with the planktonic growth of anaerobic bacteria and the formation of bacterial biofilms, thus reducing the incidence of dental caries and periodontitis. Lactoferrin chimeras have a wide range of antibacterial activities. Ruangcharoen et al. (2017) proved that, compared with minocycline hydrochloride and chlorhexidine digluconate, lactoferrin chimeric could better inhibit the formation of oral multispecies biofilms *in vitro*, and it could reduce the activity of various bacterial cells in the biofilms. Antimicrobials depend on active cells, whereas AMPs are less specific for targeting molecules and can even target metabolically dormant cells in most regions of the mature bacterial biofilm.

At present, treating cystic fibrosis combined with *P. aeruginosa* infection remains difficult. Metal AMP piscidin 1 and piscidin 3 showed activity against *P. aeruginosa* biofilm infection, mainly due to their ability to tolerate an acidic environment and high ionic strength and to cut eDNA in the presence of Cu^2+. Metal AMP Gaduscidin-1 (Gad-1) is a broad-spectrum AMP that binds Cu^2+ efficiently in acidic and neutral environments. Holo-Gad-1 can eradicate mature bacterial biofilms and prevent the formation of new biofilms, mainly because eDNA is required for adhesion during the formation of nascent biofilms (Whitchurch et al., 2002). Portelinha and Angeles-Boza (2021) demonstrated that Gad-1 has multiple forms of action and can effectively remove *P. aeruginosa* biofilms in acidic, neutral, and high-salinity environments. When GaD-1 is combined with several commonly used antibiotics (e.g., Kanamycin and ciprofloxacin) to treat bacterial and microbial infections, it can play a synergistic role and improve the survival outcome of patients. This paper lists the acting bacteria and mechanisms of several peptides with antibiofilm activity in Supplementary Table 4.

A53210128

Most AMPs can be combined with antibiotics to enhance the role of antimicrobials in preventing bacterial biofilm formation and killing mature biofilms. Antimicrobial peptides are expected to improve the antibiofilm effect and reduce the dosage of antibacterial agents. However, there are limitations to the application of AMPs. Because AMPs are trapped by anionic biofilms, are easily broken down by enzymes in the biofilms, and may even cause acute hemolytic and toxic reactions.

4.2 Nanoparticles

Nanomaterials can reduce the adhesion of bacterial biofilms, promote the delivery of antimicrobial agents, improve the permeability of antibiotics, maintain the stability of antibiotics, and directly produce resistance to biofilms through specific mechanisms without antibiotic treatment. Due to their unique physical and chemical properties, namely biological response, surface charge and small-scale effect, nanomaterials can acquire a variety of antibacterial modes and perform multi-potency interactions with bacterial cells. Nanomaterials are effective carriers of antibacterial agents and inhibit the growth of biofilms through thermal damage, oxidative stress, and physical damage, which is conducive to the treatment of bacterial biofilm infection (Makabenta et al., 2021), and are not prone to drug resistance (Pelgrift and Friedman, 2013). Because of their special structure, nanomaterials can increase antibacterial activity in the following four ways. The surface charge of nanomaterials can enhance the interaction with bacterial microbial cells and lipid molecules, thus extending the exposure time of bacterial cells to antibiotics. Some nanomaterials reduce the generation of bacterial drug resistance through the self-cracking mechanism. Nanomaterials can enhance antimicrobials' solubility, prolong antimicrobials' life cycle, maintain the effective release of antimicrobials at the target site, and deliver multiple antimicrobials to the same target site to achieve combined therapy (e.g., photothermal and photodynamic therapy). Some nanovesicles inhibit the pre-degradation or release of drugs and deliver antimicrobials to designated targets *via* membrane fusion mode (He et al., 2022). Supplementary Figure 2 shows the mechanism of action of nanomaterials for inhibiting bacterial biofilm formation.

It is known that most organic nanoparticles can improve the dispersion performance of bacterial biofilms and have good biocompatibility, which is an important research direction in the field of antibacterial biofilms. Nanomaterials provide a new idea for the treatment of bacterial biofilms in the future, which can effectively improve the therapeutic efficiency of antibiotics and reduce the drug resistance caused by biofilms. The therapeutic effect of nanomaterials in the treatment of bacterial biofilms is mainly affected by their unique physical and chemical properties and the characteristics of biofilms. The combined application of organic nanomaterials with different functions can improve the efficacy of anti-biofilm. New composites composed of organic nanomaterials and other materials with antibacterial biofilm activity can significantly enhance the ability to resist biofilms and are currently the most widely used antibacterial substances.

Nanoparticle-based therapeutic regimens are expected to be effective for removing bacterial biofilms because of their advantages: functional versatility, selectivity, traceability, high loading efficacy, and controlled drug release (Datta et al., 2018; Khan et al., 2018). Unlike conventional antimicrobials, the activated nanoparticles can be designed to work in the presence of only a trigger, which reduces the side effects of being off-target (Schwartz-Duval et al., 2020). Therefore, the active development of nanomaterials for treating bacterial biofilm-associated infections has important research implications (Gao et al., 2020M; Yu et al., 2020). Ostadhossein et al. (2021) proposed a "particle-in-particle" treatment scheme for the first time. In the absence of antibiotics, they can deliver small therapeutic nanoparticles through simple chemical methods, which can target the characteristic pH of EPS, promote the killing of bacteria mediated by bacterial biofilm pH, and then use nanoparticles to kill caries pathogen S. Under the low pH value, the metabolic state of dental biofilm can produce pathogenicity. Targeting this factor can stabilize the original ecological balance and inhibit harmful pathogenic microorganisms. Particle-in-particle therapeutic approaches have been shown to provide excellent drug delivery, especially during oncology treatment (Xu F. et al., 2020; Zhang et al., 2020). Carbon dots (CDots), a new class of carbon-based nanoparticles, have the advantages of a simple fabrication process, adjustable luminescence function, and wealthy off-energy groups (Nguyen et al., 2020), which can provide unique conditions for antibacterial biofilms. One study confirmed that CDots could reduce the amount of caries pathogen S while killing bacterial biofilm EPS. *In vivo*, nanoparticles can effectively kill *S. mutans* and balance the oral environment (Ostadhossein et al., 2021).

Nanomaterials are effective in preventing the formation of bacterial biofilms on the surface of implantable medical devices. Metal nanoparticles are the key types of nanoparticles that have intrinsic anti-biofilm activity. Some metallic nanomaterials interact with the EPS of bacterial biofilms through surface charge interactions, and they can release soluble ions targeting bacterial microorganisms or EPS (Hiebner et al., 2020). Silver is one of the metal nanoparticles with high sterilization capacity. Silver nanoparticles (Ag-NPs) effectively prevented biofilm formation of *S. aureus* and oral mixed flora (*Streptococcus oralis*, *P. gingivalis*, and *Actinomyces naeslundii*) biofilm formation. Ag-NPs with maximum antibacterial activity after three repeated irradiations (Pérez-Tanoira et al., 2022). Habimana et al. (2018) developed a substance (GNP+PK) that treated gold nanoparticles (GNP) with the enzyme protease K (PK). They treated the bacterial biofilm on the surface of medical devices for 24 hours with enzyme protease K, gold particle, and GNP+PK, respectively. The total biomass of *Pseudomonas fluorescens* biofilm decreased by 40%, 77%, and 74%, while the thickness was reduced by 52%, 72%, and 78%, respectively. This study confirmed that GNP+PK particles could kill cells in *P. fluorescens* biofilm, mechanically separate cells in suspension, and damage the structure of bacterial biofilm, showing better anti-biofilm efficacy than PK or GNP. Slomberg et al. (2013) combined NO and silica nanoparticles to examine the effects of these materials on *S. aureus* and *P. aeruginosa* biofilms. In this process, the bacterial biofilm was first placed in a biological

A53210128

reaction incubator for 48 hours and then treated the biofilm with nanoparticles for 24 hours. They found that the morphology and volume of nanoparticles both affected the effectiveness of bacterial biofilm elimination. Chitosan (CS) carries a positive charge on its surface and can adsorb to the surface of bacterial microorganisms. It binds to the surface of bacterial cells carrying a negative charge using electrostatic interaction, and the permeability of bacterial cell membrane changes, leading to apoptosis (Rashki et al., 2021). At the same time, chitosan can penetrate the bacterial cell membrane and interact with nucleic acids to interfere with the DNA/RNA synthesis process, triggering intracellular reactions that lead to cell death. Pan et al. (2022) combined CS with artificial nano enzymes. They found that the conjugate is an efficient, economical, and environmentally friendly antibiofilm preparation, which may eventually become an effective alternative to eradicate bacterial biofilms.

Nanosponges can prevent the formation of biofilms or eliminate biofilms those already formed and exhibit broad-spectrum antimicrobial membrane activity against pathogenic single and double-species biofilms, with no toxicity to mammals. Nabawy et al. (2021) reported the ability of biodegradable polymer-stabilized oil-in-water nanosponges to inhibit methicillin-resistant *S. aureus* and *P. aeruginosa* biofilms. Raj et al. (2022) synthesized chitosan-gum arabic-coated liposomes-alizarin nanocarriers. They found that this material can eliminate the biofilm formed by *S. aureus* and *Candia albicans*, which helps improve drug penetration and release in biofilm cells. However, low stability and water solubility limit the broad application of nanomaterials. At present, a new method has been proposed for the treatment of biofilm-associated infections, namely "nanoscale bacterial debridement", which can separate bacteria from biofilm in a specific way, effectively kill bacteria, and reduce the biomass of biofilm (Li et al., 2021). However, as a new type of nanomaterial, "nanoscale bacterial debridement" has received little relevant research. Biofilm removal by separating bacteria and biofilm has broad research prospects and needs further investigation. Most nanomaterials have been shown to be effective solutions for preventing bacterial biofilm formation (Baelo et al., 2015; Cheeseman et al., 2020). Since biofilms exhibit a high antibacterial bacterial microbial community embedded in EPS, not all nanoparticles will be able to destroy bacterial biofilms. Although organic nanomaterials play an excellent role in inhibiting the formation of bacterial biofilms, they are less effective against stationary and persistent bacteria (Li et al., 2021). The cytotoxicity and abnormal distribution of complex tissues are common problems in nanomaterials application. Therefore, more in-depth research is needed to focus on the overlooked aspects of bacterial biofilm processing.

4.3 Catabolite control protein A inhibitor

Catabolite control protein A (CcpA) is the primary regulator of the trans-activation of carbon catabolite repression. It can induce and stimulate the upregulation of cidA and icaA gene expression. The cidA and icaA genes can play a role in synthesizing polysaccharide intercellular adhesins. They can be involved in encoding cave proteins that are involved in lysing bacterial cells and releasing eDNA (Sadykov et al., 2019). At the same time, CcpA can inhibit small noncoding RNA RsaI transcription and then affect bacterial biofilm formation (Bronesky et al., 2019; Bulock et al., 2022). CcpA of *S. aureus* (SaCcpA) can also affect bacterial biofilm formation, antimicrobial resistance development, and virulence factor expression. Catabolite control protein A inhibitor can inhibit the DNA-binding ability of SaCcpA, which is expected to eliminate the virulence factor of *S. aureus* strains. Silver, as an inhibitor, can target SaCcpA, eliminate alpha-hemolysin expression in bacterial cells, and reduce bacterial virulence (Liao et al., 2017). However, silver ions are toxic, and silver-containing preparations (e.g., silver sulfadiazine) are generally used only as topical treatments. Huang et al. (2020) identified a specific small molecule inhibitor that disrupts the SaCcpA-DNA complex product and reduces the expression of α-hemolysin encoded by the hla gene. The Sak gene is a staphylokinase that can convert plasminogen into plasmin (Tam and Torres, 2019). It can inhibit the formation and development of biofilms and separate mature biofilms by activating plasminogen and splitting fibrin from the host. After treatment with the Sak gene, *C. albicans* and *S. aureus* biofilms integrity and biomass decreased (Liu et al., 2019). Zheng et al. (2022) proposed that CcpA can bind to the promoter region of the Sak gene and inhibit Sak gene expression, thus regulating the formation and development of bacterial biofilms. This method has low cost and minor side effects and is expected to be a drug for treating *S. aureus*-related biofilm infections.

4.4 Bacteriophage

Bacteriophage is a virus that can infect and kill bacteria. Compared to common antibiotics, bacteriophage has the advantages of functional specificity, more robust tolerance, higher safety, narrower scope of action, and cost-effectiveness (Principi et al., 2019), and it cannot infect human or animal cells. Bacteriophages can penetrate the structure of bacterial biofilm and eradicate or prevent bacterial biofilm (Łusiak-Szelachowska et al., 2020), which is expected to be an alternative therapy for antibiotics. Supplementary Figure 3 shows the multiple mechanisms by which bacteriophages counteract bacterial biofilm formation. Haemolysinase is a phage-derived enzyme that can hydrolyze the peptidoglycan of the cell wall, which in turn can disrupt the structure of bacterial biofilms (Gray et al., 2018; Sharma et al., 2018). Bacteriophage infection of host cells mainly involves the following steps: (i) adhesion to the bacterial cell surface using phage receptor binding proteins; (ii) the phage genome enters the cytoplasm; (iii) phage for protein assembly; (iv) release of progeny phage (Tian et al., 2021).

Novel phage Φ 15 produces a polysaccharide depolymerase that hydrolyzes the EPS of a single species of single-species *Pseudomonas putida* and inhibits biofilm formation (Cornelissen et al., 2011). Rai et al. (2020) used CV staining to determine the biofilm content. They found that phage PD1 and PE2 could effectively prevent the formation of *S. aureus* biofilms, while PD1, PE1, and P3 could disperse mature biofilms. Phage Φ29 and phage T4 could inhibit the formation of *S. aureus* biofilms (Sybesma et al.,

A53210128

2016). Phages from the order Caudovirales, Myoviridae family, could reduce the proliferation of *P. aeruginosa* in the floating state. At the same time, this phage could also reduce the metabolic activity of endotracheal cannula-associated biofilm and destroy the already-formed *P. aeruginosa* biofilms (Oliveira et al., 2020). The phage mixture (LPSTLL, LPST94, LPST153) has a wide host range and lytic activity, which can play a role in reducing the biofilm of *Salmonella* spp. (Islam et al., 2019).

Combining bacteriophage and antibiotics can improve the therapeutic effect of bacterial biofilms and achieve reduced phage resistance without increasing the toxicity of antimicrobials. For example, the combination of bacteriophage T4 and tobramycin can significantly reduce *E. coli* tolerance to tobramycin (Hemmati et al., 2021). Combining specific phage and amoxicillin can improve the synergistic effect on *K. pneumoniae* B5055 biofilm (Bedi et al., 2009). Bacteriophages can be used alone or in combination with various bacteriophages in treating bacterial biofilms. Phage mixtures are effective in preventing the formation of bacterial biofilms and removing mature biofilms because they produce fewer types of phage resistance and significantly increase the host spectrum compared to phage alone. However, bacteriophage therapy also has limitations: for example, bacteriophages increase antibiotic resistance, bacteriophage DNA replication and protein synthesis need to interfere with bacteria metabolism, and bacteriophages are related to the growth conditions of bacterial microorganisms (Tagliaferri et al., 2019; Łusiak-Szelachowska et al., 2020). Since bacteriophages are viruses and pathogenic factors, there may be potential hazards. Therefore, when combining phages and antibiotics for treating bacterial biofilms, we should fully consider the possible adverse effects to prevent contraindications to the pairing.

4.5 Quorum sensing inhibitors

The communication mechanism between bacteria and microorganisms is called the quorum sensing system, which can control the expression of various virulence genes at different stages of bacterial biofilm formation and development (Dijkshoorn et al., 2007). Inhibition of this system can impair the formation of bacterial biofilm. As a small signal molecule, an autoinducer can mediate the communication between bacteria and microorganisms in the QS system to coordinate the development of bacterial cells. Significant changes in intracellular gene expression levels may occur when bacterial population densities reach concentration thresholds set by autoinducer agents while under the influence of the external environment (Hemmati et al., 2020). Gene expression level can induce or inhibit various virulence factors in bacterial cells and affect biofilm formation. Autoinducer peptides (AIP), Autoinducer-2 (AI-2), and N-acyl-homoserine lactones (AHLs) are three of the most studied QS signaling molecules (Muras et al., 2022). AIP is synthesized by Gram-positive bacteria. It cannot penetrate bacterial cells but binds to specific transmembrane receptors in cell membranes or cells to stimulate signal transduction pathways and promote the transcription of target genes. AHLs are usually produced by Gram-negative bacteria and can spread into bacterial cells to bind to specific receptor proteins that activate corresponding transcription factors and regulate gene expression (Duplantier et al., 2021). Blocking the production of AHLs can reduce the biological activity of AHL synthase and decrease the concentration of AHLs, which in turn interferes with the QS system. The AI-2 molecule is an autoinducer that mediates the signaling process between Gram-negative and Gram-positive bacteria, which is influenced by osmotic pressure and pH. The signaling molecule will be broken down when exposed to low osmotic pressure. AI-2 signaling molecules can affect bacterial biofilm formation, antibiotic resistance, virulence factor secretion, and cell motility Li and Zhao (2020).

Quorum sensing inhibitors (QSI) are produced by prokaryotes or eukaryotes. It can block the quorum sensing system, which may reduce efflux pump expression and destroy bacterial biofilm formation (Hemmati et al., 2020). QSI has been shown to interfere with AI-2 and the Competence Stimulation Peptide system to prevent the formation of oral bacterial biofilms (Muras et al., 2020). Non-steroidal anti-inflammatory drugs (e.g., Meloxicam and aspirin) can be used as potential QS inhibitors, which can affect the QS signaling molecules of *P. aeruginosa* and the formation and maturation of its biofilm (Almeida et al., 2018). Some commonly used antimicrobials (e.g., erythromycin, azithromycin, piperacillin-tazobactam, streptomycin, and ciprofloxacin) have high levels of QSI activity (Skindersoe et al., 2008). Natural products, antibiotics and compounds can affect the function of QSI. Bacteria may be resistant to a single QSI preparation, reducing its effective biological activity. Bacteria may be resistant to a single QSI preparation, reducing its effective biological activity. Therefore, it is recommended to combine the application of QSI and antibiotics to inhibit resistance to QSI without increasing the toxicity of antibiotics (Wang et al., 2016), which can effectively improve the therapeutic effect. When resveratrol was combined with aminoglycoside antibiotics (gentamicin, streptomycin, amikacin) to treat bacterial microorganisms, it significantly reduced the formation of bacterial biofilms compared with various substances alone (Zhou et al., 2018). Therefore, QSI can target the quorum sensing system in bacteria and may be a potential therapeutic solution for bacterial biofilms.

4.6 Enzymes involved in biofilm degradation

Enzymes are involved in ESP generation, intercellular communication, maturation and dispersion of biofilms, with high specificity. It can remove specific components from biofilms, helping to inhibit the extracellular matrix and quorum-sensing system of bacterial microorganisms (Ivanova et al., 2015). Enzymes capable of hydrolyzing ESP components have anti-biofilm activity, including oxidase (Nguyen and Burrows, 2014), polysaccharide degrading enzyme (Saggu et al., 2019), and proteolytic enzyme (Wille and Coenye, 2020). Therefore, enzymes are preferred among biological methods for inhibiting biofilms (Tan et al., 2020). Table 2 shows several enzymes and their mechanisms of action.

Soluble enzymes are unstable under different biofilm growth conditions and are not reusable. Enzyme immobilization can achieve enzyme stability, improve utilization, and reduce activity

A53210128

loss (Perwez et al., 2017). The immobilization includes adsorption, crosslinking, embedding, encapsulation and covalent coupling. Perwez et al. (2021) proposed m-combi-Cross linked Enzyme Aggregate (m-combi-CLEA), a novel biofilm inhibition method that can inhibit the biofilms of *E. coli* and *S. aureus*. The bacterial biofilms treated with enzyme mixtures in the form of CLEA showed inhibition rates could reach 75-78%, promising an alternative to antibiotics. The magnetic effect of CLEA helps achieve enzyme recirculation.

4.7 Aptamers

Aptamers are single-stranded oligonucleotide molecules or peptides produced *in vitro*. Because of its specific three-dimensional structure can select target molecules (e.g., cells, proteins, antimicrobial agents, small molecules, and metal ions) by specific linkage and high affinity. These properties make the aptamers highly active against bacterial biofilms and antimicrobials. Their antibacterial effects may be generated through the depolarization of cell walls of bacterial microorganisms. Aptamers may be an effective alternative to inhibit the development of biofilms (Shatila et al., 2020). Supplementary Figure 4 briefly shows the primary mechanism of action of aptamers in inhibiting bacterial biofilm formation. Aptamers are suitable alternative substances in the treatment of biofilms due to their flexible diagnostic and therapeutic properties. Mao et al. (2018) developed an aptamer-targeted graphene oxide (GO) therapeutic strategy against bacterial biofilms, defining the coupling as aptamer-GO. They found it can inhibit 93.5 ± 3.4% of *Salmonella typhimurium* biofilms, showing superior antibacterial biofilm properties and effectively becoming a long-term therapeutic option for treating bacterial biofilms. As a special targeting agent, aptamers are expected to improve the effective concentration of antibiotics and reduce the possibility of missing targets, which can be used to treat bacterial microbial infections. The synergistic action of aptamers and antibiotics may affect more bacterial microbial cells (Ning et al., 2015).

Shatila et al. (2020) demonstrated the inhibitory effect of DNA aptamer of *Salmonella* spp. invasion protein A (Apt177) on bacterial biofilms. They found that Apt177 could alter the three-dimensional structure of biofilms and was effective in reducing bacterial biofilm formation when applied alone or in combination with ampicillin. Enteropathogenic *E. coli* (EPEC) is a biological agent that causes diarrhea by forming a bacterial biofilm. It was found that the nucleic acid aptamer SELEX 10 Colony 5 could reduce the motion diameter of EPEC K1.1 and showed the highest biofilm inhibition effect. This aptamer can reduce the mRNA expression level of bacterial biofilm formation genes (e.g., curli gene, interaction, and motility), hinder EPEC K1.1's motility, and prevent bacterial biofilm formation (Oroh et al., 2020). Sengupta et al. (2020) reported the effectiveness of aptamer-DNA template silver nanocluster (Ag-NC) for inhibiting *P. aeruginosa* biofilm formation, and Ag-NC as a sensor is expected to be a new way to detect planktonic cells and biofilm formation. Ning et al. (2022) found that simultaneous delivery of penicillin-binding protein 2a-specific DNA aptamer and berberine *via* graphene oxide effectively inhibited the formation of MRSA biofilms, and this complex could potentially be an effective strategy for the treatment of chronic infections caused by MRSA biofilms. *P. gingivalis* can cause the occurrence of periodontitis. DNA-aptamer-nanographene oxide (NGO) achieves real-time, *in situ* detection and removal of *P. gingivalis* biofilm. The DNA-Aptamer-NGO complex serves as an antimicrobial photodynamic therapy and is a promising method that may inhibit the formation of bacterial biofilms (Pourhajibagher et al., 2022). Therefore, aptamers combined with other reagents can improve targeting specificity and inhibit the formation and development of bacterial biofilms, which is considered an ideal measure for antibacterial biofilms.

4.8 Peptide nucleic acid

Peptide nucleic acids (PNA) is a synthetic analogue of nucleic acid, composed of nucleic acid and peptide, similar in structure to DNA or RNA, and identical in physical and chemical properties to

TABLE 2 Enzymes with antibacterial biofilm activity.

Enzyme	Mechanism of action	Bacteria	Authors
Trypsin	Hydrolysis of the peptide bond on the carboxyl side of protein arginine and lysine residues	Inhibition of biofilm formation in *P. aeruginosa* and *Erysipelas rubbery* C208	(Gilan and Sivan, 2013; Banar et al., 2016)
Cellulase	Hydrolyses the β-1, 4 glycosidic bonds of hemicellulose and cellulose	Decomposition of EPS in *P. aeruginosa* biofilms	(Ibrahim et al., 2021)
α-amylase	Hydrolysis of α-1,4 glycosidic bonds in glycogen and starch		(Fleming et al., 2017)
Pectinex ultra clear	Contains polygalacturonase, pectin ester, hemicellulase and cellulase activity		(Perwez et al., 2021)
Disintegrin B produced by Aggregatibacter actinomycetem-comitans	Hydrolysis of glycosidic bonds in polysaccharides	Decomposing the mature *Staphylococcus* spp. biofilms	(Donelli et al., 2007)
Alginate lyase	Resistant alginate substances in *P. aeruginosa* biofilm substrates	*P. aeruginosa*	(Franklin et al., 2011)

A53210128

protein. PNA has a high affinity and specific binding ability, showing great potential in removing drug-resistant bacteria (Lee et al., 2019), and can hinder the formation of bacterial biofilms. Combined with conventional antibiotics, it can improve the antibacterial efficacy of antibiotics and anti-biofilm activity. There are two main reasons why pre-PNA has yet to be widely used. One is that PNA is hydrophobic and not easily dissolved in an aqueous solution. Second, due to the lack of effective carriers to transport PNA to biofilms, bacterial biofilms have low permeability to PNA (Wojciechowska et al., 2020). Meanwhile, components of bacterial cells, such as lipopolysaccharide and peptidoglycan, are also major barriers that restrict PNA entry into biofilms (Kurupati et al., 2007). Various methods have been proposed to increase the penetration of PNAs into biofilm cells: chemical changes in the structure of PNAs can enhance the hydrophilicity of PNA. Some cell-penetrating peptides (e.g., chloroquine, photochemical internalization, cationic lipids) can covalently bind to PNAs. This process helps PNAs form complementary base pairs with bacterial DNA. Filamenting temperature-sensitive mutant Z (FtsZ) remains silent in numerous bacterial cells and is one of the essential structures involved in the bacterial division process, making ftsZ a potential target for developing new antimicrobial agents. Narenji et al. (2020) showed that antisense PNAs targeting the efaA gene could reduce the formation of *Enterococcus* spp. biofilms, that anti-ftsZ materials could inhibit bacterial cell growth by interfering with *E. coli* division, and that PNAs were shown to inhibit the function of ftsZ. AcpP-PNA14-5'L is a PNA peptide based on targeting the acpP gene with a 5' membrane penetrating peptide and junction. It exhibits efficient antibacterial activity against *H. influenzae* in both planktonic and biofilm states and is not susceptible to drug resistance (Otsuka et al., 2017). Castillo et al. (2018) found that PNA can directly block the transcription of mRNAs encoding acyl carrier proteins. Certain antibiotics (such as polymyxin B) can interfere with cell wall formation and, when used in combination with PNA, are effective in preventing the formation of biofilms from Enterohemorrhagic *E. coli* 0157: H7. The combination of PNA with conventional antimicrobials has the potential to be an effective therapeutic option for the treatment of Gram-negative bacteria. In conclusion, PNA is expected to be an effective way to increase anti-biofilm activity.

4.9 Vaccine

Currently, vaccines formulated using biofilm-derived antigens are an effective way to prevent infectious diseases, which can improve the protective efficacy of existing vaccines (Loera-Muro et al., 2021). The outer membrane vesicles (OMV) derived from *Bordetella pertussis* can effectively prevent the colonization of bacterial cells in the lung of mice. Carriquiriborde et al. (2021) used OMV from the planktonic state (OMVplank) and biofilm state (OMVbiof) to create a vaccine. The OMVbiof vaccine was more affinity and immunogenic than the OMVplank vaccine in antibody induction. In addition, the *B. pertussis* biofilm-derived vaccine was found to be more protective and immunoreactive against bacterial strains with defective pertactin antigen expression than the OMVplank vaccine. Zurita et al. (2019) found that the OMVs vaccine induced respiratory CD4 tissue-resident memory cells with long-lasting protection against *B. pertussis*. It caused a durable immune response, making it an excellent alternative to third-generation pertussis vaccines. The treatment of pathogens with biofilm-derived vaccines is still in the research stage and may help treat biofilm infections. More advanced technologies are needed to identify bacterial biofilm-derived antigens in the future.

5 Conclusion and prospect

Clinically, most chronic infections are associated with biofilms of bacterial microorganisms, which are resistant to antibiotics and can grow and mature even under poor survival conditions. Biofilm-associated infection is a significant clinical problem. Biofilms can form on the surface of devices and non-devices, increasing patient morbidity and mortality and seriously threatening human life and health. In addition, the increased spread of multidrug-resistant bacteria has made biofilm infections a significant threat to hospitalized patients. Although many studies have been done to elucidate devices and non-devices surface biofilm formation, they are mainly limited to a few surfaces and specific bacterial microorganisms. Therefore, it is critical to focus on bacterial biofilm infections and work to raise awareness of the different microbial populations present on device and non-device surfaces to develop strategies for detecting and treating bacterial biofilms. Early detection of bacterial biofilms can improve treatment effectiveness and reduce medical costs. There are many strategies to resist biofilms, but relatively few to clinical treatment. In the future, we should also focus on more efficient, durable, and environmentally friendly methods and further study the safety and effectiveness of each strategy.

Supplementary material

The Supplementary Material for this article can be found online at: https://www.frontiersin.org/articles/10.3389/fcimb.2023.1137947/full#supplementary-material

SUPPLEMENTARY FIGURE 1
Different therapeutic strategies for inhibiting bacterial biofilm formation.

SUPPLEMENTARY FIGURE 2
Mechanism of action of nanomaterials against biofilms.

SUPPLEMENTARY FIGURE 3
Mechanism of action of bacteriophages with anti-biofilm activity.

SUPPLEMENTARY FIGURE 4
Mechanism of action of aptamers with anti-biofilm activity.

SUPPLEMENTARY TABLE 1
Most common bacterial organisms on the surface of medical devices.

SUPPLEMENTARY TABLE 2
Non-device-related biofilm infections.

SUPPLEMENTARY TABLE 3
Microbial and bacterial biofilm-associated infections and their adhesion surfaces.

SUPPLEMENTARY TABLE 4
Mechanism of action of antimicrobial peptide.

SUMMARY *Proteus* species, members of the *Enterobacteriaceae* family, are usually considered commensals in the gut and are most commonly recognized clinically as a cause of urinary tract infections. However, the recent identification of *Proteus* spp. as potential pathogens in Crohn's disease recurrence after intestinal resection serves as a stimulus to examine their potential role as gut pathogens. *Proteus* species possess many virulence factors potentially relevant to gastrointestinal pathogenicity, including motility; adherence; the production of urease, hemolysins, and IgA proteases; and the ability to acquire antibiotic resistance. Gastrointestinal conditions that have been linked to *Proteus* include gastroenteritis (spontaneous and foodborne), nosocomial infections, appendicitis, colonization of devices such as nasogastric tubes, and Crohn's disease. The association of *Proteus* species with Crohn's disease was particularly strong. *Proteus* species are low-abundance commensals of the human gut that harbor significant pathogenic potential; further investigation is needed.

INTRODUCTION

Proteus species are members of the *Enterobacteriaceae* family of bacteria. Most commonly, they are recognized clinically as a cause of urinary tract infections. Although *Proteus* spp. are typically considered commensals in the gastrointestinal (GI) tract, their abundance as a proportion of the microbial community is very low (<0.05%) (1). As a result, their detection in disease states using 16S profiling, and possibly metagenomics, may have rendered *Proteus* spp. undetectable due to bioinformatic abundance thresholds.

The recent identification of *Proteus* spp. as potential pathogens in Crohn's disease recurrence after intestinal resection (2, 3) serves as a stimulus to examine their potential role as gut pathogens. This review aims to provide an overview of the genus *Proteus* in terms of its known virulence factors as well as to collate the evidence surrounding the role of *Proteus* spp. in the pathophysiology of gastrointestinal diseases.

CHARACTERISTICS OF THE *PROTEUS* GENUS

Proteus spp. are Gram-negative bacteria belonging the *Enterobacteriaceae* family and are common commensals of the gastrointestinal microbiota (4). The first isolates were reported and characterized by Hauser in the late 19th century (5). The genus is currently comprised of *Proteus mirabilis*, *P. vulgaris*, *P. penneri*, *P. hauseri*, *P. terrae*, and *P. cibarius*, along with the unnamed genomospecies 4, 5, and 6 (6–10). In humans, all current members of the genus, except for *P. cibarius* and *P. terrae*, have been isolated from clinical specimens (4, 5, 7, 9, 11). Typically, the human gut is colonized by various combinations of *P. vulgaris*, *P. mirabilis*, and *P. penneri*, but they comprise less than 0.05% of the gut microbiota of healthy subjects (Fig. 1) (1, 12). While *Proteus* spp. are widely recognized as pathobionts and the gut is the reservoir of these bacteria, the research focus on this genus has been on their role in urinary tract infections rather than intestinal manifestations (13–15).

Many recent studies of the gut "microbiome" in health and disease have revealed that there are gross alterations in the relative proportions of key bacterial taxa associated with active disease, which is generically referred to as "dysbiosis." One of the hallmarks of dysbiosis in the inflammatory bowel diseases (IBDs) is the population expansion of the phylum *Proteobacteria*, specifically the *Enterobacteriaceae* (16). Other genera within the *Enterobacteriaceae* family, such as *Escherichia*, *Shigella*, *Salmonella*, and *Klebsiella*, have received due attention in this regard, while *Proteus* has not been comprehensively investigated.

Pathogenic Features

Proteus species are short (1.5- to 2-μm) straight rods that demonstrate dimorphism as "swimming" and "swarming" forms, as do some other members of the *Enterobacteriaceae* family (17). Swimmer cells predominate in liquid environments as single cells with 4 to 10 peritrichous flagella (Fig. 2, bottom right) (5, 14). The swarming behavior of *Proteus* species results in a characteristic bull's-eye pattern on a plate culture, as a result of a cyclic process of swarming and consolidation phases (18). When *Proteus* cells are placed in a viscous environment or on a solid surface, they undergo differentiation to filamentous, multinucleated, highly flagellated swarmer cells (Fig. 2, top and bottom left). Following this differentiation, a consolidation phase occurs, where the cells revert to a shorter morphotype, and metabolic preparation occurs prior to the next swarming cycle (18).

Proteus mirabilis undergoes swarming differentiation at much higher concentrations of agar (1.5 to 2%) than other swarming bacteria (19). When *Proteus* spp. swarm, there is a dramatic increase in the production of secreted proteins, including virulence factors such as the protease ZapA (17, 20, 21). *In vivo*, swarmer cells have been demonstrated in mouse models of ascending urinary tract infection only infrequently, with the occasional swarmer cell being isolated from the kidneys and bladder stones of infected mice (22, 23). The swarming phenotype can occur under both aerobic and anaerobic conditions (24) and can be induced by the concentration of amino acids, in particular

glutamine (25, 26). It has also been demonstrated that a more acidic pH, as might be expected to occur in the proximal small bowel and cecum, dramatically increased swarming behavior (27–29). Swarming has been shown to be an important factor in intracellular invasion and persistence, with 15- to 20-fold more swarmer cells than swimmer cells being capable of the intracellular invasion of uroepithelial cells (30). There is some evidence that swarming *Proteus* strains are more invasive in urinary tract mouse models than are swarm-defective mutant strains (22). Furthermore, a number of metabolites present in the intestinal tract have been shown to promote swarming, including choline, glutamine, and the most abundant polyamine in the gut, putrescine (25, 31–33). While we cannot yet conclude definitively that swarming behavior occurs in the gut *in vivo*, the combination of a viscous surface (such as the gut mucosa), the high availability of glutamine and polyamines such as putrescine (26, 31, 33), and electron acceptors for anaerobic respiration such as choline (32) makes it likely that the gut environment may be permissive for swarming.

Adhesion and mucosal attachment. Adhesion to epithelial surfaces is essential for the pathogenesis of *Proteus* infections in both the urinary and gastrointestinal tracts. Sequencing of *Proteus mirabilis* strain HI4320 revealed 17 fimbrial gene sets (operons), more than any other bacterial genome currently characterized (34–36). Six of the fimbrial types that *Proteus mirabilis* can produce have been characterized (Table 1), including mannose-resistant *Proteus*-like fimbriae (MR/P fimbriae), mannose-resistant *Klebsiella*-like fimbriae (MR/K fimbriae), nonagglutinating fimbriae (NAF) (also known as uroepithelial cell adhesin [UCA]), ambient-temperature fimbriae (ATF), *P. mirabilis* P-like pili (PMP), and *P. mirabilis* fimbriae (PMF) (5, 36). These fimbriae and adhesins play a major role in the formation of bacterial biofilms, a common complication of both urinary and gastrointestinal instrumentation (37). It is likely that the MR/P and NAF/UCA fimbrial types are most important in gastrointestinal pathogenesis, due to their role in epithelial adhesion (38–41).

A comparison of the 17 individual chaperone-usher fimbrial operons across the 7 sequenced *P. mirabilis* strains as well as 58 clinical isolates showed 99% conservation in 13 of 17 fimbrial operons, demonstrating that these genes are highly conserved across

A53210128

TABLE 1 Fimbriae and pili expressed by *Proteus* species[a]

Fimbrial type	Structure	Characteristic(s)	Contribution(s) to gastrointestinal pathogenicity	Reference(s)
MR/P	7-nm–8-nm, "thick" channeled fimbriae	Important for epithelial cell adhesion	Expression may allow mucosal cell adhesion in the gastrointestinal tract and contribute to intestinal persistence	38, 39, 69, 136
		MR/P expression undergoes phase variation, allowing for a molecular "switch" that turns on/off the expression of the *mrp* operon depending on the environment and oxygen availability, e.g., on in bladder colonization and off in kidney colonization	The repeating structures of flagellin proteins contribute to immunogenicity in the gut	
		MR/P fimbriae are potent immunogens and potential vaccine candidates		
		MR/P$^+$ *Proteus* strains are more genotoxic and cytotoxic to bladder/kidney-derived epithelial cells than MR/P$^-$ mutants	MR/P$^+$ *Proteus* strains are also likely more cytotoxic to intestinal epithelial cells	
MR/K	4-nm–5-nm, "thin" nonchanneled fimbriae	Expression is more common in *P. penneri* strains than in *P. mirabilis* strains	*P. penneri* has not been linked to gastrointestinal pathogenicity	42, 137
NAF/UCA	4-nm, "thin" nonchanneled fimbriae	Recognizes glycolipids, including asialo-GM1, asialo-GM2, lactosyl ceramide, and galectin-3		40, 41, 138
		Important for epithelial cell adhesion and colonization		
		Not present in *P. vulgaris*		
ATF		Highly expressed at 23°C, moderately expressed at 37°C	The structural subunit AtfA has significant homology with the major subunit of type 1 fimbriae from other enteric pathogens, such as *S. enterica* serovar Typhi	37, 40, 139–141
		Not considered to contribute to UTI or biofilm formation; may be more important for enteric colonization and environmental survival		
		Believed to be important for survival and persistence outside a mammalian host, at room temp		
PMP		Identified in uropathogenic *P. mirabilis* strains isolated from dogs		142
		Not present in *P. vulgaris*		
		PmpA fimbrial subunits show high homology to P-fimbriae from uropathogenic *Escherichia coli*		
		Cell surface assembly has not been confirmed		
PMF		Important in biofilms and responsible for the formation of higher-volume biofilms		37

[a]UTI, urinary tract infection.

strains isolated from various clinical sites (36). Of these, it is likely that at least two, and up to six, of the characterized fimbriae can be assembled on the cell surface at any one time (36, 42).

The regulation of motility and the expression of adhesion factors are tightly coupled; of the 17 fimbrial operons, at least 10 gene clusters possess a homolog of the *mrpJ* gene, a repressor of motility (43). MrpJ downregulates the flagellar master regulator *flhDC* via binding to the promoter sequence (43). When these cells revert back to the swimming morphology, the expression of MR/P and NAF fimbriae returns (37, 44).

A53210128

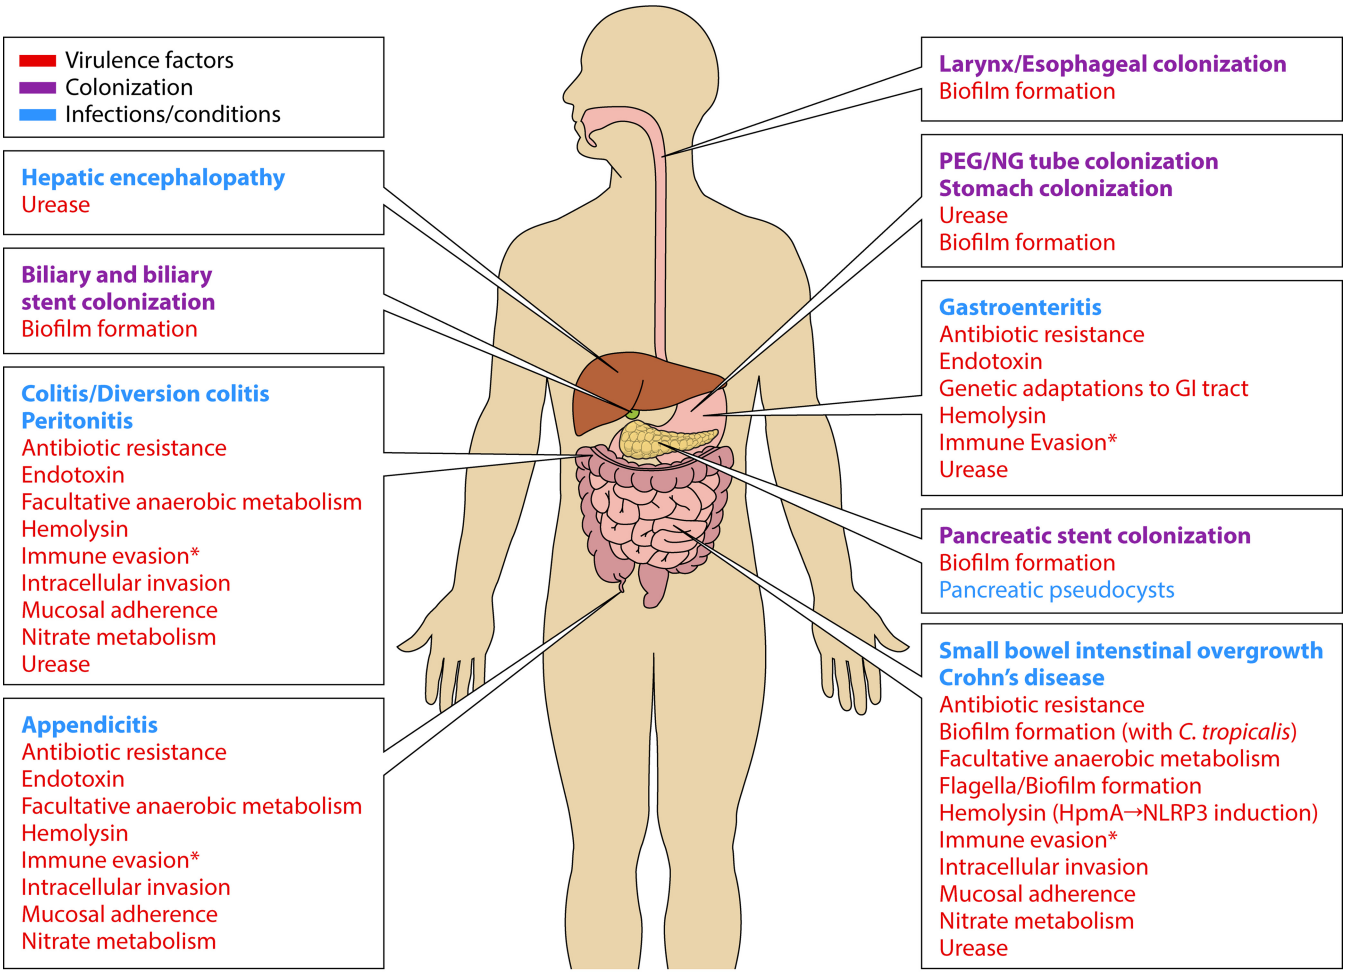

FIG 3 Potentially important *Proteus*-related virulence factors in relation to anatomical disease location and disease. *, immune evasion includes the production of the ZapA metalloprotease, O-antigens, and flagellin variation.

Furthermore, the induction of MR/P fimbriae appears coupled to the availability of oxygen (45). MR/P fimbriae are phase variant and can be "switched" on or off by a site-specific DNA recombinase (MrpI) that inverts a promoter region flanked by inverted repeats. This "invertible element" switches on or off the MR/P fimbrial operon, depending on the environmental conditions. There appears to be a growth advantage to MR/P fimbrial expression under low-oxygen conditions, such as those that would be present in the intestinal tract, likely contributing to the adhesiveness and persistence of *Proteus* species in the gut (45). The adaptation of *Proteus* species to mucosal surfaces by way of both fimbrial expression (for adherence) and swarming motility could increase the invasiveness, persistence, and pathogenicity of these species in the gut (Table 1 and Fig. 3).

Urease. The urease enzyme is a microbiological adaptation to metabolize urea, the most abundant nitrogenous waste product of human metabolism (46). Urease generates ammonia and carbonic acid as end products, with this ammonia providing a rich source of nitrogen for microbial metabolism in the gut (47). Urease confers a survival advantage to *Proteus* by providing nitrate for nonfermentative anaerobic respiration. This in turn promotes the population expansion of the *Enterobacteriaceae* (including *Proteus*) (48, 49). Additionally, as with *Helicobacter pylori*, the presence of this enzyme likely confers a survival advantage through increasing the local pH of the environment, allowing urease-positive organisms to survive in more-acidic environments such as the

[a]Gastrointestinal cell line.

upper digestive tract. *Proteus* spp. have a wide pH range at which they are able to grow, from pH 5 to 10, with an optimal pH of 7 to 8 (9). Urease activity has been confirmed for *P. mirabilis*, *P. vulgaris*, and *P. penneri*, and production is regulated by both the environmental concentration of the substrate (urea) and increased chromosomal transcription in swarming cells (50–52).

Colonization of the upper gastrointestinal tract by urease-producing *Proteus* species may cause occasional false-positive results for the [^{13}C]urea breath test (UBT), especially if the patient has already been treated with proton pump inhibitors and antibiotics for *H. pylori* eradication (53). Given that urease is a known contributor to the pathogenesis of *H. pylori*-mediated damage in the upper gastrointestinal tract, it may also contribute to the pathogenicity of *Proteus* spp. in the gut in the setting of environmental perturbations, such as changes in pH.

Hemolysins. The *Proteus* genus produces two distinct cytotoxic hemolysins, HpmA and HlyA (51, 54, 55). *P. mirabilis* and most *P. vulgaris* strains produce only HpmA, most *P. penneri* strains produce HlyA, and a few isolated *P. vulgaris* strains produce both HpmA and HlyA (54, 56, 57). HpmA has been shown to lyse erythrocytes, bladder epithelial cells, B-cell lymphoma cells, and monocytes, while HlyA can lyse erythrocytes, fibroblasts, and neutrophils (55, 56). HpmA is a cell-associated hemolysin, encoded on the *hpm* locus along with HpmB (an activator and chaperone of HpmA). The expression of these hemolysin proteins is tightly coupled to the swimming-swarming cycle, with swarming cells being 18-fold more cytotoxic than swimmer cells (30). HpmA has also been shown to lyse erythrocytes under anaerobic conditions and at multiple temperatures (58). The contribution of hemolysins to gastrointestinal pathogenesis may occur through the lysis of innate immune cells, the induction of the NOD-like receptor protein 3 (NLRP3) inflammasome, and downstream interleukin-1β (IL-1β) release (59).

Intracellular invasion and persistence. Intracellular invasion by *Proteus mirabilis* has been assessed mainly by using cellular invasion assays in cell lines ranging from uroepithelial cells to colonic cell types.

In a cell-based urinary tract model, swarming cells were 15-fold (0.18% intracellular entry) more invasive to uroepithelial cells than swimmer cells (0.012% intracellular entry) (30). After the invasion of uroepithelial cells, swarmer cells start to divide, develop septums, and differentiate back to an average of 50 to 300 swimmer cells within the cytoplasm (30). *P. mirabilis* has been identified as being intracellularly invasive in a number of cell lines (summarized in Table 2). There are differences in the intracellular invasion and uptake pathways depending on the cell type, with intracel-

A53210128

lular vacuoles containing *P. mirabilis* having a single membrane within urothelial cells and a double membrane within intestinal cells (60, 61). These mechanisms may contribute to effective intracellular colonization (cytoplasmic colonies), evasion of the host immune system, and resistance to antibiotics (60).

Translocation of Gram-negative *Enterobacteriaceae* (including *P. mirabilis*) has been demonstrated *in vitro*, in terms of both uptake and intracellular persistence. By using Caco-2 and HT-29 cells (enterocyte cell lines), it was demonstrated that *P. mirabilis* not only is invasive but also can survive intracellularly for ≥20 h without affecting the viability of enterocytes (62). The origin of the *P. mirabilis* isolate influences the invasiveness of *Proteus* species in laboratory studies, with fecal isolates showing higher invasion efficiencies (61).

Proteus mirabilis is a common cause of pathogenic infection of bladders augmented with bowel segments (enterocystoplasty). A study investigated the colonization of colonic cell lines by *P. mirabilis* as a model for stone formation in enterocystoplasty. The HT29-18N2 cell line (a mucus-secreting intestinal goblet cell subclone of HT-29 [63]) underwent widespread cellular destruction, with extensive intracellular bacterial colonies. Furthermore, upon confocal microscopy, there was colocalization of *P. mirabilis* and both human colonic mucin MUC2 and human gastric mucin (MUC5AC) (63). There is experimental evidence that *Proteus* spp. can invade at least the outer mucous layer of the gut and the inner layer to the epithelial surface if there are certain immune defects. These defects include the absence of the Lypd8 protein or defects in innate immunity (the T-bet$^{-/-}$ × Rag2$^{-/-}$ colitis [TRUC] mouse model) (64–66). *Proteus mirabilis* has many invasive characteristics; however, they remain to be directly characterized in the context of gastrointestinal disease.

Immune evasion. In addition to intracellular invasion, *P. mirabilis* also secretes an extracellular metalloprotease (ZapA) that has been shown to degrade a wide range of substrates (Table 3). This enzyme has a key role in the evasion of innate immune destruction by *Proteus* species by the proteolytic digestion of secretory IgA, IgG, and other cellular components in the urinary and gastrointestinal tracts (20, 21). Kerr et al. showed ZapA cleavage products (IgA and IgG) in the urine of patients with *P. mirabilis*, reflecting protease activity *in vivo* (67). The expression of this protein has been shown to be correlated tightly with cellular differentiation from swimmer to swarming cells by *P. mirabilis*, with increased transcription of the ZapA locus (20). ZapA hydrolyzes human β-defensin 1, a constitutively expressed innate immune antimicrobial peptide that is expressed in the colonic epithelium, as well as secretory IgA (20, 21). The expression of ZapA in the gut may provide a survival advantage to *Proteus* spp. by perturbing host mucosal immune responses, increasing the likelihood of persistent colonization. The genomic rearrangements encoding the flagellin proteins of *Proteus mirabilis* and the antigenic variability of *Proteus* species lipopolysaccharide (LPS) (both reviewed below) also contribute to evasion of the host immune system (Fig. 3).

Endotoxin and flagellins. As a Gram-negative pathogen, *Proteus* species possess intrinsic characteristics similar to those of other *Enterobacteriaceae*, such as *Escherichia coli* and *Salmonella enterica* serovar Typhimurium, including the production of flagellin

A53210128

and the proinflammatory cell wall component LPS (68, 69). A constituent of LPS, endotoxin (lipid A), is highly immunostimulatory (70). Endotoxin is sensed by the innate immune system (specifically Toll-like receptor 4) and activates the downstream signaling of NF-κB (71). This, in turn, triggers a proinflammatory cascade (mediated by tumor necrosis factor alpha [TNF-α]) that can lead to acute sepsis (72, 73).

In addition to lipid A, *Proteus* species LPS includes O-antigens (polysaccharides that are repeating oligosaccharide units, each made up of 2 to 8 sugar residues) that are highly structurally diverse. Approximately 80 O-antigen serogroups have been reported, derived from a total of 60 O-antigen gene clusters (11, 73). Antibodies to O-antigens are not uncommon in human sera, for example, 25% of blood donors have anti-*P. mirabilis* antibodies to the O36 serogroup, which is just one of the many serogroups (74). The expression levels of virulence factors, such as urease, proteases (ZapA), and hemolysin, can vary significantly between the O-antigen serogroups, with negatively charged O-polysaccharide serogroups having higher ureolytic, proteolytic, and swarming activities (75). This heterogeneity of surface structures occurs across all *Proteus* species.

In addition, bacterial flagellins, the repeating protein subunits from which flagella are built, are highly immunogenic due to their three-dimensional structure (76). Bacterial flagellin is sensed by Toll-like receptor 5, which activates a number of downstream inflammatory pathways, including MyD88 (72, 76, 77). Recombination of the flagellin genes *flaA* and *flaB*, leading to hybrid flagellin proteins with significant antigenic variation, also contributes to innate immune evasion by *Proteus* spp. (78, 79) These features contribute to the overall pathogenicity of *Proteus* spp. via stimulation of the host innate immune system by bacterial products (Fig. 3).

Conjugation, plasmid acquisition, and antibiotic resistance. *Proteus* species are inherently antibiotic resistant. Resistance to polymyxins is mediated via covalent modifications of lipid A (80). The substitution of L-arabinoso-4-amine for either the Kdo residue or the ester-linked lipid A phosphate moiety increases the overall charge of the usually negative LPS to zero, reducing the binding of cationic polymyxins (69, 80, 81). They also possess intrinsic resistance to colistin, tigecycline, and tetracycline (82). Sequencing of *P. mirabilis* strain HI4320 demonstrated the presence of genes for a conjugal transfer pilus, which allows the horizontal genetic transfer of plasmids encoding antibiotic resistance (35).

While most species of *Proteus* remain sensitive to a range of antibiotics, increasing rates of acquired antibiotic resistance in the *Enterobacteriaceae* are a growing problem (83). In 2007 to 2008, observations of *P. mirabilis* strains acquiring *Salmonella* genomic island 1 (SGI1) were reported by groups in China and Palestine (84). SGI1 is a mobile genomic element first identified in *Salmonella* Typhimurium that integrates into the recipient chromosome and carries multiple genes encoding resistance to streptomycin, trimethoprim, tetracycline, sulfonamides, chloramphenicol, fluoroquinolones, and a broad spectrum of β-lactam antibiotics (84). A further SGI1-positive *P. mirabilis* strain (NKU) has also been identified in Europe (84). Recently, an SGI1-positive *P. mirabilis* strain acquired a plasmid containing the New Delhi metallo-β-lactamase 1 gene, leading to the identification of extensively drug-resistant (XDR) *P. mirabilis* strain PM58, which is resistant to all antibiotics used for *Enterobacteriaceae* except aztreonam (82). A recently sequenced *P. mirabilis* isolate (NO-051/03) from a patient with a soft tissue infection in Europe had acquired the resistance genes for trimethoprim, β-lactams, phenicols, sulfonamides, and aminoglycosides (85).

In gastrointestinal disease, the antibiotic sensitivity profile of *Proteus* species is relevant to pathogenicity under conditions that may be exacerbated by antibiotic perturbation of the gut microbiome. Given the potential for a "bloom" of *Enterobacteriaceae* (including *Proteus* species) both in the presence of an inflammatory process (86) and with a perturbation of the enteric environment via surgery (87), the use of antibiotics should be considered a possible potentiating factor.

A53210128

Vaccine Candidates

A full review of the treatment of *Proteus* infection is outside the scope of this review.

Purified MR/P fimbrial proteins have been tested for their antigenic potential as vaccine candidates (88, 89). There has been success by using the intranasal delivery of MrpH, the fimbrial tip adhesin of *P. mirabilis* (88). A fusion protein comprised of MrpH and mannose-binding protein delivered intranasally provided 75% protection from *P. mirabilis* ascending urinary tract infection in a mouse model (88). A fusion protein comprised of MrpH from *P. mirabilis* and FimH from uropathogenic *E. coli* delivered intranasally with monophosphoryl lipid A (as an adjuvant) induced robust IgG and IgA responses in mice (89). A clinical study of an inactivated bacterial cell suspension of four bacterial species, including a strain of *P. vulgaris*, was trialed in 159 patients with a history of recurrent urinary tract infections, compared with 160 patients maintained on prophylactic sulfamethoxazole-trimethoprim (90). The group of patients who received the vaccine had a mean number of 0.36 urinary tract infections in 3 months, versus 1.60 for those receiving sulfamethoxazole-trimethoprim ($P < 0.0001$) (90).

PROTEUS SPECIES AS GASTROINTESTINAL PATHOGENS

Colonization by *Proteus* Species

Proteus species are known human digestive tract commensal organisms with abundances varying according to location (Fig. 3). Colonization occurs early. Infants from Sweden and Pakistan were assessed for *Enterobacteriaceae* based on mode of delivery (vaginal versus cesarean) and breastfeeding behavior (91). Cesarean births in Pakistan were associated with *Proteus* species colonization within 3 days, with 11 of 21 cesarean-delivered and 1 of 9 vaginally delivered infants being positive for *Proteus* spp. ($P = 0.049$) (91).

Zilberstein et al. cultured mucosal samples from the upper ($n = 20$) and lower ($n = 24$) digestive tracts of healthy controls. *Proteus* species were present in 8% of gastric samples, 46% of duodenal and jejunal samples, 19% of ileal samples, 13% of cecal samples, and 38% of samples from the transverse colon (12).

Müller compared the recovery of *Proteus* species from the stool specimens of 1,422 healthy subjects. *P. mirabilis* was identified in 2.7% of healthy subjects, which is a probable underestimate as the epithelial preference of *P. mirabilis* means that it is likely undersampled in stool specimens (92). *Proteus penneri* and *P. vulgaris* were isolated from 0.9% and 4.2%, respectively, of the same population (92). A smaller culture-based study of 60 patients with gastrointestinal symptoms who tested negative for parasites demonstrated a colonization rate of 33% (20/60 patients) for *P. vulgaris* (93).

Proteus species, especially *P. mirabilis*, are often antibiotic resistant, conferring a survival advantage when colonizing the gastrointestinal tract. In a study of multiple-drug-resistant Gram-negative bacteria in the rectum of long-term-care patients, 52 drug-resistant strains were identified, 15 of which were *P. mirabilis* strains (94). A total of 87% of patients colonized with *P. mirabilis* were also cocolonized with at least one other resistant Gram-negative bacterium (range, 1 to 4 species; median, 2 species). Of the 15 patients with a resistant *P. mirabilis* strain, only 1 patient spontaneously cleared the organism, compared to 30 to 75% clearance for other bacterial species ($P = 0.007$ for clearance of other species versus *P. mirabilis*, as determined by a log rank test), demonstrating the ability of *P. mirabilis* to cause more-persistent colonization than other Gram-negative species (94). Of the 15 *P. mirabilis* strains recovered, 13 were genetically distinct, demonstrating the heterogeneity of *P. mirabilis* populations between patients within the same health care facility (94).

Proteus spp. in Gastroenteritis

Proteus species have been associated with infectious gastroenteritis. In a comparison of 1,271 patients with diarrhea, *P. mirabilis* was more prevalent in patients with diarrhea (10.8% in affected cases versus 2.7% in healthy subjects; $P < 0.001$) (92). However, that study did not take into account the possible administration of antibiotics to affected patients or the potential bystander or overgrowth effect (92). *P. mirabilis* has also been

associated with foodborne gastroenteritis in an outbreak in Beijing, China, associated with the consumption of stewed pork (95). Shi et al. investigated genetic adaptation to the digestive tract of *P. mirabilis* species isolated from the vomit and feces of patients, obtained at the time of a foodborne outbreak (96). When three clinical isolates were compared to four local and reference strains of *P. mirabilis*, obtained from food, a healthy subject, and two patients with urinary tract infections (including reference strains HI4320 and BB2000), there was evidence of strain-level genetic adaptation to the digestive tract (96). All seven isolates harbored drug resistance genes, but only the three isolates (one from vomit, one from stool, and one from infected food) contained digestive tract toxicity genes, including one with a complete type 4 secretion system (T4SS) not identified previously in *P. mirabilis*. Active horizontal gene acquisition has been demonstrated for *Proteus mirabilis*, including a protein from *Yersinia enterocolitica*, a known GI pathogen and member of the *Enterobacteriaceae* family (96). In summary, *Proteus* species can be linked to diarrheal states, but their primary pathogenic role has not been confirmed.

Proteus spp. in the Upper Gastrointestinal Tract

Colonization of the upper gastrointestinal tract, including the esophagus and stomach, by *Proteus* species in infants and older adults has been reported, often associated with instrumentation of the oropharynx (97–101). In 13 infants with feeding tubes without gastrointestinal symptoms, *Proteus* was isolated from the throat in 8% of patients, from the gastric juice in 15% of patients, and from the duodenal fluid in 8% of patients (98). In elderly patients with nasogastric feeding tubes (NGTs), *Proteus* species were isolated from the oropharynx in 24% of patients and from gastric fluids in 26% of patients (100). In another study, colonization of the oropharynx with *Proteus* species was present in 13% of patients with percutaneous endoscopic gastrostomy (PEG) and 21% of patients with NGTs, and colonization of the stomach was present in 4% and 23% of the same patients, respectively (99).

Association with Hepatobiliary Disease

Early culture-based surveys of patients undergoing biliary surgery showed the occasional isolation of *Proteus* species from the biliary tract (13% of bile samples) (102). *P. mirabilis* has also been recovered from bile obtained during endoscopic retrograde cholangiopancreatography (ERCP) in 6% of cultured samples (103).

In a metagenomic analysis using multitag pyrosequencing, the rectosigmoid mucosal community of healthy individuals was compared with that from patients with cirrhosis. Patients with cirrhosis had an elevated proportion of *Proteus* species compared with controls; the relative abundance in healthy controls was 0.0%, versus 0.1% in patients with cirrhosis ($P < 0.00001$) (104). Urease-producing microbes, such as *Proteus* spp., in the gut are known to contribute to the pathogenesis of hepatic encephalopathy through the breakdown of urea to ammonia and carbonic acid (104, 105).

In a series of patients undergoing liver resection, *Proteus vulgaris* bacteremia was identified in two patients, and polymicrobial infections were identified in eight patients (106). In the hepatobiliary tract, *Proteus* spp. are an uncommon cause of infection and are usually related to surgical interventions, such as ERCP or abdominal surgery. Implantable devices, such as stents, are also at risk of colonization and biofilm formation (107).

Pancreatic Disease

There are isolated reports of *Proteus* species infections of the pancreas, including a patient with a large infected pancreatic pseudocyst compressing the common bile duct. The cystic contents were polymicrobial, including *Proteus vulgaris*, *Morganella morganii*, *Stenotrophomonas maltophilia*, and *Pseudomonas aeruginosa* (108).

Proteus species were found in biofilms that form on biliary and pancreatic stents placed via ERCP in 14 of 100 stents (107).

A53210128

Intestinal Disease

There are a number of reported links between *Proteus* spp. and various intestinal conditions, including small bowel intestinal overgrowth, Crohn's disease, and ulcerative colitis.

A small study of the downstream effects of small bowel ulceration caused by nonsteroidal anti-inflammatory drugs in rats identified a mixed population of *E. coli* and *P. mirabilis*. When treated with metronidazole, rats were protected from ulcer development (109). *Proteus* species were recovered from jejunal fluid in 11% of patients with small intestinal bacterial overgrowth syndrome (SIBOS), which often follows the expansion of facultative anaerobic bacterial communities (110). Viable bacterial translocation of *Proteus mirabilis* across the intact intestinal barrier has been demonstrated from the cecal and colonic mucosa of a monoassociated mouse model, with bacteria being additionally isolated from the mesenteric lymph nodes and the liver (111).

Crohn's disease. Recent research has implicated *Proteus* spp. in inflammatory bowel diseases, with evidence being derived both from patient-based microbiome surveys and mechanistic research. Ambrose et al. used culture-based techniques to compare the recovery of pathogenic gut bacteria from the ileal serosa and mesenteric lymph nodes in 45 Crohn's disease patients and 43 patients having surgery for other indications (112). Overall, Crohn's disease cases were more likely to have pathogenic bacteria recovered from the small bowel serosa (12/45 [27%] patients versus 6/41 [15%] controls). Of the 12 patients with positive serosal cultures, 4/12 patients were positive for *Proteus* spp. (33%). Additionally, involved and uninvolved mesenteric lymph nodes were assessed: 15/45 patients (33%) with involved nodes had a positive culture, and of these samples, 1/15 (7%) grew *Proteus* spp. Eleven of 45 samples of uninvolved nodes harbored bacteria, with 1/11 (9%) being positive for *Proteus* species (112). Although these data are not significant due to small numbers, they demonstrate the recovery of *Proteus* species from patients with Crohn's disease, while the recovery of *Proteus* species from lymph nodes establishes bacterial translocation, in line with the other members of the *Enterobacteriaceae* family (113).

Two microbiome studies have linked an overabundance of *Enterobacteriaceae* and *Proteus* spp. to Crohn's disease. In a pediatric study, *Proteus* species comprised 3/18 (16.7%) Gram-negative bacterial strains recovered from 12 Crohn's disease patients, compared to the total absence of *Proteus* species recovered from patients with ulcerative colitis, indeterminate colitis, and lymphonodular hyperplasia and from controls (114). A microarray-based study comparing patients with active Crohn's disease with matched healthy controls identified an overrepresentation of *Proteus* species overall, and *Proteus vulgaris* in particular, and other members of the *Proteobacteria* phylum in patients with active ileal disease requiring surgery (115).

A number of studies have addressed the mechanisms by which *Proteus* and other *Enterobacteriaceae* may contribute to the development of inflammatory bowel diseases. The TRUC mouse model of ulcerative colitis has been used to demonstrate that *Proteus mirabilis* and *Klebsiella pneumoniae* can elicit colitis and that this propensity for the development of colitis can be transmitted to wild-type mice via microbiome transfer (65).

Crohn's disease has been associated with changes in nitrogen metabolism. Ammonia produced from the breakdown of urea by bacterial urease provides a source of nitrogen for respiration and amino acid synthesis by pathogenic facultative anaerobes from the *Proteobacteria* phylum (49).

Interactions between the *Enterobacteriaceae*, which include *Proteus* species, and fungi (*Candida tropicalis*) have recently been implicated in the dysbiosis that characterizes Crohn's disease (116). When Crohn's disease patients were compared with first-degree relatives of Crohn's disease patients and healthy controls, bacterial dysbiosis was identified in affected patients and unaffected first-degree relatives. Crohn's disease patients had an increased presence of *Candida tropicalis*. Complex interactions between *Enterobacteriaceae* species (*Serratia marcescens* and *E. coli*) and *Candida*

A53210128

tropicalis were confirmed in laboratory studies, showing that flagellated and/or fimbriated bacteria combined with fungal hyphae to form a robust biofilm, with these three species combined forming the thickest biofilm ($P < 0.0001$). It was postulated that biofilms enriched for immunomodulatory microbial components (lipopolysaccharides and oligomannans, etc.) may perpetuate inflammation in dysbiotic patients through the induction of proinflammatory cytokine responses and of apoptosis. *Proteus* spp. were also strongly positively correlated with the abundance of *Candida* in patients with familial Crohn's disease ($r = 0.709$; $P < 0.005$), raising the possibility that *Proteus* spp. are capable of the same interactions, although this was not demonstrated, possibly due to their low abundance (116).

Seo et al. demonstrated that in the presence of intestinal injury and colonization with *P. mirabilis*, a marked proinflammatory IL-1β response occurs, via the activation of the NOD-like receptor protein 3 (NLRP3) inflammasome (59). This occurs only in the presence of the *P. mirabilis* hemolysin HpmA, which appears to induce host macrophage induction of NLRP3. Preexisting injury or inflammation was necessary for the induction of NLRP3 activity and IL-1β by *P. mirabilis* (dextran sodium sulfate [DSS]-induced colitis), as inflammatory monocytes were required, suggesting that *P. mirabilis* may act to perpetuate and accelerate preexisting inflammation rather than induce it. *Proteus mirabilis* was as efficient at inducing IL-1β as pathogenic *Salmonella* spp., but the presence of the HpmA hemolysin was essential for the induction of IL-1β. IL-1β has been shown to be associated with disease activity in IBD patients (117, 118); however, in that study, most other anaerobic or facultative anaerobic commensals induced TNF-α expression but not IL-1β (59). When hemolysin expression levels were compared across *P. mirabilis* strains from multiple clinical sources (pyelonephritis, catheter-associated, and fecal isolates), fecal isolates had the highest hemolytic activity and had significantly higher hemolytic titers than those of the catheter-associated strain ($P = 0.001$) but not those of the pyelonephritis strain ($P = 0.065$) (119).

Proteus species have been associated with the postoperative recurrence of Crohn's disease by two independent groups (2, 3). Metagenomic surveys of patients at the time of surgery and 6 and 18 months postoperatively demonstrated that patients were more likely to have disease recurrence in the presence of detectable *Proteus* genera ($P = 0.008$) and the absence of detectable *Faecalibacterium* ($P < 0.001$) (3). The combination of detectable *Proteus* species and absent *Faecalibacterium* (<0.1%) in postoperative ileal biopsy specimens was associated with an increased risk of recurrence, with an odds ratio (OR) of 14 (95% confidence interval [CI], 1.7 to 110; $P = 0.013$). Smoking, an independent risk factor for postoperative disease recurrence, was also associated with an increased presence of *Proteus* spp. ($P = 0.0130$) (3). In another study by Mondot et al. of 20 Crohn's disease patients undergoing ileocolonic resection, the presence of a *Proteus mirabilis* operational taxonomic unit (OTU) was predictive of recurrence at 6 months postoperatively (2).

A recent review of consecutive Crohn's disease patients with intra-abdominal abscesses as a result of active disease demonstrated infection with *Proteus* spp. in 4.8% of cases, which was associated with high rates of quinolone resistance (120). Whether the presence of *Proteus* spp. in association with postoperative recurrence is a primary pathogenic event or secondary to disease recurrence remains to be elucidated. However, the association in both studies was established prospectively and longitudinally, with predictive association, making a pathogenic role more likely.

Other large intestinal diseases. Kanareykina et al. obtained samples (mouth, stomach, small intestine, and feces) from 65 patients with ulcerative colitis; performed culture-based enumeration; and identified *Proteus mirabilis*, *Proteus vulgaris*, or the closely related species *Morganella morganii* or *Providencia rettgeri* (Fig. 1) in nearly all cases (121). In 40/65 patients, these species were recovered from more than one anatomic site. A *Proteus* species protein "vaccine" was then administered and resulted in clinical improvement in moderate to severe cases of ulcerative colitis as well as a decrease in bacterial counts. However, no details of the vaccine composition or any

A53210128

objective disease activity metrics were described, and the study overall was of low quality (121).

A recent study of children with and without appendicitis showed increases in the relative abundances of 12 genera, of which *Proteus* species were the only representatives of the *Enterobacteriaceae* family (0.015% versus 0%; $P = 0.028$) (122).

Proteus bacteria have been implicated in the perpetuation of colonic inflammation in diversion colitis (123). Inflammatory conditions of the bowel increase the local concentrations of inducible nitric oxide synthase, leading to high levels of nitrate that cannot be metabolized, except by the microbiota (124). This favors the expansion of bacteria that are able to metabolize nitrate under anaerobic conditions, leading to a survival advantage and population expansion of *Proteus* spp. and other nitrate-reducing *Enterobacteriaceae* (48, 123).

Nosocomial Infections and *Proteus* Species Complicating Gastrointestinal Disease

Proteus species, especially *P. mirabilis* and *P. vulgaris*, are common causes of nosocomial opportunistic infections. Many patients with preexisting gastrointestinal diseases are liable to secondary *Proteus* infections, often in the context of polymicrobial infections. *Proteus* species can also cause peritonitis following perforations of the gastrointestinal tract; in one report of 383 patients with peritonitis, *Proteus* species were identified in 87 (23%) patients (125).

Proteus species can colonize medical devices placed in the gastrointestinal tract, including ventriculoperitoneal shunts (126), nasogastric tubes (99, 100), biliary and pancreatic stents (107), and tracheoesophageal voice prostheses (127). *Proteus* bacteria have been shown to be contaminants of gastroscopes and colonoscopes after insufficient disinfection (128). Infections can also be acquired in the hospital setting due to environmental contamination, with *P. vulgaris* persisting on dry, hard surfaces for up to 2 days (129). There are reports of hospital-based and community epidemics of infection with person-to-person spread, with most patients acquiring gastrointestinal carriage prior to infection (13, 130).

CONCLUSIONS

Proteus species are hardy, adaptable, and potentially pathogenic residents of the human gastrointestinal tract and have been underappreciated as a cause of gastrointestinal disease. Host-microbe and microbe-microbe interactions by *Proteus* spp., and the pathogenicity of this genus that may result from population expansion in response to environmental changes, are emerging as important aspects of disease associated with this genus. The possible contribution of *Proteus* spp. to intestinal diseases and infections has been somewhat neglected. Research into the virulence of *Proteus* spp. in the urinary tract using the bacteriology of ileal conduits (131) and intestinal segments (60, 132) for bladder augmentation suggests that *Proteus* spp. should be examined more closely for their potential as gastrointestinal pathogens.

There is increasing evidence that *Proteus* species may play a role in inflammatory bowel disease through the direct action of the bacteria, compounded by host immune evasion and perturbation. As Gram-negative organisms, *Proteus* species are intrinsically proinflammatory as a result of the production of lipopolysaccharide (LPS) and immunostimulatory flagellin proteins. There may be an association between *Proteus* species and inflammatory bowel disease, especially Crohn's disease, mainly through population expansion and immune activation. Their low population abundance does not preclude a potential large pathogenic effect.

Genetic characterization of enteric isolates compared to urinary tract isolates will be important for determining the effect of virulence factors on gastrointestinal pathogenesis.

Research on the gut microbiome as an ecosystem is informing our understanding of *Proteus* species, yet there are still unanswered questions. These include obtaining confirmation that *Proteus* species can swarm within the human gut and addressing the

A53210128

effect of individual environmental changes (e.g., surgery, pH, or oxygen concentrations) on the mucosa-associated *Proteus* population.

ACKNOWLEDGMENTS

A.L.H. was supported via a Dora Lush postgraduate scholarship from the National Health and Medical Research Council (NHMRC). St Vincent's Research Endowment Fund and the Australasian Gastro Intestinal Research Foundation supported M.A.K. The University of Queensland Diamantina Institute and The University of Queensland supported M.M. The Leona M. and Harry B. Helmsley Charitable Trust supported this work.

We have no conflicts of interest.

M.A.K. and A.L.H. devised the concept. A.L.H. acquired data, screened papers, interpreted the data, and wrote the manuscript. M.A.K., S.C.N., and M.M. provided critical revision of the manuscript for important intellectual content.

Amy L. Hamilton is a Clinical Scientist from St Vincent's Hospital and the University of Melbourne. She graduated from Monash University, Melbourne, Australia, with a bachelor of science, with Honors in Microbiology and Immunology. She has worked on a number of investigator-initiated clinical trials in gastroenterology and is passionate about translational research in inflammatory bowel disease as a way of improving long-term outcomes for patients. She has a special interest in the gut microbiome and its role in the etiology of inflammatory bowel diseases, with this research focus allowing her to utilize both basic science and translational skills. She has completed her Ph.D. in the Department of Medicine at the University of Melbourne, addressing the microbiology of Crohn's disease after surgical resection. She has been a member of Professor Michael A. Kamm's research group since 2010.

Michael A. Kamm is Gastroenterologist at St Vincent's Hospital Melbourne and Professorial Fellow at the University of Melbourne, Melbourne, Australia, since 2008. He was previously Chairman of Medicine and Director of the Physiology and Inflammatory Bowel Disease Units at St Mark's Hospital in London, United Kingdom, from 1989 to 2008 and Professor of Gastroenterology at Imperial College London. He treats and researches in the fields of inflammatory bowel disease (IBD) and functional bowel disorders. Professor Kamm has conducted multidisciplinary research, spanning basic science, translational, and clinical aspects of gut disorders. In the field of the gut microbiota and IBD, he has studied mechanisms of inflammation, including recognition of bacterial antigens by dendritic cells and the immunological and clinical therapeutic effects of putative prebiotics and probiotics. Most recently, he conducted investigator-initiated studies into the perioperative management of Crohn's disease ("POCER" study) and fecal microbiota transplantation in ulcerative colitis ("FOCUS" study), both changing outcomes for patients and identifying specific bacteria associated with clinical outcomes.

Siew C. Ng is Professor at the Department of Medicine and Therapeutics, The Chinese University of Hong Kong. She received her medical degree from St Bartholomew's and Royal London School of Medicine and obtained her Ph.D. from Imperial College London. Dr. Ng's main research interests include inflammatory bowel disease, gut microbiota, and colorectal cancer, aiming to further our understanding of the pathogenesis of inflammatory intestinal disorders via clinical trials and translational research. She is President of the Hong Kong IBD Society, Scientific Secretary of the International Organization of IBD, and member of the Management Committee of the International IBD Genetics Consortium. She has published over 150 peer-reviewed papers in international journals, including *Nature Genetics*, *Nature Communications*, *Lancet*, *Gastroenterology*, and *Gut*. She is a pioneer of IBD Epidemiologic and Microbiome research in Asia-Pacific. Her work has received over 20 Prestigious National and International Awards.

Mark Morrison is the Chair in Microbial Biology and Metagenomics at The University of Queensland Diamantina Institute (UQDI), since October 2013. An authority in metagenomic and molecular microbiology, he is currently Australia's science representative to the International Human Microbiome Consortium. Professor Morrison obtained his Ph.D. from the University of Illinois, Urbana, IL. After 20 years in the United States, he returned to Australia in 2006 as CSIRO's first appointment via the Science Leader Scheme (leading the Gut Health Flagship Research Program). Since 2007, he has held a Professorship within the School of Chemistry and Molecular Biosciences, The University of Queensland. Professor Morrison aims to translate genomic and metagenomic data sets into sound biological frameworks, helping to produce novel diagnostic, organismal, and enzyme-based technologies. While Professor Morrison's focus was initially on microbial physiology and metabolism, he has since attained international acclaim for his efforts to successfully develop and use genomics and related methods to study anaerobic "commensal" gut bacteria.

Characteristics and Outcomes of Polymicrobial Bloodstream Infections in the Emergency Department: A Matched Case–control Study

Jiun-Nong Lin, MD, Chung-Hsu Lai, MD, Yen-Hsu Chen, MD, Lin-Li Chang, PhD, Po-Liang Lu, MD, Shang-Shyue Tsai, PhD, Hsing-Lin Lin, MD, and Hsi-Hsun Lin, MD

Abstract

Objectives: Polymicrobial bloodstream infection (BSI) is a critical condition and has been increasingly reported; however, the authors were unable to find an emergency department (ED) patient-based study in the literature.

Methods: A retrospective matched case–control study with a ratio of 1:3 among patients with polymicrobial BSIs in an ED was conducted. The case group was patients aged > 16 years with polymicrobial BSIs. Patients matched for age and sex with monomicrobial BSIs were sampled as the control group. Demographic information, underlying conditions, microbiologic data, and outcomes were collected for further analysis.

Results: From January 2005 to December 2007, a total of 112 episodes of polymicrobial BSIs among 109 patients were included. Two pathogens were isolated among 87 (77.7%) episodes and three were found among 25 (22.3%) episodes. A history of hospitalization within 90 days was an independent risk factor for polymicrobial BSIs ($p = 0.003$). Intraabdominal infection ($p < 0.001$) and respiratory tract infection ($p = 0.017$) were more likely to be associated with polymicrobial BSIs. Gram-negative and Gram-positive bacteria were documented in 95.5 and 46.4% episodes of polymicrobial BSIs, respectively. Inappropriate antimicrobial treatment was observed in 53.6% of polymicrobial BSIs, but only accounted for 23.8% of monomicrobial BSIs ($p < 0.001$). The overall 30-day mortality rate of the polymicrobial group was significantly higher than those with monomicrobial BSIs (30.3 and 11.6%, respectively; $p < 0.001$).

Conclusions: Patients with polymicrobial BSIs had a high mortality rate. Acknowledgment of the clinical and microbiologic characteristics and recognition of patients at risk for polymicrobial BSIs are critical in EDs.

Blood cultures are frequently used to evaluate patients with fever in emergency departments (EDs). More than 3.1 million blood cultures, associated with 2.8% of all ED visits, are ordered annually in the United States.[1] Although almost half of all blood cultures ordered in the ED may not be necessary, patients with positive blood cultures more often than not have a serious infection and need admission for further treatment.[1,2]

Polymicrobial bloodstream infection (BSI), defined as the presence of at least two different microorganisms found from the blood cultures, has been reported increasingly, with rates ranging from 6% to 32% of all BSI episodes.[3–7] The mortality rate of hospitalized patients with polymicrobial BSIs ranged from 21% to 63%, approximately twice the rate of those with monomicrobial infections.[3,4,8,9] Most patients with

polymicrobial BSIs have underlying medical conditions including malignancy, neutropenia, gastrointestinal disease, genitourinary disease, recent surgical procedures, or the presence of central venous catheters.[3–7,10,11] Nevertheless, the majority of investigations of polymicrobial BSIs are limited to unselected populations or neutropenic patients with underlying malignancy.

Despite the critical nature of polymicrobial BSIs in EDs, to our knowledge, no emergency patient-based study for polymicrobial BSIs could be found in the literature. Therefore, we performed a retrospective matched case–control study among patients with polymicrobial BSIs with the following objectives: 1) to explore clinical characteristics and underlying diseases, 2) to identify isolated microorganisms, 3) to define the sources of infections, 4) to evaluate empirical antimicrobial treatment, and 5) to compare their survival rates.

METHODS

Study Design

We conducted a retrospective matched case–control study to compare polymicrobial with monomicrobial BSIs in patients arriving at an ED. This study was approved by the institutional review board of E-Da Hospital in Taiwan.

Study Setting and Population

This study was carried out at E-Da Hospital, a 1,000-bed university-affiliated hospital in southern Taiwan with approximately 60,000 annual ED visits. The records of all positive blood cultures collected at an ED between January 2005 and December 2007 from patients aged > 16 years were reviewed.

Study Protocol

The medical records of included patients were each reviewed by two authors. If any discrepancy was found, the medical records were inspected again by these two authors together. Demographic information of age and sex, underlying illness, clinical condition, microbiology, source of bacteremia, and outcome were collected from the medical records. Clinical data were analyzed by case episodes. All patients with polymicrobial BSIs were enrolled into the case group, whereas those with monomicrobial BSIs were enrolled in the control group. For the purpose of comparison, we performed matching by a blinded observer unaware of the clinical outcomes. Patients with polymicrobial BSIs were matched by sex and age (±3 years) with a ratio of 1:3 to those with monomicrobial BSIs during the same study period.

Episodes were considered distinct if separated by at least 7 days and if the reason for visiting the ED was different. Monomicrobial and polymicrobial BSIs were defined as one species and two or more species that were isolated from blood cultures, respectively. Shock was defined as systolic pressure less than 90 mm Hg or requiring inotropic agents to maintain blood pressure during the ED stay. The sources of BSIs were determined clinically on the basis of the presence of an active infection site coincident with BSIs or isolation of the organism from other clinical specimens prior to or on the same date as the onset of BSIs. If a polymicrobial BSI was presumed to be due to two different sources, the episode was excluded from our study. If the source of a BSI could not be attributed to any known source, it was classified as a primary BSI.

According to the blood culture collection guidelines of E-Da Hospital, two sets of blood cultures collected 30 minutes apart with proper site preparation and aseptic technique were ordered routinely by physicians if infection was suspected. If patients received antibiotics within 24 hours, BACTEC resin-containing blood culture bottles were used (Becton Dickinson Diagnostic Instrument System, Sparks, MD). All blood culture samples were processed by the BACTEC 9240 system (Becton Dickinson). Susceptibilities to antimicrobial agents were determined according to the Clinical and Laboratory Standards Institute criteria of the year.[12–14] If the blood cultures yielded skin flora, including coagulase-negative staphylococci, micrococci species, diphtheroids, *Bacillus* species, or *Propionibacterium acnes* in only one culture, these microorganisms were regarded as contaminated,[15] and these episodes were excluded from our study.

Antimicrobial therapy was considered inappropriate if the regimen included antimicrobial agents that were not effective against all of the pathogens isolated from the blood cultures via in vitro susceptibility testing or the lack of antibiotic therapy during the ED stay. We classified the inappropriate antibiotics therapy into four groups: 1) use of improper kinds of antibiotics (such as enterococci, which should be treated with penicillin but were treated with a cephalosporin); 2) use in resistant microorganisms (such as extended-spectrum β-lactamase-producing *Enterobacteriaceae* and methicillin-resistant *Staphylococcus*); 3) combination therapy needed but not received (such as two or three isolates in polymicrobial BSIs, which cannot be treated by only one antibiotic); and 4) no antibiotics use during the ED stay.

Outcome Measures

We used the overall 30-day mortality for outcome analysis. The causes of mortality were determined by the medical records. If patients were discharged within 30 days after admission and were not followed up at our hospital, telephone contact was made to collect the required information. Patients who were lost to follow-up were excluded from our study.

Data Analysis

We used the SPSS software package (version 14.0, SPSS Inc., Chicago, IL) to analyze the results. Categorical variables were analyzed using the chi-square test or Fisher exact tests, as appropriate. Continuous variables were analyzed using the Student's t-test. Univariate odds ratios (ORs) were computed by the Mantel-Haenszel test. To identify the risk factors for polymicrobial BSIs, underlying conditions that could contribute to polymicrobial BSIs and were associated with a level of significance of less than 0.20 in univariate analyses were included in a logistic regression model for multivariate analysis (conditional backward stepwise model). The OR, 95% confidence interval (CI), and p-value

15532712, 2010, 10, Downloaded from https://onlinelibrary.wiley.com/doi/10.1111/j.1553-2712.2010.00871.x by Schweizerische Akademie Der, Wiley Online Library on [02/06/2025]. were calculated for each factor. The Hosmer-Lemeshow goodness-of-fit test was used to assess the fitness of the model. Survival data were analyzed by Kaplan-Meier plots. Associations between variables and survival were compared using the log-rank tests. All p-values were two-tailed and a p-value < 0.05 was considered statistically significant.

RESULTS

Characteristics of Enrolled Episodes

During the study period, a total of 4,290 positive blood cultures were documented among 162,760 ED visits (Figure 1). A total of 112 episodes of polymicrobial BSIs among 109 patients were included in our study. Three patients had two episodes of polymicrobial BSIs. Two pathogens were isolated among 87 (77.7%) episodes, and three pathogens were found among 25 (22.3%) episodes. Sixty patients were male and 52 were female, and their median age was 65 years (mean ± SD = 64.0 ± 15.7; range = 18–89 years).

Underlying Conditions

After matching, no significant differences by age or sex were noted between case and control groups. The prevalence of underlying conditions is shown in Table 1. The presence of malignancy (p = 0.018) and a history of hospitalization within 90 days (p = 0.003) were associated with polymicrobial BSIs. However, multivariate regression analysis showed that only patients with a history of hospitalization within 90 days were predisposed to polymicrobial BSIs (OR = 1.92; 95% CI = 1.25 to 2.97; p = 0.003).

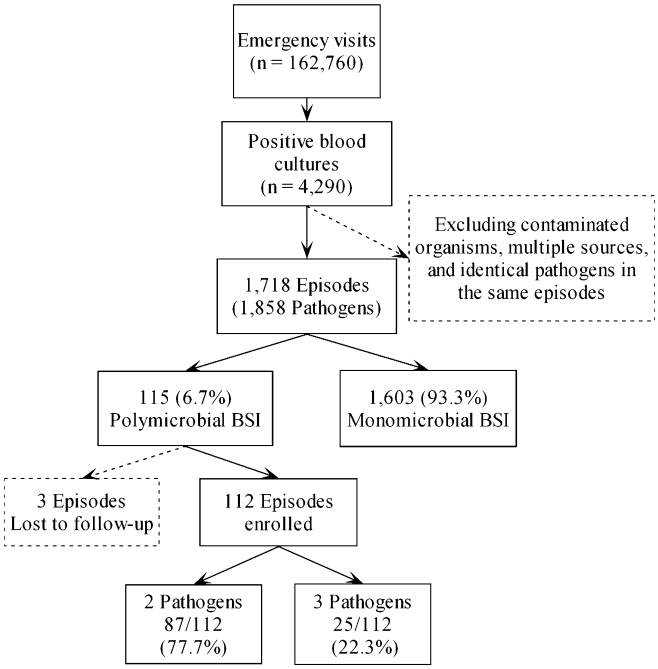

Figure 1. Patient enrollment, number of bacteremic episodes, and number of isolates in polymicrobial BSIs. BSI = bloodstream infection.

Table 1
Demographic Characteristics, Underlying Conditions, and Clinical Manifestations of 112 Polymicrobial and 336 Monomicrobial BSI Episodes

Primary bacteremia	12 (10.7)	48 (14.3)	0.72 (0.37–1.41)	0.337
Others*	0	4 (1.2)	—	—

BSI = bloodstream infection.
*Including central nervous system infection and ear, nose, and throat infection.

Sites of Infections

The sources of infections could be identified in 89.3% of polymicrobial BSIs and in 85.7% of monomicrobial BSIs. The most common source of polymicrobial BSIs was intraabdominal infection (33.9%). Comparing with monomicrobial BSIs, sources of polymicrobial BSIs were significantly more likely attributed to intraabdominal infection (p = 0.001) and lower respiratory tract infection (p = 0.017). On the contrary, monomicrobial episodes were significantly more likely to arise from the urinary tract infection (p < 0.001; Table 2).

Pathogens of Bacteremia

The isolates of polymicrobial and monomicrobial BSIs are presented in Table 3. Only one episode of *Candida albicans* was found in the group of polymicrobial BSIs. Gram-positive bacteria were found in 95.5% of polymicrobial BSIs, and Gram-negative bacteria were identified in 46.4%. The most frequent isolates of Gram-negative and Gram-positive bacteria in polymicrobial BSIs were *Escherichia* species (57.1%) and streptococci (26.8%), respectively.

Table 4 shows the microorganisms isolated from patients with polymicrobial BSIs according to their infection sites. Gram-negative bacteria could be recognized in the majority of urinary tract infections (73.8%), lower respiratory tract infections (86.7%), catheter-related BSIs (85.7%), and intraabdominal infections (78.4%). In contrast, Gram-negative bacteria could be identified in only half of skin and soft tissue infections. The most common polymicrobial combination in both lower respiratory tract infection and intraabdominal infection was *Escherichia coli* and *Klebsiella pneumoniae* coinfection (25 and 23.7%, respectively).

Antimicrobial Therapy

Inappropriate antimicrobial treatment was found in 53.6% of patients with polymicrobial BSIs and was significantly more frequent than in those with monomicrobial BSIs (23.8%; OR = 3.69; 95% CI = 2.36 to 5.78; p < 0.001; Table 1). Figure 2 shows the proportions of inappropriate antimicrobial therapy in polymicrobial BSIs by different sites of infections. The types of inappropriate antibiotics use are demonstrated in Figure 3. One-third of polymicrobial bacteremic patients should have received combination therapy of antibiotics but did not.

Survival Analysis

The overall 30-day mortality rates of patients with polymicrobial and monomicrobial BSIs were 30.3 and 11.6%, respectively. Patients receiving inappropriate antibiotics had a higher mortality rate than those who were treated with appropriate antibiotics (p = 0.011). Among these mortality cases, 70 died directly due to infections, and three patients died of other etiologies (hepatocellular carcinoma rupture, spontaneous subarachnoid hemorrhage, and respiratory failure due to pulmonary metastasis in a hepatocellular carcinoma patient). In the survival analysis, patients with polymicrobial BSIs had a significantly higher overall mortality rate than those with monomicrobial BSIs (p < 0.001; Figure 4). Patients infected with two or three microorganisms had a significantly higher overall 30-day mortality rate than those with only one isolate (p < 0.001 and p = 0.001, respectively). However, there was no statistical difference between the group of two-pathogen and three-pathogen polymicrobial BSIs (p = 0.234).

DISCUSSION

Our study found that polymicrobial BSIs accounted for 6.7% of all BSI episodes in the ED, which is similar to the previous reports of general population studies.[4,16] We also identified that a history of hospitalization within 90 days was an independent risk factor for polymicrobial BSIs, as was bacteremia due to lower respiratory tract infection or intraabdominal infection. Polymicrobial BSIs are known to be associated with hospital-acquired infections in several studies.[8,9,17] Intraabdominal infection is also a well-known cause of polymicrobial bacteremia.[9] Lower respiratory tract infections have also been associated with multiple pathogens. Lauderdale et al.[18] reported that polymicrobial infection occurred in 4% to

BSI = bloodstream infection; ESBL = extended-spectrum β-lactamase; MRSA = methicillin-resistant *S. aureus*.
*The rate of Gram-positive bacteria in one episode of polymicrobial BSI was 46.4% (52/112), significantly higher than monomicrobial BSI (OR = 2.77; 95% CI = 1.77 to 4.34; p < 0.001).
†The rate of Gram-negative bacteria in one episode of polymicrobial BSI was 95.5% (107/112), significantly higher than monomicrobial BSI (OR = 6.80; 95% CI = 2.68 to 17.25; p < 0.001).
‡Including *Providencia alcalifaciens, Chryseobacterium meningosepticum, Serratia marcescens, Moraxella* spp., *Plesiomonas shigelloides, Weeksella virosa, Vibrio cholerae, Vibrio vulnificus, Flavobacterium* spp., *Shewanella putrefaciens* Bv. 1, *Stenotrophomonas maltophilia*, *Pasteurella multocida*, *Methylobacterium* spp., *Pantoea agglomerans*, *Lactobacillus* spp., *Leclercia adecarboxylata*, *Listeria monocytogenes*, *Stomatococcus mucilaginosus*, and *Roseomonas* spp.

39% of patients with community-acquired pneumonia. *Streptococcus pneumoniae* is found to be the most common pathogen mixed with other pathogens in western countries.[19–21] However, our study revealed that *K. pneumoniae* is the most common isolate in the polymicrobial bacteremic patients. This may be due to the high prevalence rate of *K. pneumoniae* infection in Taiwan.[22]

With regard to the microbiology of polymicrobial BSIs, we noted that nearly all episodes included at least one isolate of Gram-negative bacilli, but only around half of episodes involved Gram-positive bacteria. In a study of inpatient polymicrobial BSIs, 44% of the infections involved at least one Gram-negative bacterium and 43% involved Gram-positive bacteria.[4] In another large study of polymicrobial BSIs among malignancy patients, 76% of the infections involved at least one Gram-negative bacillus, and 50% involved Gram-positive organisms.[16] The culture rate of Gram-positive bacteria was similar to our study of emergency-based patients, but the yielding rate of Gram-negative bacteria has differed in the literature. Because these results are important to provide the information for empirical antimicrobial treatment in clinical practice, more studies involving patients with different underlying diseases and different populations are necessary.

Empirical treatment is given before results of blood cultures are available, and the prescription of empirical antibiotics may be dependent on a clinical basis alone. Our study showed that the empirical antibiotics treatment was inappropriate in 53.6% of patients with polymicrobial BSIs, which is much higher than those with monomicrobial BSIs. Regarding the causes of inappropriate use of antibiotics, we found that no combination therapy occurred in one-third of episodes. In contrast to monomicrobial BSIs, treating multiple pathogens with only one antibiotic could be inadequate, even when a broad-spectrum antibiotic was prescribed. For example, enterococci are intrinsically resistant to cephalosporins. If a broad-spectrum cephalosporin is used for polymicrobial infections including enterococci, the treatment will be inadequate. So acknowledging the common causative microorganisms in each site of infection is important to guide empirical antibiotics treatment.

Our study also found that almost a fourth of bacteremic patients received no antibiotics during their ED stay, neither for polymicrobial nor for monomicrobial

BSIs. Indeed, there is no indicator available to precisely predict the presence of bacteremia.[23,24] Delayed or absent antibiotic treatment is most often due to inaccurate clinical evaluation of the risk factors for severe infection or bacteremia.[25] Adequate education and interdisciplinary coordination may improve clinical performance.

The mortality rate of patients with polymicrobial BSIs ranged from 14% to 43%, approximately two times the mortality rate of those with monomicrobial BSIs.[26] The higher mortality in polymicrobial BSIs was reported to be related to inappropriate antimicrobial treatment.[4,16,17,27,28] As a result, the empirical antimicrobial therapy that could cover the possible pathogens is

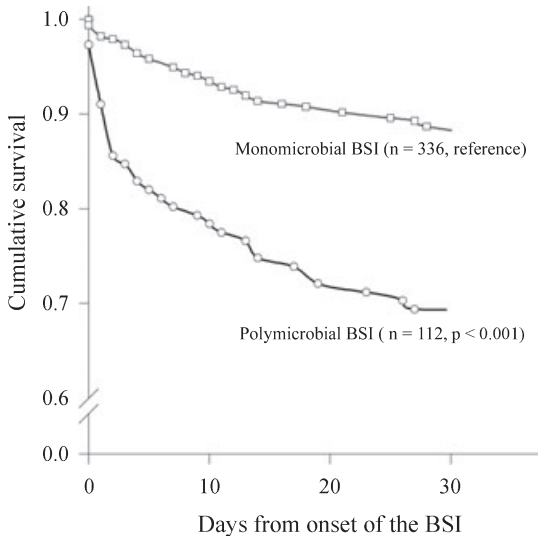

Figure 4. Kaplan-Meier survival curves of the 30-day cumulative survival rate for patients with polymicrobial and monomicrobial BSIs in the ED. BSI = bloodstream infection.

essential for treating patients at risk for polymicrobial BSIs. Effective and early antimicrobial therapy administered during an ED stay for BSI has been demonstrated to improve survival rates.[25,28,29] Although the organisms and the number of causative isolates will not be known at the time of blood cultures, recognizing patient-specific risk factors, the suspicious infection sources, and the most common pathogens, as well as the regional and institutional patterns of antibiotic resistance, will help physicians to provide adequate empirical antibiotics therapy.

LIMITATIONS

First, our study was conducted at a single hospital in southern Taiwan, limiting its generalizability. Second, although there is a standard practice regarding the use of blood cultures, we could not ascertain that all emergency physicians adhered to established guidelines. Therefore, omission of patients with polymicrobial BSIs could exist. Third, while there is an antibiotics use policy in our hospital, the prescription of empirical antibiotics may be dependent on the personal experiences of physicians. Fourth, the data used in our analysis were collected from medical records. There may be inconsistencies among the completeness of these data. Finally, because all of the univariate and multivariate analyses were carried out in an exploratory fashion, some risk factors may not have been detected or explored in our study. Further prospective studies with specific hypotheses are necessary to accurately determine these risk factors.

CONCLUSIONS

Our study provides important information about the clinical and microbiologic manifestations of ED patients with polymicrobial BSIs. Inasmuch as the mortality rate of patients with polymicrobial BSIs is significantly higher than those with monomicrobial infection, identifying patients at risk for polymicrobial BSIs, knowing the most common microorganisms in different infection sites, and being familiar with the epidemiology of regional and institutional patterns of antibiotic resistance are of paramount importance to provide adequate antimicrobial therapy in EDs.

Academic Emergency Medicine Now Offers CME Credit

Academic Emergency Medicine is now offering continuing medical education (CME) credits for reading select articles in the journal and successfully completing a test on the content.

Physicians interested in completing the exam should log on to www.wileyblackwellcme.com. Upon successfully finishing the activity, physicians will receive an electronic certificate of completion, which can be printed and saved online under the user's profile.

The program is free to subscribers of the journal. **The first feature will appear in the January 2011 issue.**

Stay tuned for updates!

About ARHAI Scotland

ARHAI Scotland overall vision is to:

Enable Scotland to adopt an evidence based and innovative approach to minimising the burden of infection and antimicrobial resistance (AMR).

Our mission is to:

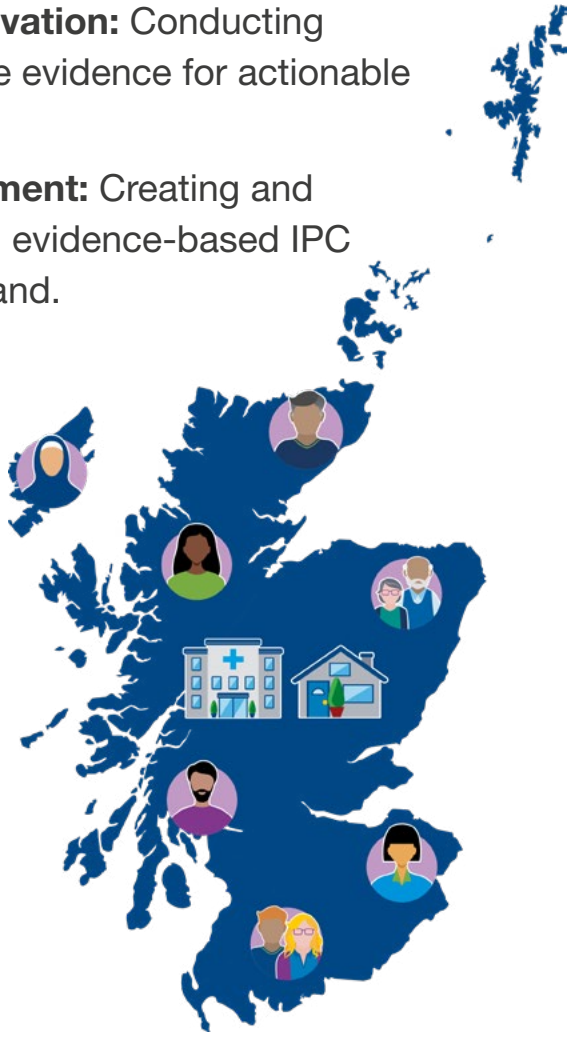
Enhance the health and wellbeing of the population by reducing infection and antimicrobial resistance within Scottish care settings.

We will achieve this by:

- establishing a robust evidence base for best practices
- developing mechanisms for monitoring key priority areas
- connecting with the broader health, social care, and public health systems
- collaborating with key delivery partners, including NHSScotland boards, care providers, and other national bodies as commissioned by the Scottish Government

The work of ARHAI Scotland is grounded in delivering a comprehensive range of functions in collaboration with stakeholders across health, care, and other sectors. ARHAI Scotland's functions include:

- **Surveillance and monitoring:** Assessing the impact of infections and antimicrobial resistance on health.
- **Clinical assurance:** Reducing risk in the healthcare built environment.
- **Programme coordination:** Overseeing national Infection Prevention and Control (IPC) and Antimicrobial Resistance (AMR) programmes.
- **Expert advice and horizon scanning:** Providing specialised IPC/AMR guidance and foresight.
- **Outbreak response:** Preparing for and responding to healthcare-associated infection (HCAI) outbreaks and incidents.
- **Workforce development:** Collaborating with NHS Education for Scotland to cultivate a confident, knowledgeable, and competent IPC workforce.
- **Professional practice:** Promoting high standards of professional conduct.
- **Research and innovation:** Conducting research to generate evidence for actionable interventions.
- **Guidance development:** Creating and maintaining national evidence-based IPC guidelines for Scotland.

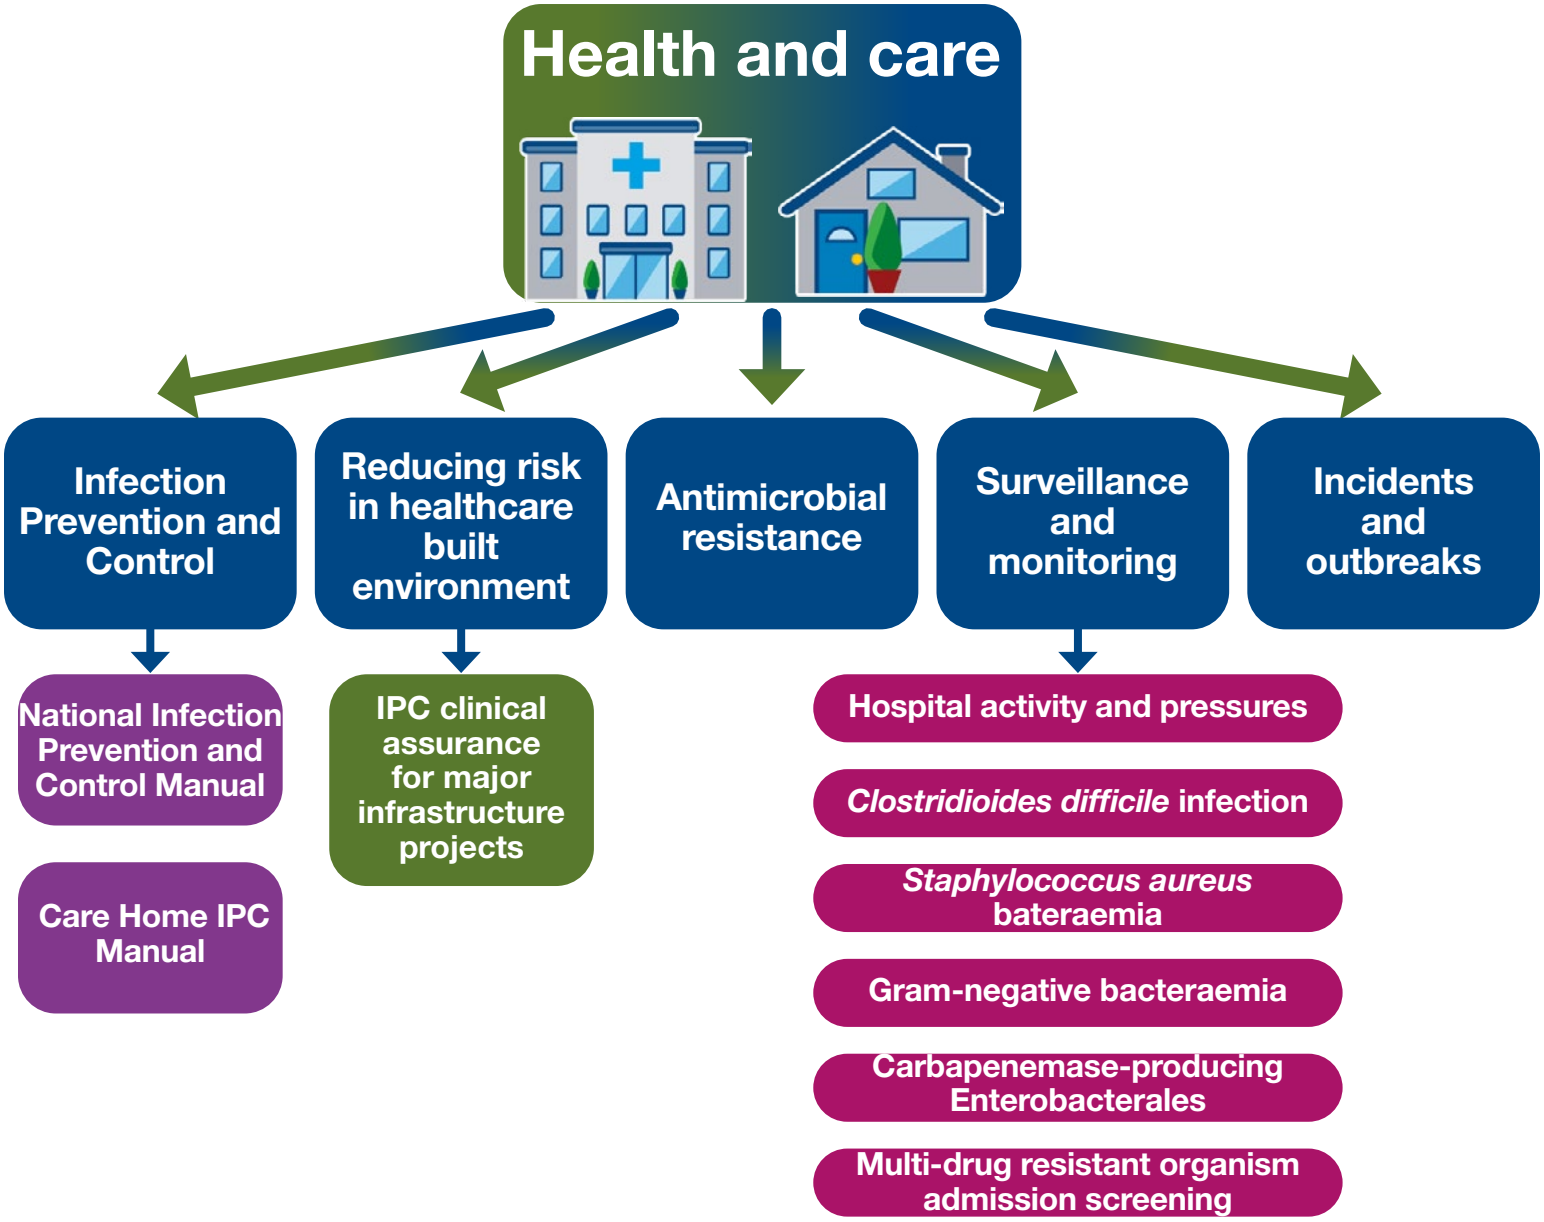


ARHAI Scotland Activities in 2023

Globally, healthcare associated infections (HCAI) and antimicrobial resistance (AMR) continue to pose a significant threat to patient safety in all settings where care is delivered.

This annual report showcases the key initiatives undertaken by ARHAI Scotland in 2023 to support Infection Prevention and Control (IPC), prevent HCAI, and contain AMR. Alongside a planned programme of work, ARHAI Scotland continued to provide responsive IPC expert advice throughout the year.

Click below to read more about ARHAI Scotland's work in 2023.

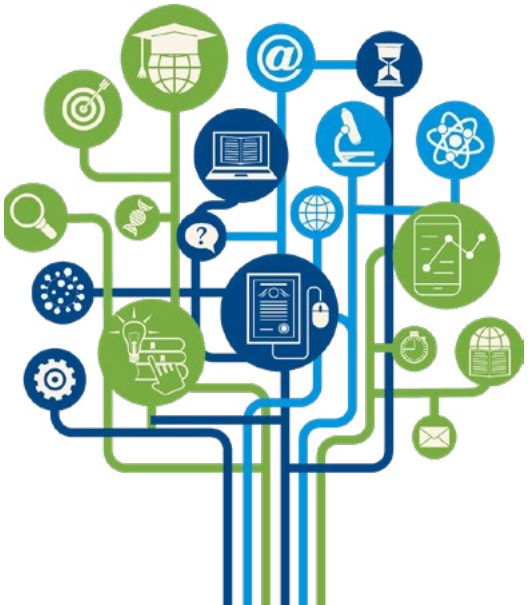


Infection Prevention and Control

National Infection Prevention and Control Manual (NIPCM)

The National Infection Prevention and Control Manual (NIPCM) first published in 2012 provides national evidence-based guidance for Infection Prevention and Control (IPC) which is considered best practice for all health and care settings in Scotland. The NIPCM has continued to expand year on year. The development of new content is informed by horizon scanning, national learning via incidents and outbreaks and stakeholder needs, leading the way as a single national resource for IPC guidance. The NIPCM aims to provide the most up to date evidence-based guidance, enhanced where necessary by expert opinion, to allow healthcare workers to make informed risk assessments in the application of IPC measures.

Following the removal of dedicated COVID-19 pandemic content as part of a phased process in 2022, 2023 has refocused efforts on ensuring the NIPCM is maintained and populated with new guidance which is evidence based, user friendly and meets accessibility standards. A series of annual activities are undertaken to support NIPCM functionality and the delivery of IPC guidance and associated tools. An annual review of the development methodology was also undertaken and 2023 saw the commencement of a new pilot methodology which aimed to increase the robustness and transparency of NIPCM content development where a considered judgement form (CJF) is applied to each pilot literature review. In addition to recommendations and good practice points, the CJF records the reliability of the evidence considered. Expert opinion is used to consider the benefits versus harms as well as any feasibility issues. Doing so supports the practical clinical operationalisation to inform the recommendations and good practice points and consistency of the conclusions within the evidence. The pilot methodology has been published and can be found **here**. The pilot will continue in 2024 when the final development process will be ratified via internal governance groups.



Following completion of three literature reviews in 2023, the NIPCM was strengthened to reflect the following points:

Hand hygiene: skin care. This update provided some additional background information on what skin integrity is and how to maintain it, and the signs and symptoms of contact dermatitis.

Surgical hand antisepsis. The review update clarified that where surgical hand rubbing is the preferred method for surgical hand antisepsis, hand hygiene should be performed using a non-antimicrobial liquid soap and water prior to entering the theatre or care area. The rationale for this is to physically remove contamination (which hand rub products are unable to do).

Indication and techniques for hand hygiene. The need to remove hand and wrist jewellery before performing hand hygiene was expanded to include embedded jewellery (dermal piercings).

It was recognised that after the COVID-19 pandemic, it was necessary to address the use of Personal Protective Equipment (PPE) in the delivery of patient care and make clear the risk assessment required in selecting individual items of PPE. **Appendix 15** underwent a significant change to stipulate the PPE required based on exposure to blood and body fluids and suspected infection. The Appendix 15 tables are intended to be more user friendly than previous versions.

Notable was the commencement of the transmission-based precautions (TBPs) definitions literature review update in 2023 with significant progress made in the analysis of the vast evidence base to inform re-classification of transmission routes. The need for this review was made apparent during the COVID-19 pandemic and ARHAI Scotland are leading the way in this work by challenging the historical droplet/aerosol dichotomy and reviewing the key factors which impact transmission in health and care settings. A dedicated working group will be convened in 2024 to finalise new recommendations and oversee implementable changes to Chapter 2 of the NIPCM. Alongside this work, a review of the literature pertaining to surgical face masks and respiratory protective equipment was commenced to ensure full alignment with published changes to TBPs.

ARHAI Scotland completed a **rapid review of the literature** to consider post cataract surgery endophthalmitis in July 2023 which was used to inform the development of a **cataract IPC pathway** in support of the Centre of Sustainable Delivery (CfSD). This group brought together key IPC and specialist ophthalmology stakeholders from across Scotland to develop a nationally approved evidence-based set of principles aimed at reducing variation and mitigating against any perceived IPC risks associated with increasing the throughput of cataract surgeries, whilst providing a means of monitoring through national data sets. This work was published in the Journal of Hospital Infection and will be included in the NIPCM in 2024.

Care Home IPC Manual

Within the NIPCM website, ARHAI Scotland have a dedicated section for all Care Home IPC guidance, supporting materials and resources. As part of the Care Home IPC section, staff can navigate through the Care Home Infection Prevention and Control Manual (CH IPCM) which is based on evidence and promotes best practice. The content of the CH IPCM is fully aligned to the evidence based NIPCM.

The content of the CH IPCM continues to evolve since publication of Chapter 1: Standard Infection Control Precautions (SICPs) and Chapter 2: Transmission Based Precautions (TBPs) in 2021. Within the CH IPCM, there is a National Cleaning Specification (NCS) section which provides a guide for care home staff to plan their cleaning services and to record local cleaning activities. The NCS supports care home staff to plan, train and monitor standards of cleaning services provided throughout their care home.

In addition to the core chapters, the Care Home section in the NIPCM website also contains multiple appendices and supporting materials which are constantly updated as the evidence base evolves. Throughout 2023, collaboration with Care Home stakeholders ensured that ARHAI Scotland Care Home IPC guidance and materials were relevant and context specific.

ARHAI Scotland continues to support the interim Scottish Health Protection Network Guidance Group from a community IPC perspective and in 2023 developed an IPC Chapter for inclusion in the 'Health protection in children and young people settings, including education' Guidance. Assistance was provided for an IPC review of the National Childsmile Executive Standards for Nursery and School Toothbrushing Programme content and to the Care Inspectorate publication entitled 'Space to Grow'. During 2023, the IPC Respiratory and Gastrointestinal support resources for Care Homes was also updated and refreshed.

Reducing risk in the healthcare built environment

During 2023, ARHAI Scotland continued to focus on reducing risk in the healthcare-built environment by providing access to infection prevention and control (IPC) guidance and supportive tools. ARHAI Scotland also supported NHS Boards through the design, construction and commissioning of new health care facilities.

ARHAI Scotland assesses potential IPC risks at all stages of health care construction and refurbishment as part of NHSScotland Assure's key stage assurance review (KSAR) process, and also supports local NHS boards and IPC teams with subject matter expertise during environmental incidents and outbreaks.

Expert IPC advice continued to be provided through developing guidance and educational materials to assist local IPC Teams in reducing risk in all healthcare buildings.

The water services literature review utilising the new National Infection Prevention and Control Manual (NIPCM) methodology gathered speed and involved extensive consultation with stakeholders. It is anticipated that the water services literature review and associated manual content/ recommendations will continue to progress with publication expected late summer 2024.The dental unit water lines literature review was initiated with publication also expected in 2024. A further notable review was the commencement of the ventilation literature review which will be for inclusion within Chapter 4 of the NIPCM. The question set for this literature review is being developed and is expected to significantly progress throughout 2024.

The focus for the year ahead is the continued development of Chapter 4 of the NIPCM content; tools specifically designed to reduce risk; and evidence to support the safe management of risks from the complex components within the built environment. This will include the review of outbreak and incident assessment to improve reporting of incidents relating to the built environment.

IPC clinical assurance for major infrastructure projects

The multidisciplinary team within the NHSScotland Assure Assurance service continues to review the design, construction and maintenance of major health care infrastructure developments across NHSScotland at key stages during the project lifecycle. ARHAI Scotland provide IPC support as subject matter experts through the KSAR processes, ensuring an overarching focus on IPC and infection risk during all stages of the building lifecycle.

Support has been given to board IPC teams which resulted in completion of a further 11 KSARs in 2023, enabling progression of design and construction of the healthcare built environment estate across NHSScotland.

During 2023, as part of the Assurance Service, ARHAI Scotland supported two NHS boards' project teams through the commissioning of National Treatment Centres which opened this year: NHS Fife (Victoria Hospital, Kirkcaldy) and NHS Highland (Raigmore Hospital, Inverness).

In addition to Assurance reviews, ARHAI Scotland have continued to support IPC project teams across respective boards regarding construction projects out with KSAR review specialist support or general built environment board enquiries.

During 2023, IPC support was formally included within the NHSScotland Design Assessment Process (NDAP). The NDAP process in addition to the review process is included within the Assurance process. IPC support is provided to NHS boards during the design of their facility with the aim of ensuring IPC requirements are met in advance of the Assurance Review being undertaken.

ARHAI Scotland are developing a suite of resources (Notes for Boards) to assist board IPC teams through health care construction projects and the KSAR process for delivery over 2024. The first resource is KSAR: Notes for Board Infection Prevention and Control Teams and advises IPC teams of what the KSAR process is and what can be expected throughout each of the stage reviews. Work has also commenced on Notes for Boards: Summary of guidance for the design of Neonatal units, level 2 and 3 care units, and Bone marrow transplant units and haemato-oncology units. These will be published in 2024. A Notes for Boards: Air sampling in operating theatres has also commenced and is expected to publish in 2024.

Antimicrobial resistance

Antimicrobial resistance (AMR) happens when microbes, such as bacteria, fungi, viruses and parasites change and no longer respond to medicines designed to kill them. This change is an adaption of the microbe's genetics and is driven by the exposure of the microbe to antimicrobials in humans, animals and the environment. The result of this AMR is that certain infections become increasingly difficult or impossible to treat. This is a global concern.

Causes of antimicrobial resistance

Antimicrobial resistance happens when bacteria change and become resistant to the antimicrobials used to treat the infections they cause.

Over-prescribing of antimicrobials

Patients not finishing their treatment

Over-use of antimicrobials in livestock and fish farming

Poor infection control in hospitals and clinics

Lack of hygiene and poor sanitation

Lack of new antimicrobials being developed

As **The King's Fund essay, 'What if antibiotics stopped working?'** highlighted, antimicrobials (including antibiotics) add 20 years on average to life expectancy across the world through their ability to prevent and treat infection. This ability is central to managing infectious disease, making surgery and childbirth safer, protecting people undergoing transplants and cancer treatments, and supporting animal health and food production.

AMR is a natural phenomenon therefore it cannot be fully prevented but human activity is accelerating the emergence and spread. Accordingly, the focus, as set out in the **UK Government 20-year vision for antimicrobial resistance**, is to effectively contain, control and mitigate AMR by 2040. This long-term vision is supported by five-year AMR national action plans (NAP). This ARHAI annual report is published at an important point with the transition from the 2019 to 2024 NAP **'Tackling antimicrobial resistance'** to the 2024–2029 NAP to **'Confronting antimicrobial resistance'**.

In 2023, ARHAI Scotland provided intelligence on the trends in antimicrobial use and resistance. ARHAI Scotland's work on monitoring antimicrobial use and resistance is aligned with the 'One Health' approach to tackling AMR in the UK AMR NAP. This 'One Health' approach works across sectors and recognises that many of the same bacteria infect humans and animals and may be found in the environment as they share the same ecosystem and calls for action across and between sectors.

Data and intelligence on the trends in antimicrobial use and resistance in humans and animals for 2023 will be published in the annual Scottish One Health Antimicrobial Use and Antimicrobial Resistance (SONAAR) report in November 2024. The publication on the **ARHAI Scotland website** will coincide with World Antibiotic Awareness Day and European Antibiotic Awareness Week.

ARHAI Scotland's 2023 achievements

- **Undertook near real time monitoring and reporting of use of antibiotics commonly used for respiratory infections to support antimicrobial stewardship activities coordinated by the Scottish Antimicrobial Prescribing Group aimed at optimising antibiotic use in the community.**

- **Using our AMR early warning system, undertook monitoring for instances of organisms displaying unexpected antimicrobial resistance (see NIPCM Appendix 13 Table 6). This work is intended to enable a timely scientific and public health response to potential emerging AMR issues, informs infection control practices and appropriate therapy, and is critical to contain the development and spread of AMR.**

- **Supported our stakeholders to access quarterly data on antimicrobial use and resistance through ARHAI Indicators dashboards in Discovery to inform clinical practice across NHSScotland.**

AMR is a serious and complex problem but there are actions which, if taken, will make a difference. In 2024, ARHAI Scotland will continue to play our part and will support the delivery of the UK AMR NAP implementation plan and measurement of impact within Scotland, building on our role in monitoring and reporting trends in antimicrobial use and resistance in human and animal health.

Key activities for ARHAI Scotland in support of the UK AMR NAP will include:

Reducing the burden of infections, AMR and exposure to antimicrobials through leadership, expert advice and guidance on infection prevention and control.

Developing and utilising data and intelligence to inform actions – this aims to enable decisions to be based on robust surveillance data and intelligence.

Identifying unwarranted variation and health inequalities – this aims to improve the information available to identify where the burden of antibiotic use and AMR is greatest. This will help to target future interventions where they will have the greatest impact.

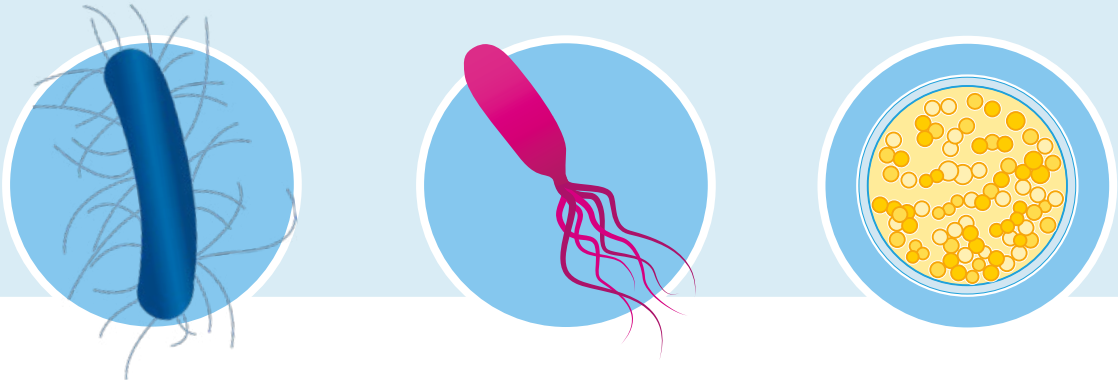
Surveillance and monitoring

Surveillance of healthcare associated infection in Scotland

ARHAI Scotland coordinate the national surveillance programme of healthcare associated infection (HCAI) monitoring the burden of key HCAI, supporting benchmarking and providing intelligence to inform the development of interventions.

In 2023, the surveillance of three key infection types continued:

- ***Clostridioides difficile*** **infection (CDI)**
- ***Escherichia coli*** **bacteraemia (ECB)**
- ***Staphylococcus aureus*** **bacteraemia (SAB)**



National surveillance of surgical site infection (SSI) remained paused during 2023 though some boards continued with local surveillance.

Trends in key HCAI rates **continued to be published quarterly** in 2023 and provided in **Discovery**, supporting local NHS boards with data for benchmarking and to inform quality improvement and reduction strategies.

Surveillance priorities for 2024

- Complete a review of the national HCAI surveillance programme ensuring a focus on reducing risk and harm.
- Complete review of paused SSI surveillance programme including a focus on smarter solutions for surveillance to reduce the burden of data collection.
- Support the implementation of the redeveloped surveillance system for healthcare associated infection in intensive care units (ICU).
- Continue to support the development of a competent and confident infection prevention and control (IPC) workforce by delivery of epidemiology and surveillance training in conjunction with NHS Education Scotland.

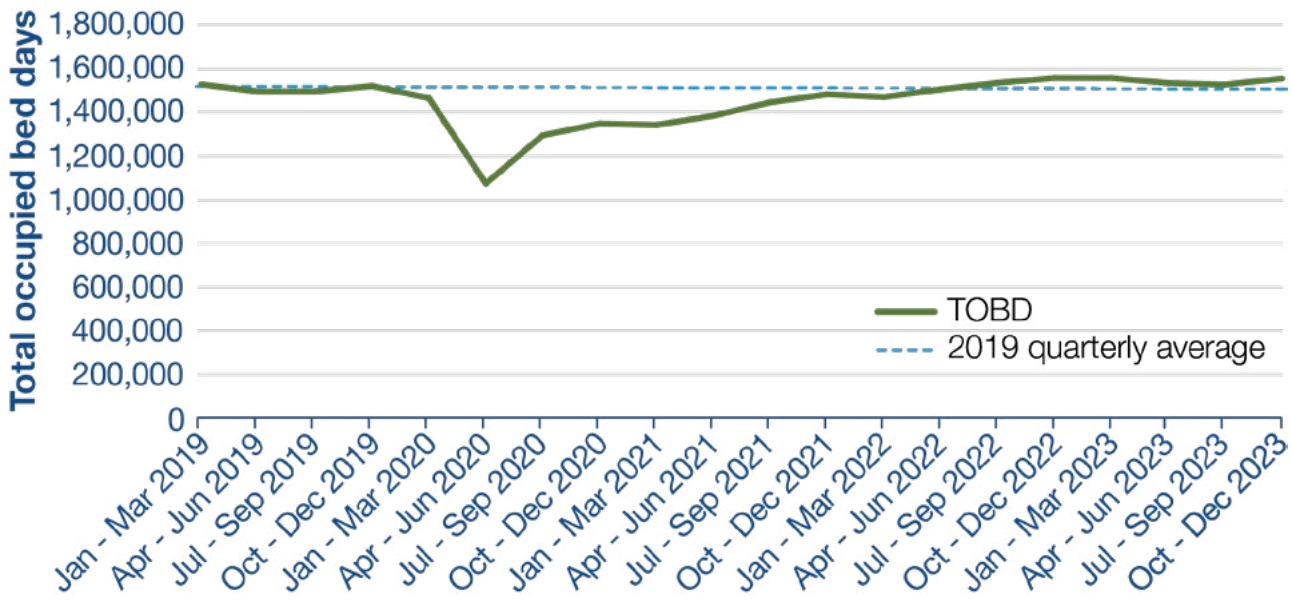
Hospital activity and pressures

Healthcare delivery, activity and the inpatient population is evolving and healthcare systems remain under pressure following the pandemic. Changes within the system can affect the risk of Healthcare Associated Infection (HCAI) in the hospital population and present a challenge to the interpretation of epidemiological data. Interpretation can be supported by consideration of other contextual measures describing healthcare. HCAI outcome data should be interpreted with caution and in the context of the wider healthcare system.

Hospital activity

6,217,510 occupied bed days in **2023**, compared to **6,112,174** in **2022**.

Total occupied bed days, by quarter*

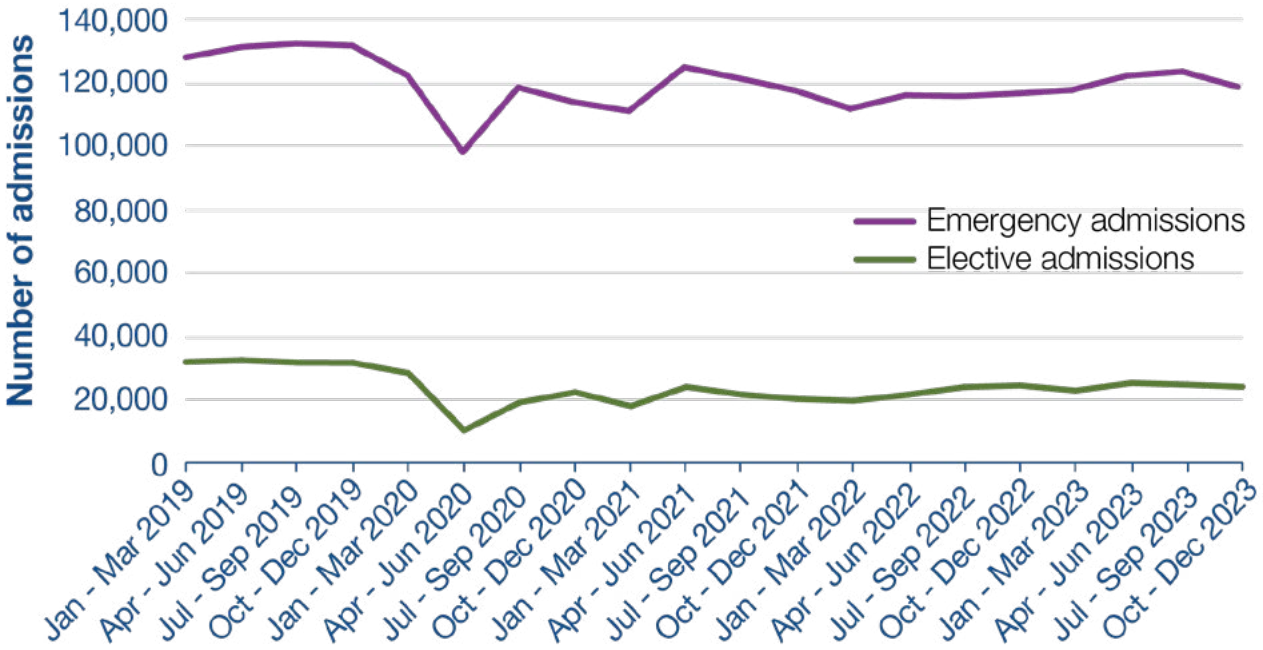


*The dashed line represents the quarterly average for the calendar year 2019 of 1,520,807 Total Occupied Bed Days (TOBD).

98,144 elective inpatient admissions in **2023** compared to **90,995** in **2022**.

482,997 emergency inpatient admissions in **2023** compared to **461,069** in **2022**.

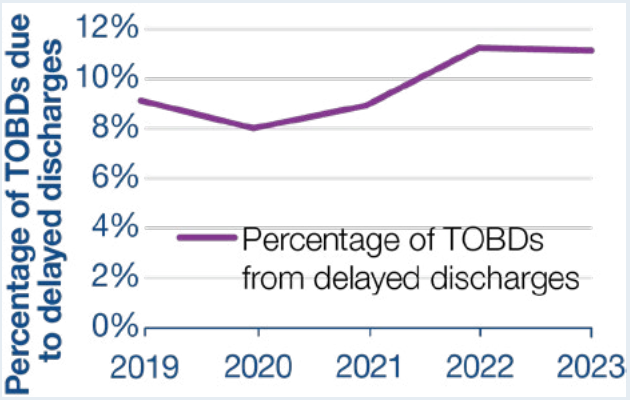
Number of elective and emergency admissions, by quarter



Hospital pressures

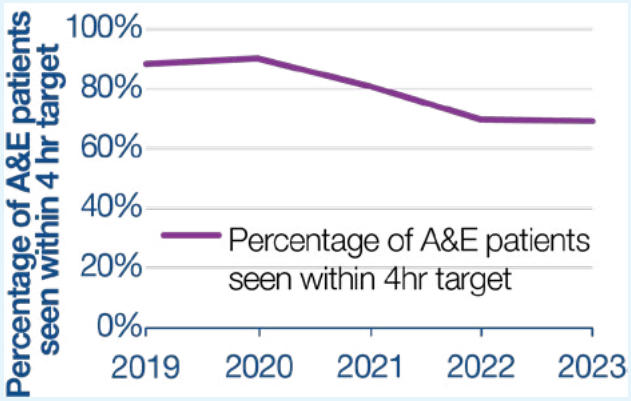
Delayed discharges

The percentage of total occupied bed days due to **delayed discharges** **decreased** by **0.9%** in **2023 (11.1%)** compared to **2022 (11.2%)**.



Accident and Emergency (A&E) attendances

69.6% of **Accident and Emergency (A&E) attendances** were seen within the **4-hour target** in **2023**, a **decrease** from **70.2%** in **2022**.



Clostridioides difficile infection

Epidemiological data

In **2023**, there were **1,209** cases of ***Clostridioides difficile* infection (CDI)** reported in **patients aged 15 years and older** in **Scotland**, **compared** to **1,053** cases in **2022**.

The **annual incidence rate** was **22.2** per 100,000 population.

There has been a **14.8% increase** in the **rate** between **2022** and **2023**.

The **rate in 2023** was **14.5% higher compared to 2019**.

No linear trend over the **past five years** was observed.

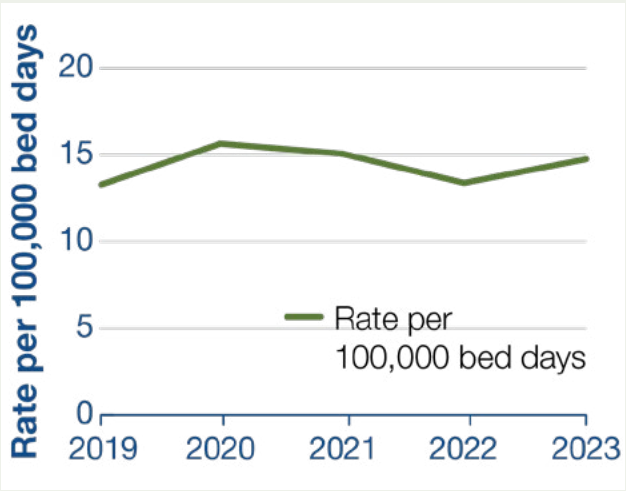
A53210128

Healthcare associated CDI

There were **917 cases** in **patients aged 15 years and older** in **2023**.

The **annual incidence rate** was **14.7** per 100,000 bed days.

There has been a **10.2% increase** in the **rate** between **2022** and **2023**.



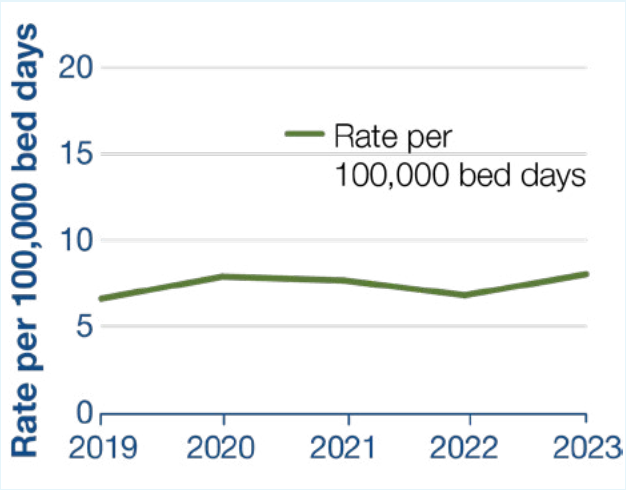
The **five year trend** has remained **stable**.

Hospital acquired CDI

Of the **917** healthcare associated CDI cases, **503** were **hospital acquired infections**.

The **annual incidence rate** was **8.1** per 100,000 bed days.

There has been a **17.5% increase** in the **rate** between **2022** and **2023**.



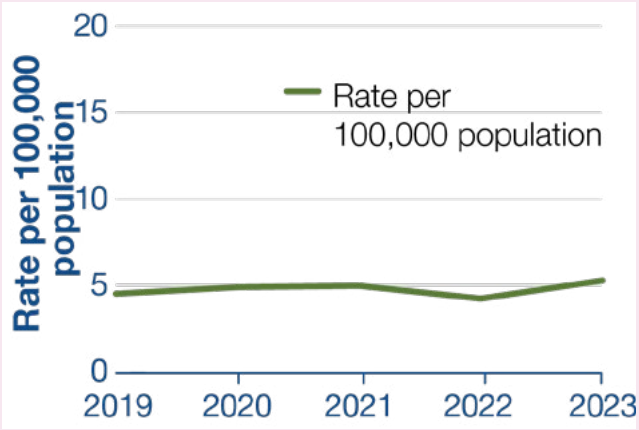
The **five year trend** has remained **stable**.

Community associated CDI

There were **292 cases** in **patients aged 15 years and older** in **2023**.

The **annual incidence rate** was **5.4** per 100,000 population.

There has been a **24.3% increase** in the **rate** between **2022** and **2023**.



The **five year trend** has remained **stable**.

Annual funnel plot analysis

NHS Highland and **NHS Lanarkshire** had **higher annual rates** of **healthcare associated CDI compared** with the **Scottish average rate**.

No NHS boards had **higher annual rates** of **community associated CDI compared** with the **Scottish average rate**.

Note: NHS board rates are **not adjusted** for **differences in the patient population**.

NHS boards are required to submit improvement plans in response to **higher than average quarterly rates** of **healthcare or community associated CDI**, as identified through the **exception reporting process**.

Three improvement plans were developed by **NHS boards** during **2023** in response to **higher than average quarterly rates** of **healthcare associated CDI**.

For further information please see the **quarterly epidemiological reports**.

All cause case fatality

In **2023**, the **30 day all cause case fatality rate** for **CDI** in **patients aged 15 years and older** was **10.8%**.

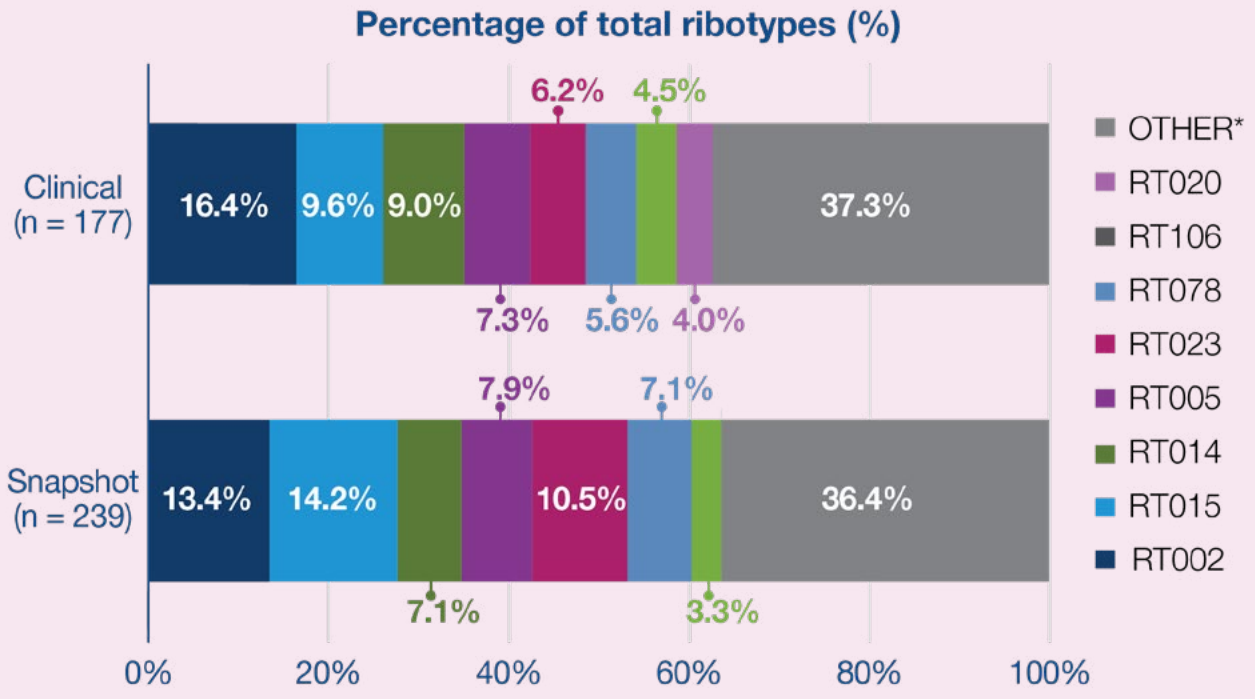
The **CDI case fatality five year trend** has remained **stable**.

Note: rates are **not adjusted** for **differences** in the **patient population over time**.

Molecular epidemiological data

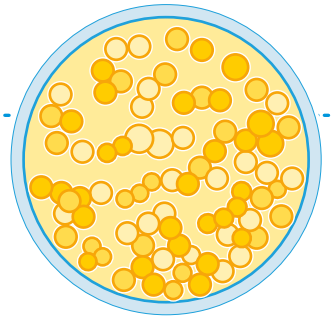
The **three most prevalent ribotypes** reported by **clinical surveillance** in **2023** were **RT002 (16.4%)**, **RT015 (9.6%)** and **RT014 (9.0%)**.

The **three most prevalent ribotypes** (RT) reported by the **snapshot surveillance scheme** in **2023** were **RT015 (14.2%)**, **RT002 (13.4%)** and **RT023 (10.5%)**.



*OTHER contains ribotypes, each with a prevalence of <3%.

Staphylococcus aureus bacteraemia



Epidemiological data

In **2023**, there were **1,712** cases of ***Staphylococcus aureus* bacteraemia (SAB)** reported in **Scotland**, compared to **1,590** cases in **2022**.

The **annual incidence rate** was **31.4** per 100,000 population.

There has been **7.7% increase** in the **rate** between **2022** and **2023**.

The **five year trend** has **increased** with a **3.4% average increase** each year.

96.7% (n = 1,656) of **all SAB cases** were **meticillin-sensitive *Staphylococcus aureus* (MSSA)**.

3.3% (n = 56) of **all SAB cases** were **meticillin-resistant *Staphylococcus aureus* (MRSA)**.

The **rate** of **MSSA bacteraemia** in **2023** was **30.4** per 100,000 population.

There has been a **7.5% increase** in the **rate** between **2022** and **2023**.

The **five year trend** has **increased** with a **3.3% average increase** each year.

The **rate** of **MRSA bacteraemia** in **2023** was **1.0** per 100,000 population.

The **rate** has **remained stable** between **2022** and **2023**.

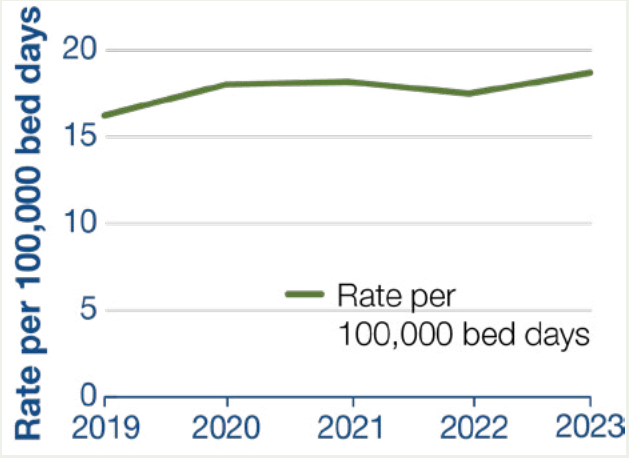
The **five year trend** has remained **stable**.

Healthcare associated SAB

There were **1,162** cases in **2023**.

The **annual incidence rate** was **18.7** per 100,000 bed days.

The **rate** has **remained stable** between **2022** and **2023**.



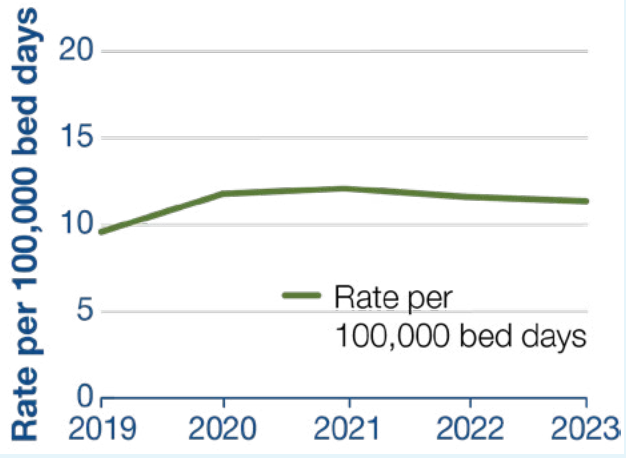
The **five year trend** has **increased** with a **2.6% average increase** each year.

Hospital acquired SAB

Of the **1,162** healthcare associated SAB cases in **2023**, **706** were **hospital acquired infections**.

The **annual incidence rate** was **11.4** per 100,000 bed days.

The **rate** has **remained stable** between **2022** and **2023**.



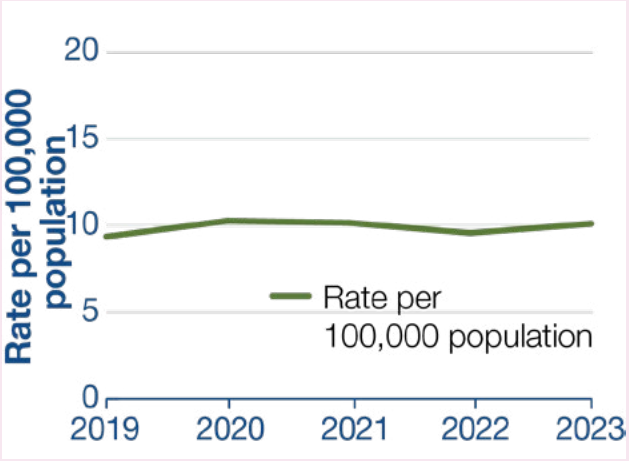
The **rate in 2023** was **18.5% higher compared to 2019**. **No linear trend** over the **past five years** was observed.

Community associated SAB

There were **550** cases in **2023**.

The **annual incidence rate** was **10.1** per 100,000 population.

The **rate** has **remained stable** between **2022** and **2023**.



The **five year trend** has remained **stable**.

Annual funnel plot analysis

NHS Tayside had a **higher annual rate** of **healthcare associated SAB**, compared with the **Scottish average rate**.

NHS Ayrshire & Arran and **NHS Shetland** had a **higher annual rate** of **community associated SAB compared** with the **Scottish average rate**.

Note: NHS board rates are **not adjusted** for **differences in the patient population**.

NHS boards are required to submit improvement plans in response to **higher than average quarterly rates** of **healthcare or community associated SAB**, as identified through the **exception reporting process**.

Two improvement plans were developed by **NHS boards** during **2023** in response to **higher than average quarterly rates** of **healthcare associated SAB**.

One improvement plan was developed by an **NHS board** during **2023** in response to **higher than average quarterly rates** of **community associated SAB**.

For further information please see the **quarterly epidemiological reports**.

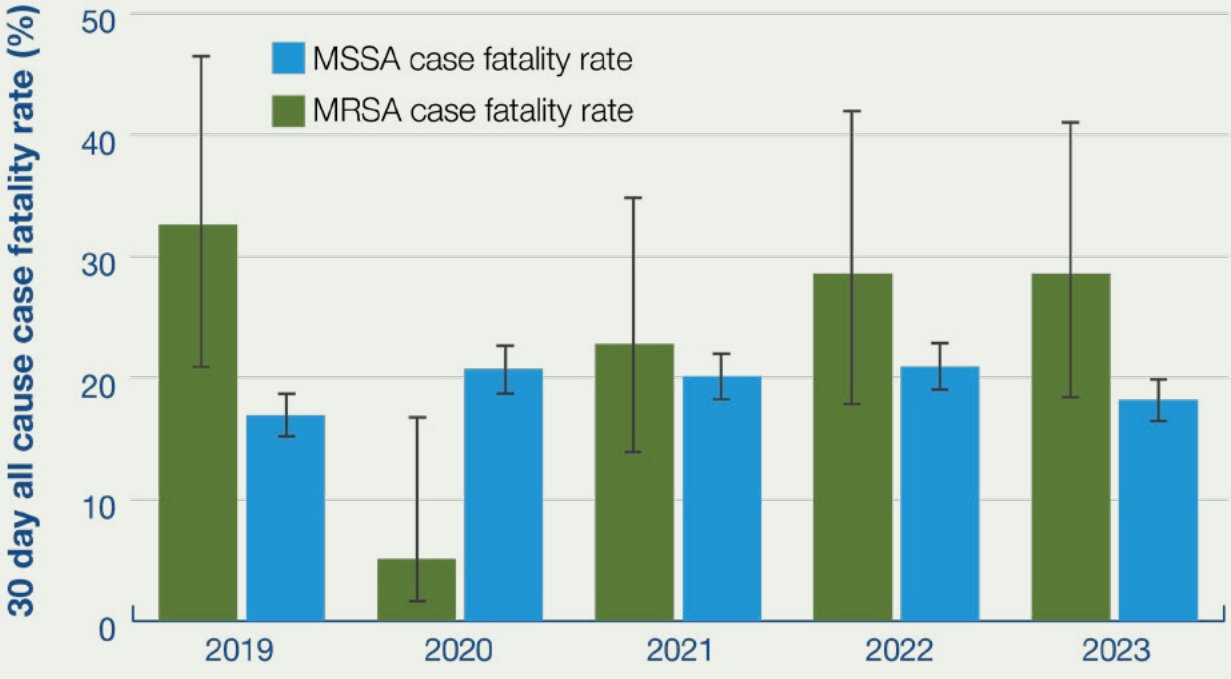
All cause case fatality

In **2023**, the **30 day all cause case fatality rates** for **SAB** were

28.6% for MRSA | **18.2% for MSSA**

The **MRSA** and **MSSA** **case fatality five year trends** have remained **stable**.

Note: rates are **not adjusted** for **differences** in the **patient population over time**.



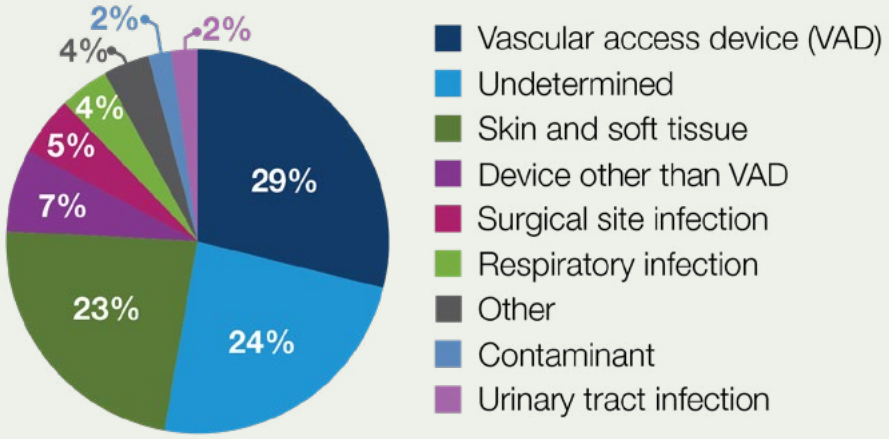
In **2023**, **entry points** of **healthcare associated SAB** were known for **75.7%** of cases.

The most common entry points (as determined by the clinical team) include:

29.4% Vascular access device (VAD)

22.9% Skin and soft tissue

Healthcare associated SAB entry points



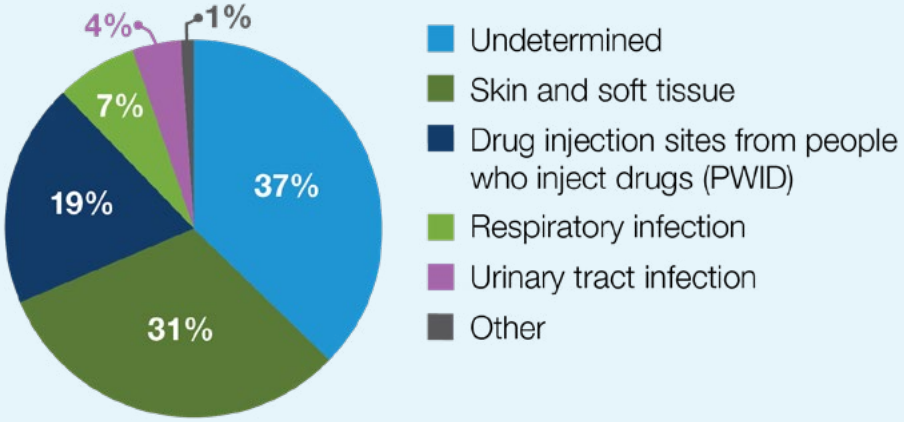
In **2023**, **entry points** of **community associated SAB** were known for **62.9%** of cases.

The most common entry points (as determined by the clinical team) include:

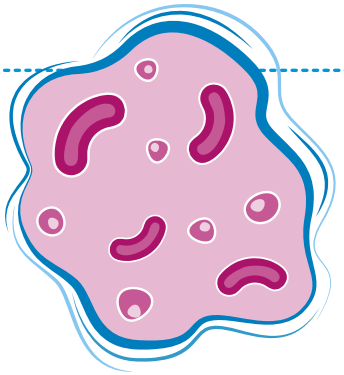
31.5% Skin and soft tissue

19.5% Drug injection sites from people who inject drugs (PWID)

Community associated SAB entry points



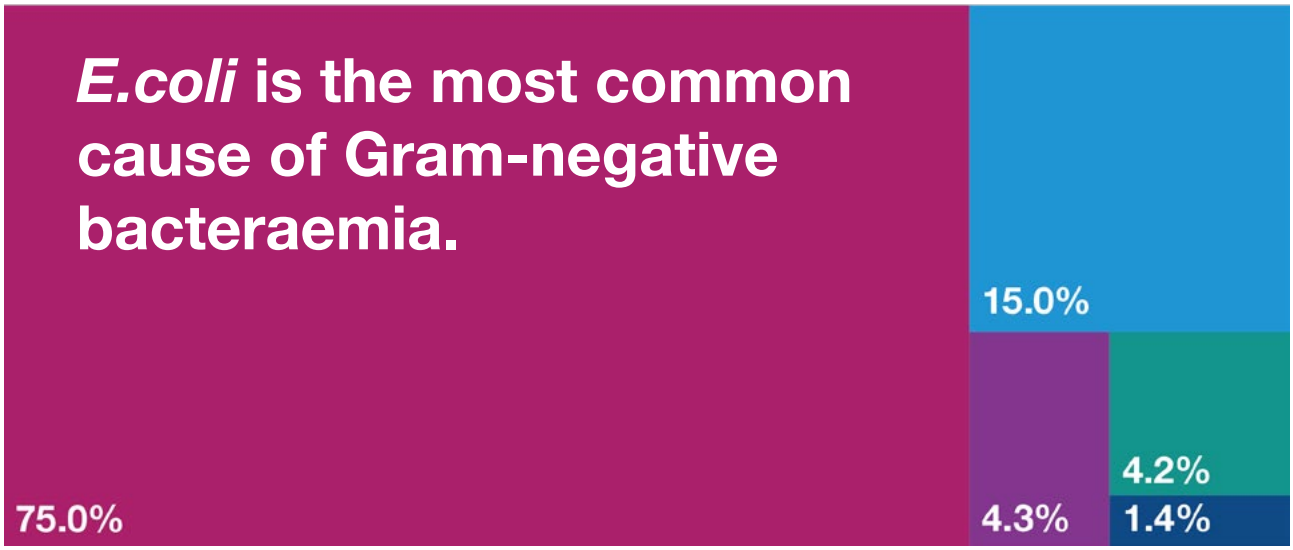
Gram-negative bacteraemia



Epidemiological data

In **2023**, there were **5,744 Gram-negative bacteraemia** in **Scotland** caused by **5 key Gram-negative pathogens**.

E.coli is the most common cause of Gram-negative bacteraemia.



- *Escherichia coli* (n=4,309)
- *Pseudomonas aeruginosa* (n=248)
- *Acinetobacter* species (n=82)
- *Klebsiella pneumoniae* (n=863)
- *Klebsiella oxytoca* (n=242)

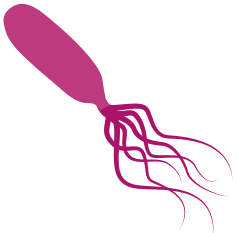
In **2023**, there were **4,309** cases of ***Escherichia coli* bacteraemia (ECB)** reported in **Scotland**, compared to **4,218** cases in **2022**.

The **annual incidence rate** was **79.1** per 100,000 population.

The **rate** has **remained stable** between **2022** and **2023**.

The **rate in 2023** was **9.3% lower compared to 2019**.

No linear trend over the **past five years** was observed.



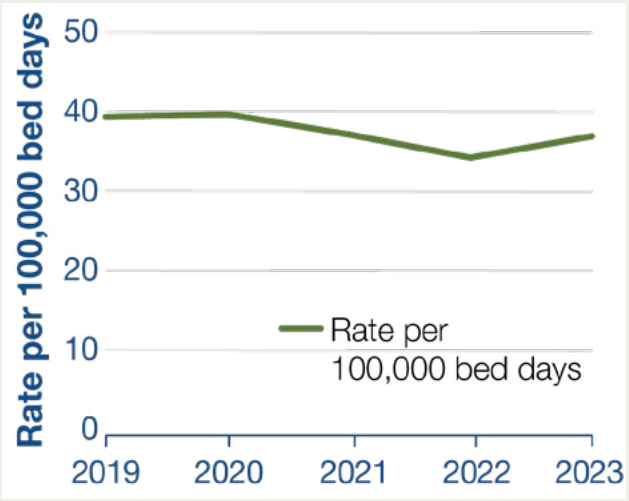
A53210128

Healthcare associated ECB

There were **2,293** cases in **2023**.

The **annual incidence rate** was **36.9** per 100,000 bed days.

There has been a **7.9% increase** in the **rate** between **2022** and **2023**.



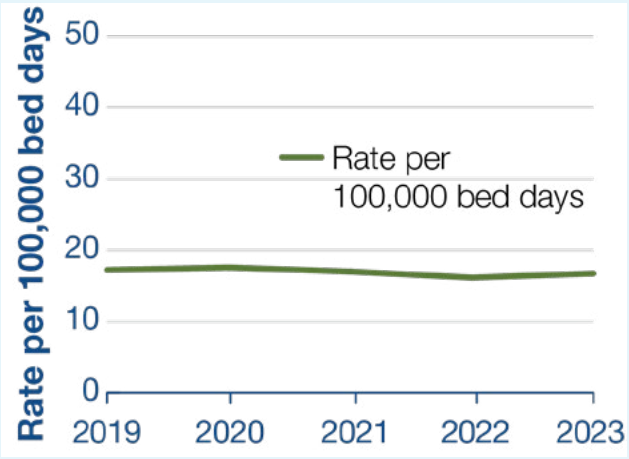
The **rate in 2023** was **6.2% lower compared to 2019**.
No linear trend over the **past five years** was observed.

Hospital acquired ECB

Of the **2,293 healthcare associated ECB cases**, **1,041** were **hospital acquired infections**.

The **annual incidence rate** was **16.7** per 100,000 bed days.

The **rate** has **remained stable** between **2022** and **2023**.



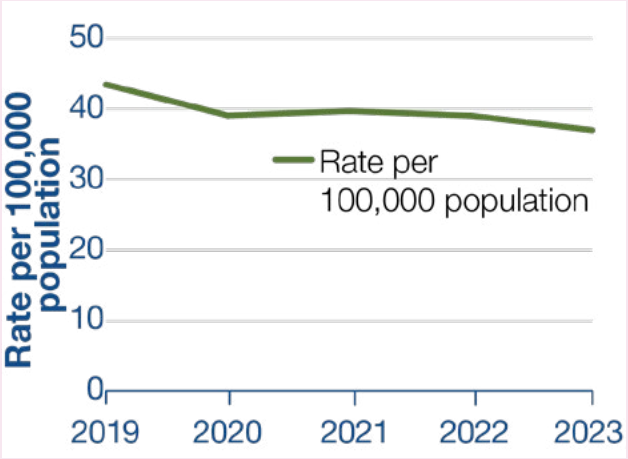
The **five year trend** has remained **stable**.

Community associated ECB

There were **2,016** cases in **2023**.

The **annual incidence rate** was **37.0** per 100,000 population.

The **rate** has **remained stable** between **2022** and **2023**.



The **five year trend** has **decreased** with a **3.2% average decrease** each year.

Annual funnel plot analysis

NHS Forth Valley and **NHS Tayside** had **higher annual rates** of **healthcare associated ECB compared** with the **Scottish average rate**.

NHS Ayrshire & Arran, **NHS Dumfries & Galloway** and **NHS Lanarkshire** all had **higher annual rates** of **community associated ECB compared** with the **Scottish average rate**.

Note: NHS board rates are **not adjusted** for **differences in the patient population**.

NHS boards are required to submit improvement plans in response to **higher than average quarterly rates** of **healthcare or community associated ECB**, as identified through the **exception reporting process**.

Three improvement plans were developed by **NHS boards** during **2023** in response to **higher than average quarterly rates** of **healthcare associated ECB**.

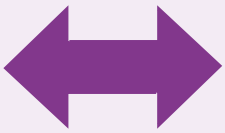
Six improvement plans were developed by **NHS boards** during **2023** in response to **higher than average quarterly rates** of **community associated ECB**.

For further information please see the **quarterly epidemiological reports**.

All cause case fatality

In **2023**, the **30 day all cause case fatality rate** for **ECB** was **12.8%**.

The **ECB case fatality five year trend** has remained **stable**.



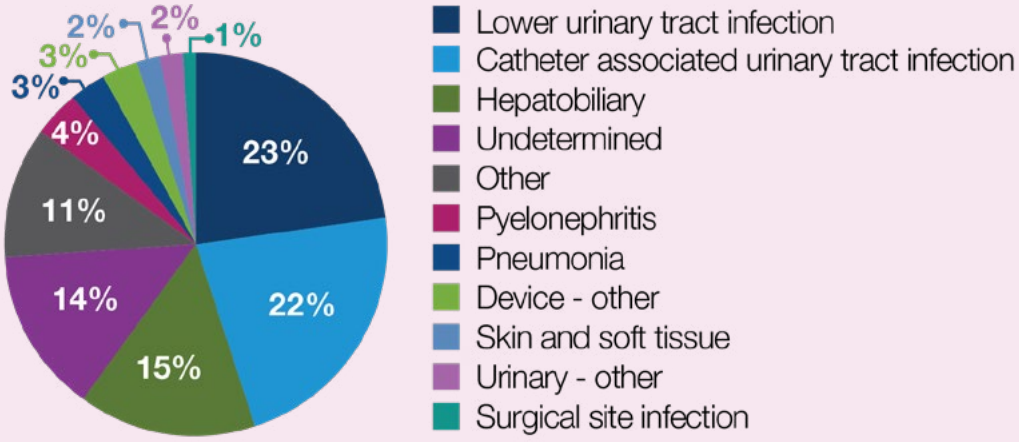
Note: rates are **not adjusted** for **differences** in the **patient population over time**.

In **2023**, the **primary infections** for **healthcare associated ECB** were known for **86.0%** of cases.

The most common primary infections (as determined by the clinical team) include:

23.2% Lower urinary tract infection
22.0% Catheter associated urinary tract infection
14.7% Hepatobiliary infection

Primary infections of healthcare associated ECB in 2023

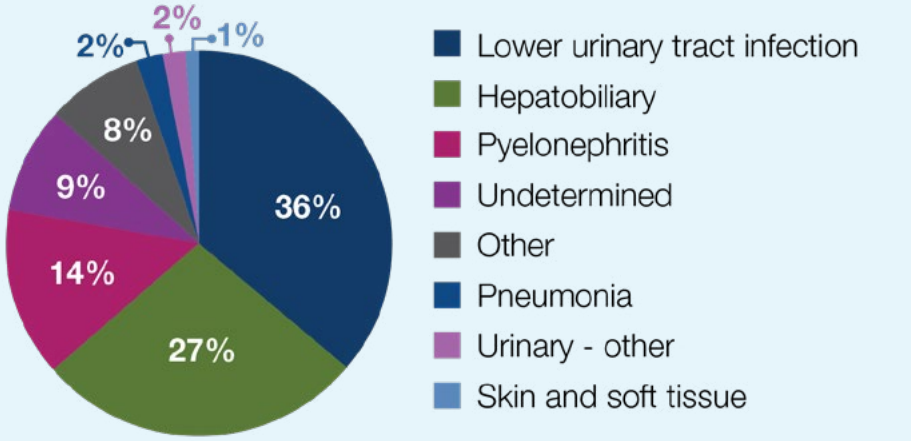


In **2023**, the **primary infections** for **community associated ECB** were known for **90.7%** of cases.

The most common primary infections (as determined by the clinical team) include:

35.7% Lower urinary tract infection
26.7% Hepatobiliary infection
14.5% Pyelonephritis

Primary infections of community associated ECB in 2023



Carbapenemase-producing Enterobacterales

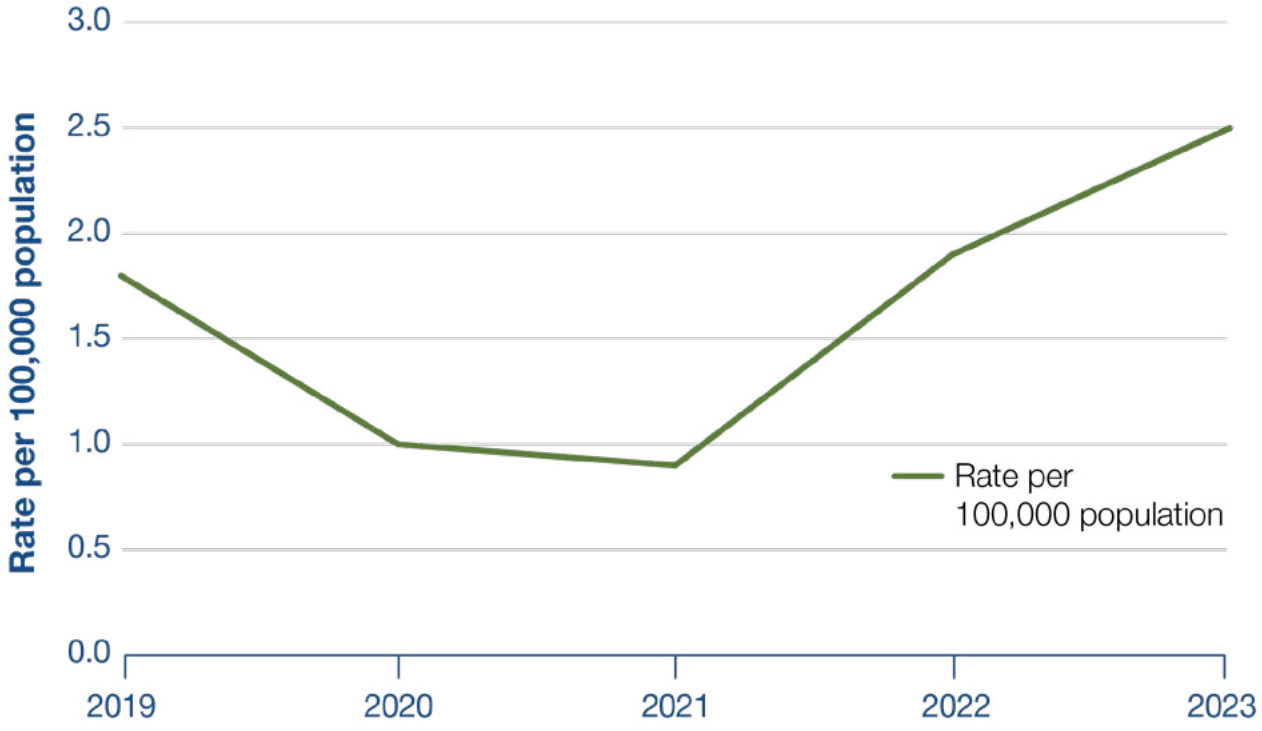
In **2023**, there were **135 cases** of **carbapenemase-producing Enterobacterales (CPE) reported** in **Scotland**, **compared** to **102** in **2022**.

The **annual incidence rate** of **CPE** was **2.5** per 100,000 population.

There has been a **32.4% increase** in the **rate** between **2022** and **2023**.

The **rate in 2023** was **39.6% higher compared to 2019.**

Rate of CPE per 100,000 population in Scotland, 2019 to 2023



Further detail on antimicrobial use and antimicrobial resistance, including Carbapenemase-producing organisms and CPE enzymes, will be published in the annual SONAAR report.

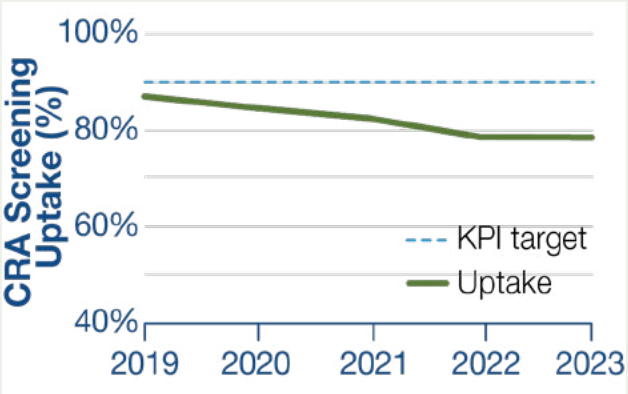
Multi-drug resistant organism admission screening

MRSA CRA screening

In **2023**, **78.5%** of patients audited underwent a **clinical risk assessment (CRA)** for **meticillin-resistant *Staphylococcus aureus* (MRSA)**.

This **remains below** the **90%** Key Performance Indicator and uptake has **remained stable** between **2022** and **2023**.

The **five year trend** in reported uptake has **decreased** with a **2.8% average decrease** each year.

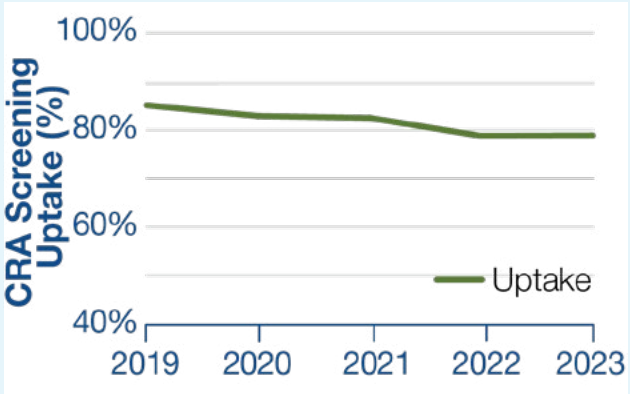


CPE CRA screening

In **2023**, **78.3%** of patients audited underwent a **clinical risk assessment (CRA)** for **carbapenemase-producing Enterobacterales (CPE)**.

Uptake has **remained stable** between **2022** and **2023**.

The **five year trend** in reported uptake has **decreased** with a **2.0% average decrease** each year.



These MRSA and CPE CRA uptake data continue to be monitored by ARHAI Scotland and feedback is provided to NHS boards on a quarterly basis.

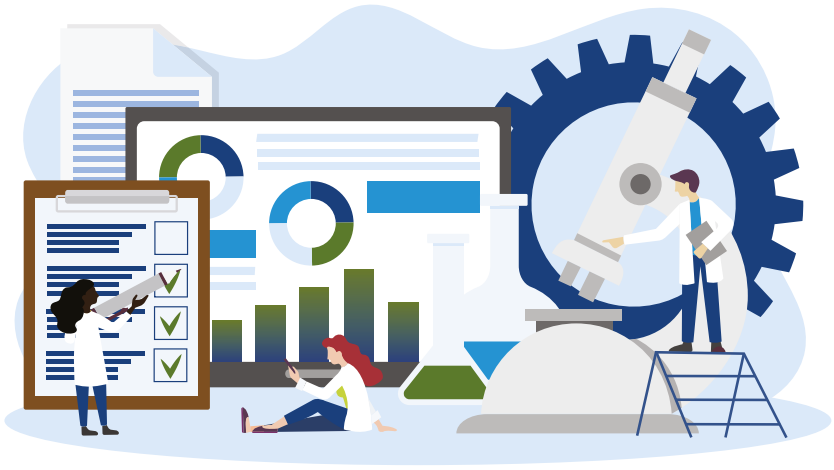
Education and training materials are available on TURAS to support NHS staff in carrying out the two-step admission screening process.

Incidents and outbreaks

ARHAI Scotland supports local Infection Prevention and Control Teams (IPCTs) and Health Protection Teams (HPTs) throughout Scotland to prevent, prepare for, and manage incidents and outbreaks, allowing the sharing of lessons learned throughout the region.

IPCTs and HPTs identify incidents, outbreaks and data exceedances, including decontamination incidents and near misses, in line with **Chapter 3 of the National Infection Prevention and Control Manual (NIPCM)**, which are assessed using the Healthcare Infection Incident Assessment Tool (HIIAT). In collaboration with key stakeholders, work is ongoing to revise the format of the HIIAT, with the aim to address potential variation that may occur with the assessment criteria, to provide a more structured approach in determining the risks associated with an incident or outbreak, and for consistency in the subsequent reporting across Scotland.

HIIAT assessed incidents, outbreaks and data exceedances are reported to ARHAI Scotland through the Outbreak Reporting Tool (ORT), which aims to facilitate the collation of epidemiological data and lessons learned which contribute to the development of national guidance and help inform local incident and outbreak management. The ORT continued to evolve in 2023 with the creation and introduction of the respiratory short form. Any incident/outbreak from key respiratory viruses (COVID-19, influenza and respiratory syncytial virus (RSV) only), where IPC measures align with the checklist and NIPCM and ARHAI support is not requested can be reported through the respiratory short form using a minimum dataset to ease the reporting burden for NHS boards.



In **2023**, there were **181** **healthcare infection incidents** and **outbreaks reported** to ARHAI Scotland (excluding incidents and outbreaks where COVID-19 or Norovirus is the sole pathogen), with HIIATs categorised as **Red**, **Amber** or **Green**.

Of these 181 reports, there were:

32 Red	21 Amber	128 Green

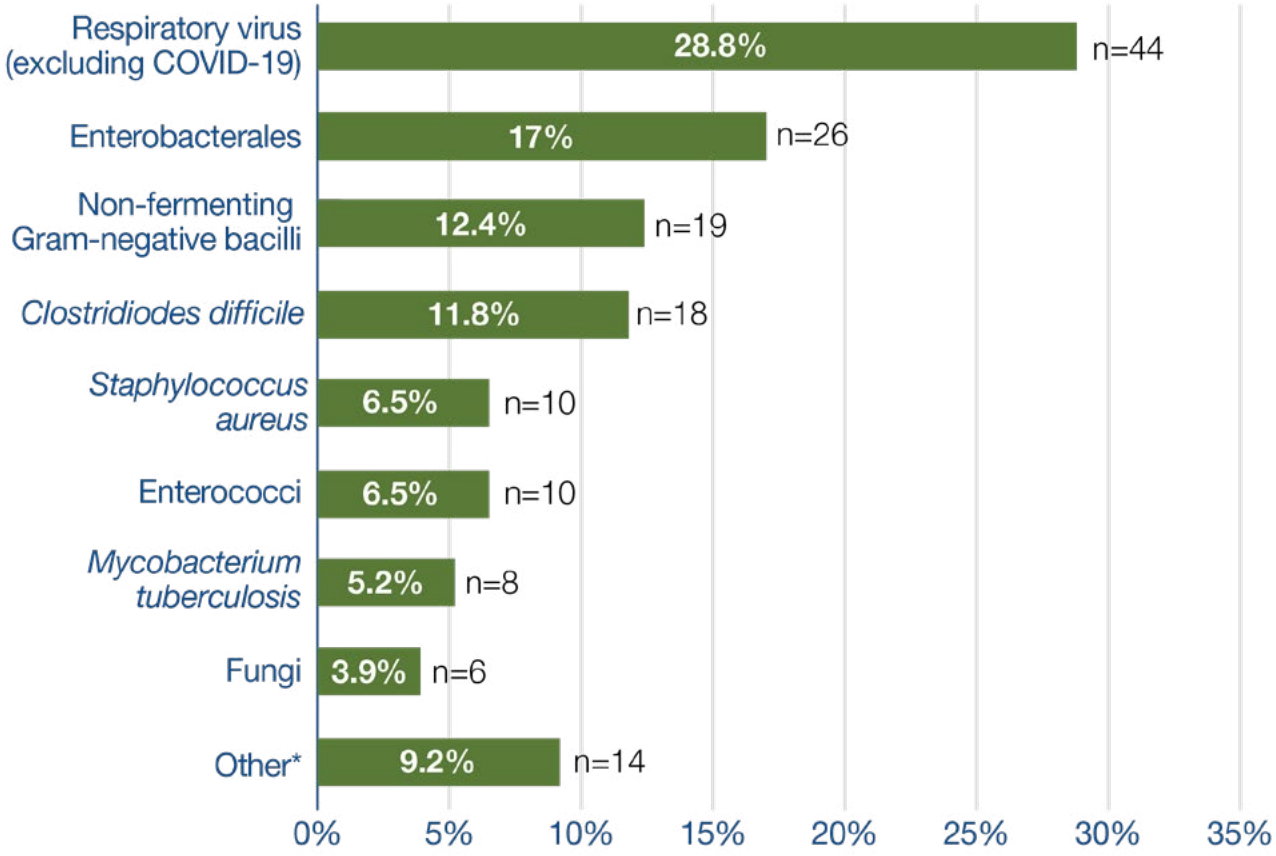
Of the **181** **incidents and outbreaks**, **153** were **reported with one or more patient cases**.

39 incidents involved a single patient case.

4 incidents stated two or more pathogens were involved.

3 incidents were from an unknown causative pathogen.

Percentage of key organism types as reported from incidents and outbreaks with one or more patient cases

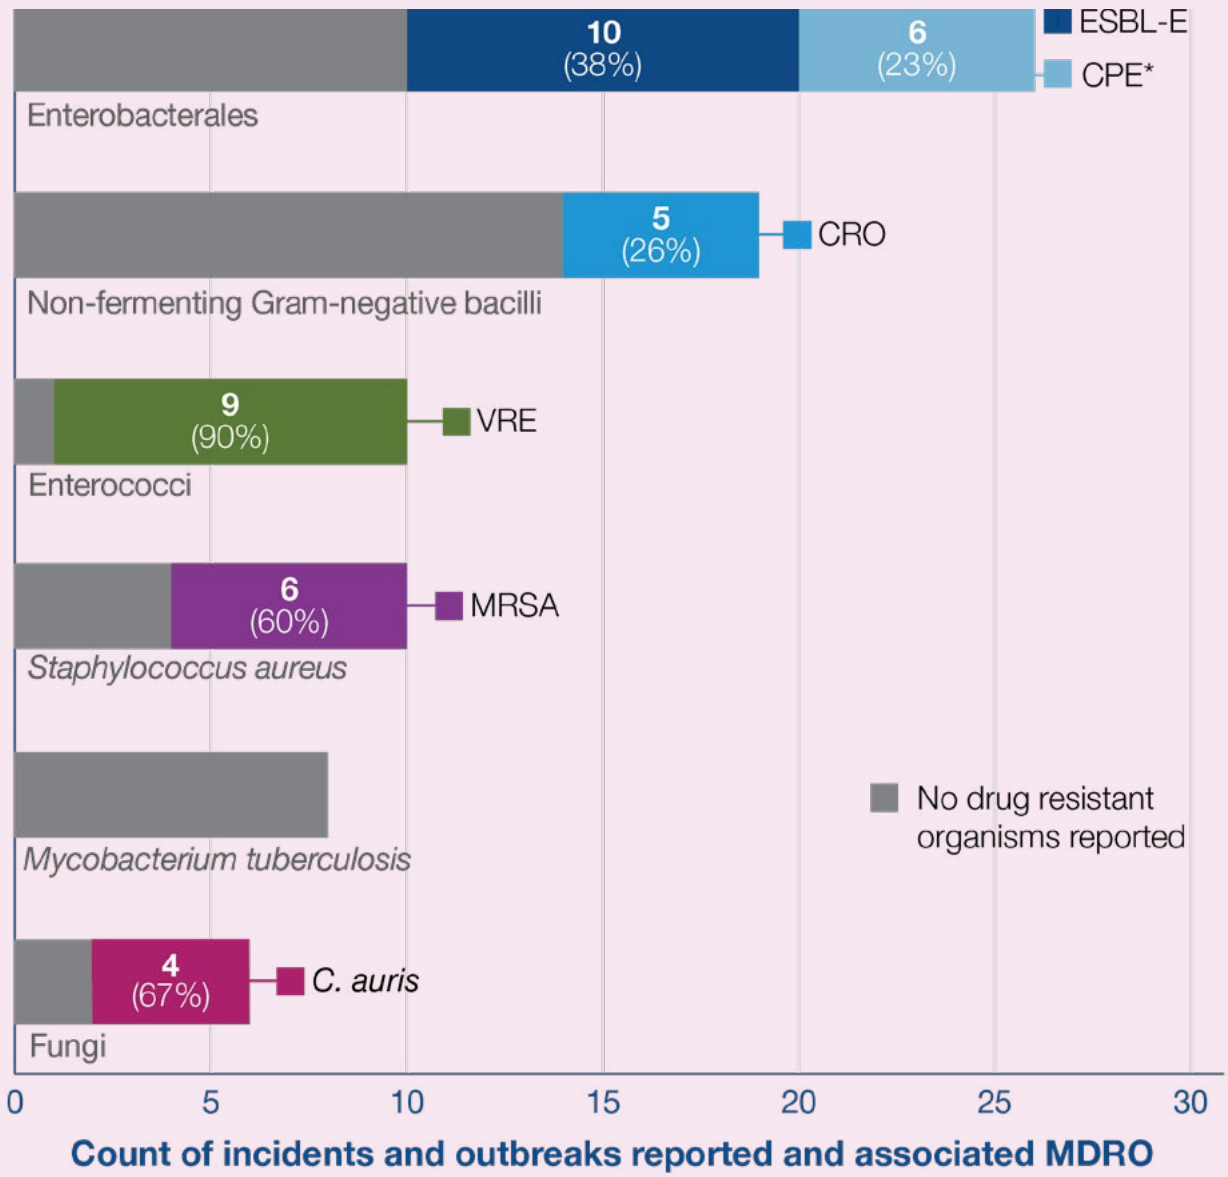


*Other includes: Gastroenteritis viruses (excluding norovirus), other Gram-negatives, other Gram-positives and scabies.

Note: some incidents included multiple organisms so total percentages may not add up to 100%.

Incidents and outbreaks with multi-drug resistant organisms

NHS boards also notify ARHAI Scotland if causative pathogens are multi-drug resistant organisms (MDRO).



*Organisms reported as CPE are not counted as ESBL-E separately.

- ESBL-E – Extended beta-lactamase producing Enterobacterales
- CPE – Carbapenemase-producing Enterobacterales
- CRO - Carbapenem-resistant organism
- VRE – Vancomycin-resistant Enterococcus
- MRSA – Meticillin-resistant *Staphylococcus aureus*
- *C. auris* – *Candida auris* (any susceptibility pattern)

Infection Prevention and Control workforce development

During 2023, NHS Education for Scotland (NES) and ARHAI continued to work collaboratively to embed education across key priority areas, to support improving people's health through a competent and skilled Infection Prevention and Control (IPC) workforce.

Winter preparedness

The winter preparedness campaign for 2023/24 launched 9 infographics containing key IPC messages. The report on our campaign that ended in February 2024 showed better engagement compared to the winter of 2022/23, with more people visiting our website and downloading our content. Our Winter Preparedness 2023/24 video on Vimeo was a hit, with 1,349 views, making it the most-watched video out of over 500 videos posted on our NES Vimeo account in the last 5 months.

Care home webinars

To support adoption and implementation of the Care Home Infection Prevention and Control Manual (CH IPCM), ARHAI Scotland delivered a series of themed national webinars entitled 'Clean Care Homes' to a target audience of care home staff across Scotland. The webinars were planned and jointly delivered with our partners in the Care Inspectorate and the Scottish Social Services Council and feedback was very positive.

Healthcare built environment

Project work was prioritised to develop and deliver learning and development opportunities for the specialist healthcare-built environment workforce. This included identifying priority areas for executive and non-executive NHSScotland board members and the delivery of two senior leadership development sessions.

IPC educational animations

An educational animation aimed at increasing staff awareness of potential risks associated with the improper use of clinical hand wash basins was produced and is hosted on **TURAS**. To support this work, **a safe use of clinical wash hand basin poster** was produced to be placed at all hand hygiene sinks.

A further suite of four educational animations which will identify IPC risks associated with the design, construction, commissioning and handover of healthcare water and above ground drainage systems also commenced. The preparatory work for the animations has begun and two of the four are complete with the remaining two to be undertaken in 2024. The development of the first animation is underway and will conclude in 2024 and sequentially all four will be available by the end of 2024.

Antimicrobial resistance

To continue to embed the importance of reducing the development and transmission of antimicrobial resistance (AMR), ARHAI Scotland provided sessions on post-graduation education to local universities. During Scottish Antimicrobial Prescribing Group network events, topics were presented and discussion groups led. Working in collaboration with NES, subgroups were facilitated on antimicrobial stewardship and AMR.

Surveillance and epidemiology

ARHAI Scotland and NES developed and delivered courses on **Epidemiology and Surveillance for IPC** and **Outbreak Simulation Training**. The learning outcomes for the epidemiology and surveillance course included foundational epidemiology for HCAI with a focus on epidemiological methods for outbreak investigations. The outbreak simulation training allowed participants to apply and enhance their knowledge, skills and confidence in outbreak management in a realistically simulated Incident Management Team environment. These courses will continue to be delivered during 2024.

ARHAI Scotland launched a Sharepoint site with training materials designed to support IPC staff with ongoing mandatory national surveillance programmes. In addition to links to key protocols and resources, ARHAI Scotland compiled additional video guides for users on the mandatory national surveillance programmes. These materials have been developed to support infection prevention and control teams to collect, submit and validate data according to surveillance definitions.

Education and training goals for 2024

- **Focus on educational content beyond social media campaigns to better reach our target audience.**
- **Introduce new educational tools and resources to support the launch of recommendations from the Transmission Based Precautions (TBPs) literature review.**
- **To continue support for adoption and implementation of national IPC guidance, a further series of Care Home themed webinars will be delivered**
- **Further development and creation of a suite of educational animations**
- **Continued education sessions feeding into the post-graduation programme**
- **Continue to deliver epidemiology and surveillance training to the IPC workforce.**
- **Expand the suite of training materials to support the provision of national surveillance data and outbreak reporting.**

List of abbreviations and acronyms

A&E	Accident and Emergency
AMR	Antimicrobial Resistance

Appendix 1 – Publication metadata

Publication title

ARHAI Scotland 2023 Annual Report

Description

This release provides information on activity within Antimicrobial Resistance and Healthcare Associated Infection (ARHAI) Scotland for the period January to December 2023.

Theme

Healthcare associated infections in Scotland

Topic

Healthcare associated infections

Infection prevention and control

Format

Online resource (PDF)

Data source(s)

Infection Prevention and Control Guidance: N/A

Reducing Risk in the Healthcare Built Environment: N/A

Antimicrobial Resistance: N/A

Hospital Activity and Pressures:

Total occupied bed days: **Public Health Scotland, ISD(S)1**.

Elective admissions data: **Public Health Scotland, Acute hospital activity and NHS beds information**.

Emergency admissions data: **Public Health Scotland, Acute hospital activity and NHS beds information**.

Delayed discharges data: **Scottish Health and Social Care Open Data platform, Delayed discharges in NHSScotland**.

Accident & Emergency (A&E) waiting times data: **Scottish Health and Social Care Open Data platform, Monthly A&E Activity and Waiting TimesScottish Health and Social Care Open Data platform, Monthly A&E Waiting Times**.

***Clostridioides difficile* infection**:

Case data: Electronic Communication of Surveillance in Scotland (ECOSS).

Data linkage source: general / acute inpatient and day case Scottish Morbidity Records (SMR01): Public Health Scotland.

Healthcare associated denominator: Public Health Scotland ISD(S)1 total occupied bed days.

Community associated denominator: National Records of Scotland (NRS) mid-year population estimates.

Case fatality data: NRS.

Molecular typing data: ECOSS, Enteric Bacterial Infections Service (EBIS SMiRL, Glasgow).

***Staphylococcus aureus* bacteraemia:**

Case data: ECOSS Enhanced Surveillance Web Tool.

Healthcare associated denominator: Public Health Scotland ISD(S)1 total occupied bed days.

Community associated denominator: NRS mid-year population estimates.

Case fatality data: NRS.

Gram-negative bacteraemia (*Klebsiella pneumoniae*, *Klebsiella oxytoca*, *Pseudomonas aeruginosa* and *Acinetobacter species* bacteraemia):

Case data: ECOSS.

Gram-negative bacteraemia (*Escherichia coli* bacteraemia):

Case data: ECOSS and ECOSS Enhanced Surveillance Web Tool.

Healthcare associated denominator: Public Health Scotland ISD(S)1 total occupied bed days.

Community associated denominator: NRS mid-year population estimates

Case fatality data: NRS.

Multi-drug resistant organism admission screening: National Multi-drug resistant organism (MDRO) Admission Screening Uptake Monitoring Tool.

Carbapenemase-producing Enterobacterales: ECOSS, Scottish Antimicrobial Resistance Service (SAMRS SMiRL, Glasgow).

Population denominator: NRS mid-year population estimates.

Incidents and Outbreaks: Healthcare infection incidents and outbreaks reported to National Services Scotland (NSS) through the Healthcare Infection, Incident and Outbreak Reporting Template (HIIORT) reporting process and the ARHAI Scotland Outbreak Reporting Tool (ORT).

Infection Prevention and Control Workforce Development: N/A

Date that data are acquired

Infection Prevention and Control Guidance: N/A

Reducing Risk in the Healthcare Built Environment: N/A

Antimicrobial Resistance: N/A

Hospital Activity and Pressures: 28 May 2024

***Clostridioides difficile* infection:** 19 March 2024

***Staphylococcus aureus* bacteraemia:** 19 March 2024

Gram-negative bacteraemia (*Klebsiella pneumoniae*, *Klebsiella oxytoca*, *Pseudomonas aeruginosa* and *Acinetobacter species* bacteraemia):
8 April 2024

Gram-negative bacteraemia (*Escherichia coli* bacteraemia):
19 March 2024

Multi-drug resistant organism admission screening: 27 March 2024

Carbapenemase-producing Enterobacterales: 9 April 2024

Incidents and Outbreaks: 11 June 2024

Infection Prevention and Control Workforce Development: N/A

Release date

15 October 2024

Frequency

Annual

Timeframe of data and timeliness

The latest iteration of data are to 31 December 2023, therefore ten months in arrears.

Continuity of data

Infection Prevention and Control Guidance: N/A

Reducing Risk in the Healthcare Built Environment: N/A

Antimicrobial Resistance: N/A

Hospital Activity and Pressures: Please see each **data source** for any relevant information.

***Clostridioides difficile* infection:** Changes in the hospital population and activity during the pandemic period may have affected the epidemiology of *Clostridioides difficile* infection and comparison of results should be interpreted with caution.

In 2023, a small number of *C. difficile* isolates were typed using whole genome sequencing (WGS) derived from multi locus sequence type (MLST) due to an ongoing shortage of DNA polymerase, and ribotypes were inferred from the sequence type. Polymerase chain reaction (PCR) ribotyping was resumed in early 2023.Caution is advised in interpretation of the annual ribotype distributions due to the differences in typing methods.

***Staphylococcus aureus* bacteraemia:** Changes in the hospital population and activity during the pandemic period may have affected the epidemiology of *Staphylococcus aureus* infection and comparison of results should be interpreted with caution.

Gram-negative bacteraemia (*Klebsiella pneumoniae*, *Klebsiella oxytoca*, *Pseudomonas aeruginosa* and *Acinetobacter species* bacteraemia):

Changes in the hospital population and activity during the pandemic period may have affected the epidemiology of Gram-negative bacteraemia and comparison of results should be interpreted with caution.

Gram-negative bacteraemia (*Escherichia coli* bacteraemia): Changes in the hospital population and activity during the pandemic period may have affected the epidemiology of Gram-negative bacteraemia and comparison of results should be interpreted with caution.

Multi-drug resistant organism admission screening: Changes in the hospital population and activity during the pandemic period may have affected screening uptake; results of the clinical risk assessment (CRA) screening audits for meticillin-resistant *Staphyloccocus aureus* (MRSA) and carbapenemase-producing Enterobacterales (CPE) should be interpreted with caution.

Carbapenemase-producing Enterobacterales: Changes in the hospital population and activity during the pandemic period, including international travel restrictions, may have affected the epidemiology of CPE and comparison of results should be interpreted with caution.

Incidents and Outbreaks: Changes in the hospital population and activity during the pandemic period may have affected the epidemiology of healthcare incidents and outbreaks and comparison of results should be interpreted with caution.

Infection Prevention and Control Workforce Development: N/A

Revisions statement

These data are not subject to planned major revisions. However, our aim is to continually improve the interpretation of the data and therefore analysis methods are regularly reviewed and may be updated in the future.

Revisions relevant to this publication

Infection Prevention and Control Guidance: N/A

Reducing Risk in the Healthcare Built Environment: N/A

Antimicrobial Resistance: N/A

Hospital Activity and Pressures: Please see each **data source** for any relevant information.

***Clostridioides difficile* infection:** Details provided in **quarterly publication**.

***Staphylococcus aureus* bacteraemia:** Details provided in **quarterly publication**.

Gram-negative bacteraemia (*Klebsiella pneumoniae*, *Klebsiella oxytoca*, *Pseudomonas aeruginosa* and *Acinetobacter species* bacteraemia): N/A

Gram-negative bacteraemia (*Escherichia coli* bacteraemia): Details provided in **quarterly publication**.

Multi-drug resistant organism admission screening: N/A

Carbapenemase-producing Enterobacterales: Due to data quality updates the number of CPE cases in 2023 is reported as 102 cases, whereby this was previously reported as 103 cases in the ARHAI Scotland 2022 Annual Report.

Incidents and Outbreaks: N/A

Infection Prevention and Control Workforce Development: N/A

Concepts and definitions

Statistical significance:

Please note an increase or decrease stated in this report refers to a statistically significant change ($p < 0.05$), and where a trend is referred to as stable, or there has been no change, this means that there has been no significant increase or decrease.

Origin of infection:

Clostridioides difficile infection, *Staphylococcus aureus* bacteraemia and *Escherichia coli* bacteraemia: Cases are presented by origin of infection, where definitions are applied as per each surveillance protocol to classify cases as hospital acquired, healthcare associated, community associated or unknown. Please see the **quarterly publications**, corresponding **methods & caveats** document and individual surveillance protocols for **CDI** and **SAB/ECB** for full details.

Case fatality:

Clostridioides difficile infection, *Staphylococcus aureus* bacteraemia and *Escherichia coli* bacteraemia: The definition of 30 day all cause case fatality is any death occurring within 30 days of the first positive specimen date within each infection episode. Therefore, the data includes deaths where

Clostridioides difficile infection, *Staphylococcus aureus* bacteraemia or *Escherichia coli* bacteraemia may not have been either the underlying or contributory cause of death. All cause case fatality depends solely on the number of deaths identified and is not subject to bias that may be introduced as a result of inaccuracies in completion of the death certificate or coding of the cause of death. If more than one episode occurs in the 30 days prior to death, only the latest episode will be counted as resulting in a death. Some cases may not be able to be linked to NRS death data due to missing or invalid Community Health Index (CHI) numbers.

Year-to-year comparisons:

The current calendar year 2023 is compared to the previous calendar year 2022 using two sided z-tests for proportions and rate ratio tests (using Poisson counts) for incidence rates. A resulting p-value of less than 0.05 was deemed statistically significant to determine an increase or decrease relative to the previous year.

Five-year trends:

Incidence rates and incidence proportions over the past five years are modelled using Poisson regression and negative binomial regression respectively. This is performed to determine the presence of a significant upwards or downwards linear trend in the changing incidence rate/ proportion, and the corresponding rate of change of the best-fit gradient over the past five years from 2019 to 2023.

Where a year-on-year increase or decrease has been reported, this represents a significant linear trend over the past five years.

Where no five year increases or decreases have been detected, these are reported as stable.

Where a change over the past five years has been detected, but the trend is not linear, a direct year-to-year comparison between the incidence rate in 2023 and the incidence rate in 2019 has been made.

Funnel plots:

Funnel plot analyses are used to determine if any NHS board's rate is significantly higher than the NHSScotland average rate. The incidence rates for each NHS board are plotted against NHS board size/hospital activity,

with 95% confidence intervals calculated from the NHSScotland average. Any NHS board above the 95% confidence interval are deemed to be exceptions. Funnel plots are generated on a quarterly basis in the **quarterly epidemiological reports**; in this report the funnel plots incorporate the full year's data for 2023, and therefore as a result, some NHS boards may be above the 95% confidence interval upper limit in the annual funnel plot who may not have exceeded the quarterly funnel plots limits.

Infection Prevention and Control Guidance: N/A

Reducing Risk in the Healthcare Built Environment: N/A

Antimicrobial Resistance: N/A

Hospital Activity and Pressures: Total occupied bed days: Total number of occupied bed days for years 2019 - 2023, as per **Public Health Scotland ISD(S)1**.

Elective admissions data: Details are provided within **Public Health Scotland Acute hospital activity and NHS beds information quarterly publication**.

Emergency admissions data: Details are provided within **Public Health Scotland Acute hospital activity and NHS beds information quarterly publication**.

Delayed discharges data: Details are provided on the **Scottish Health and Social Care Open Data platform**. These data include the number of hospital bed days occupied by people aged 18 and over who were clinically ready for discharge (excluding NHS Golden Jubilee). Data are presented as a percentage of TOBDs, whereby a comparable number of total hospital occupied bed days are used which excludes TOBDs from NHS Golden Jubilee, paediatric specialties and TOBDs from children's hospitals.

A&E waiting times data: Details are provided within **Scottish Health and Social Care Open Data platform, Monthly A&E Waiting Times.Scottish Health and Social Care Open Data platform**

***Clostridioides difficile* infection:** Details provided in **surveillance protocol and quarterly publication**.

***Staphylococcus aureus* bacteraemia:** Details provided in **surveillance protocol and quarterly publication**.

Gram-negative bacteraemia (*Klebsiella pneumoniae*, *Klebsiella oxytoca*, *Pseudomonas aeruginosa* and *Acinetobacter species* bacteraemia):
Gram-negative organisms including Enterobacterales and non-fermenters, cause serious infections including bacteraemia, pneumonia, meningitis, and surgical site infections (SSIs). Gram-negative bacteraemia is a public health and clinical concern because of:

1. The severity of infection, commonly occurring among vulnerable patients often at the extremes of life and/or with comorbidities.
2. The large number of cases of Gram-negative bacteraemias each year, and high prevalence of Gram-negative infections.
3. The association with receiving healthcare in community and healthcare settings.
4. Their ability to become resistant to multiple classes of antibiotics, limiting treatment options.

Further details provided in the **SONAAR Annual Report**.

Gram-negative bacteraemia (*Escherichia coli* bacteraemia): Details provided in **surveillance protocol and quarterly publication**.

Multi-drug resistant organism admission screening: Screening for MDRO on admission to hospital is a key intervention for early identification and management of patients who are colonised or infected, reducing the risk of introduction of MDRO into healthcare settings.

MRSA and CPE CRA screening policies are in place for all acute hospitals in Scotland. The two-stage screening process includes a CRA to identify patients at high risk of colonisation or infection with either MRSA or CPE, followed by microbiological testing as indicated by the CRA.

Uptake of the MRSA CRA has been a **level 3 HCAI Key Performance Indicator (KPI) since 2013**. The MRSA screening uptake monitoring tool was extended in 2018 to include assessment of CPE CRA uptake for the same patients included in the MRSA KPI audits.

Carbapenemase-producing Enterobacterales: CPE are bacteria that produce enzymes that inactivate carbapenems and other classes of antibiotics. Infections caused by CPE are difficult to treat and are associated with increased mortality.

A case of CPE is defined as one isolate per patient per enzyme and organism combination per year as confirmed by the Scottish Microbiology Reference Laboratory. Further details provided in the **SONAAR Annual Report**.

Incidents and Outbreaks: Healthcare infection incidents and outbreaks reported to NSS. Healthcare associated infection incidents and outbreaks are defined within **Chapter 3 of the National Infection Prevention and Control Manual**.

Individual NHS boards report the MDRO status of organisms. These are typically ascertained by local phenotypic susceptibility testing, reference laboratory phenotypic or genotypic testing or a combination. For more information see the **Reference laboratory referral guide**.

Further details provided in the **SONAAR Annual Report**.

Infection Prevention and Control Workforce Development: N/A

Relevance and key uses of the statistics

Infection Prevention and Control Guidance: N/A

Reducing Risk in the Healthcare Built Environment: N/A

Antimicrobial Resistance: Details provided in the **SONAAR Annual Report**.

Hospital Activity and Pressures: Figures provided are used for management information for resource planning, surveillance and research in NHSScotland.

***Clostridioides difficile* infection:** Details provided in **quarterly publication**.

***Staphylococcus aureus* bacteraemia:** Details provided in **quarterly publication**.

Gram-negative bacteraemia (*Klebsiella pneumoniae*, *Klebsiella oxytoca*, *Pseudomonas aeruginosa* and *Acinetobacter species* bacteraemia): The outputs of the surveillance programme are intended to support the NHS boards in controlling and reducing the burden of Gram-negative bacteraemia.

Gram-negative bacteraemia (*Escherichia coli* bacteraemia): Details provided in **quarterly publication**.

Multi-drug resistant organism admission screening: These audit data measure uptake of the two-stage admission screening process of CRA followed by microbiological testing of those considered to be at risk of carrying MRSA or CPE based on CRA response, in NHSScotland as per policies. These audit data are collected to support the assurance element of quality improvement processes and gather intelligence to inform and target local interventions where CRA screening uptake is suboptimal. ARHAI Scotland provide enhanced feedback to NHS boards on a quarterly basis.

Carbapenemase-producing Enterobacterales: Details provided in the **SONAAR Annual Report**.

Incidents and Outbreaks: To identify risks or trends in the organisms, types of infection, procedures, patients, or clinical specialities associated with healthcare infection incidents and outbreaks. This informs the production of guidance, tools or policy and assists in preparing for, preventing, detecting, and managing healthcare infection incidents and outbreaks.

Infection Prevention and Control Workforce Development: N/A

Accuracy

Infection Prevention and Control Guidance: N/A

Reducing Risk in the Healthcare Built Environment: N/A

Antimicrobial Resistance: N/A

Hospital Activity and Pressures: Details available as per each **data source**.

***Clostridioides difficile* infection:** Details provided in **quarterly publication**.

The **snapshot programme** aims to obtain a representative sample of isolates from CDI cases across all NHS boards in Scotland, however not all NHS boards have submitted the required number of isolates as specified by the Snapshot protocol therefore the data should be interpreted with caution.

***Staphylococcus aureus* bacteraemia:** Details provided in **quarterly publication**.

Gram-negative bacteraemia (*Klebsiella pneumoniae*, *Klebsiella oxytoca*, *Pseudomonas aeruginosa* and *Acinetobacter species* bacteraemia): Gram-negative bacteraemia data are the product of the ECOSS. Participating laboratories routinely report all identifications of organisms, infection or microbiological intoxication and where possible the antimicrobial resistance data unless they are known to be of no clinical or public health importance. The collected data are used for the identification of single cases of severe disease, outbreaks, antimicrobial resistance patterns and longer-term trends in the incidence of laboratory reported infections, enhanced surveillance, health protection, analytical and statistical use.

Gram-negative bacteraemia (*Escherichia coli* bacteraemia): Details provided in **quarterly publication**.

Multi-drug resistant organism admission screening: While audit data does not present the same robust scientific data as surveillance, it provides a nationally representative measure of CRA screening uptake and is valuable for identification of areas for targeted implementation of quality improvement measures. A minimum of 3,500 patients are audited annually for NHSScotland in order to measure uptake with sufficient precision, with each NHS board auditing a representative number of patients.

For each eligible patient admitted during the audit period, data are collected for the most recent opportunity for the CRA to have been undertaken. It is acknowledged that all patients are eligible for CPE CRA admission screening though not all areas are included in the screening audit. These areas will not be represented in these data. Patients are selected for audit based on the **Protocol for CRA MRSA Screening National Rollout in Scotland**, with the exception of NHS Golden Jubilee from which only CPE CRA screening uptake audits are submitted (as all patients are screened for MRSA). In order to maximise the representativeness of the national KPI measure whilst ensuring flexibility at a local level, NHS boards are asked that data collection throughout the year should be spread as much as possible across; hospital, wards, high/low impact specialties, medical/surgical specialties, elective and emergency admissions.

Carbapenemase-producing Enterobacterales: Details provided in the **SONAAR Annual Report**.

Incidents and Outbreaks: NSS are aware that the healthcare infection incident assessment tool (HIIAT) is subjective and there is variation in how NHSScotland boards assess and therefore report healthcare infection incidents. The extent of variation in assessment and unreported incidents has not been fully quantified.

Infection Prevention and Control Workforce Development: N/A

Completeness

Hospital Activity and Pressures: Details available as per each **data source**.

***Clostridioides difficile* infection:** Details provided in **quarterly publication**.

The **snapshot programme** aims to obtain a representative sample of isolates from CDI cases across all NHS boards in Scotland, however not all NHS boards have submitted the required number of isolates as specified by the Snapshot protocol therefore the data should be interpreted with caution.

***Staphylococcus aureus* bacteraemia:** Details provided in **quarterly publication**.

Gram-negative bacteraemia (*Klebsiella pneumoniae*, *Klebsiella oxytoca*, *Pseudomonas aeruginosa* and *Acinetobacter species* bacteraemia): All data for the reporting period have been included in the analysis.

Gram-negative bacteraemia (*Escherichia coli* bacteraemia): Details provided in **quarterly publication**.

Multi-drug resistant organism admission screening: A minimum of 3,500 patients are audited annually for NHSScotland in order to measure uptake with sufficient precision, with each NHS board auditing a representative number of patients. All NHS boards submitted at least their required minimum number of patients audited and all completed audits submitted data for the reporting period have been included in the analysis.

Carbapenemase-producing Enterobacterales: Details provided in the **SONAAR Annual Report**.

Incidents and Outbreaks: NSS are aware that the HIIAT is subjective and there may be some variation in how NHS boards assess and therefore report healthcare infection incidents. The extent of variation in assessment and unreported incidents has not been fully quantified.

Infection Prevention and Control Workforce Development: N/A

Comparability

Changes in the hospital population and activity during the pandemic period may have affected the comparison of results and therefore should be interpreted with caution.

Infection Prevention and Control Guidance: N/A

Reducing Risk in the Healthcare Built Environment: N/A

Antimicrobial Resistance: N/A

Hospital Activity and Pressures: Details available as per each **data source**.

***Clostridioides difficile* infection:** Details provided in **quarterly publication**.

***Staphylococcus aureus* bacteraemia:** Details provided in **quarterly publication**.

Gram-negative bacteraemia (*Klebsiella pneumoniae*, *Klebsiella oxytoca*, *Pseudomonas aeruginosa* and *Acinetobacter species* bacteraemia): Details provided in **SONAAR Annual Report**.

Gram-negative bacteraemia (*Escherichia coli* bacteraemia): Details provided in **quarterly publication**.

Multi-drug resistant organism admission screening: There are no comparable data on CRA screening uptake.

Carbapenemase-producing Enterobacterales: Details provided in the **SONAAR Annual Report**

Incidents and Outbreaks: Reporting of all HCAI outbreaks is not mandatory elsewhere in the UK and comparable data are not published.

Infection Prevention and Control Workforce Development: N/A

Accessibility

It is the policy of NSS to make its website and products accessible according to published guidelines.

Coherence and clarity

Development of guidance: all National Infection Prevention and Control Manual (NIPCM) reviews and resources are produced using a **defined process** which ensures clarity and coherence.

Value type and unit of measurement

Total occupied bed days per year and quarter.

Count of emergency admissions per year and quarter. Count of elective admissions per year and quarter.

Percentage of total occupied bed days due to delayed discharges (%) = Number of bed days occupied by people aged 18 and over who were clinically ready for discharge (excluding NHS Golden Jubilee) / Total number of occupied bed days (excluding bed days from NHS Golden Jubilee and all paediatric specialties/children's hospitals) * 100.

Percentage of A&E attendances seen within 4-hour target (%) = Total number of patients seen within 4 hours in A&E / Total number of patients who attended A&E * 100.

Healthcare associated and hospital acquired cases and incidence rates (per 100,000 total occupied bed days) for *Clostridioides difficile* infection, *Escherichia coli* bacteraemia and *Staphylococcus aureus* bacteraemia.

Community associated cases and incidence rates (per 100,000 population) for Clostridioides difficile infection, *Escherichia coli* bacteraemia and *Staphylococcus aureus* bacteraemia.

30 day all cause case fatality rate for *Clostridioides difficile* infection, *Staphylococcus aureus* bacteraemia and *Escherichia coli* bacteraemia = count of cases with death occurring within 30 days of positive specimen date / total number of cases.

Percentage of *C. difficile* ribotypes (%) = count of each ribotype or ribotype group / total number of isolates submitted for typing.

Percentage of each SAB entry point (%) = count of healthcare associated or community associated SAB with a specific entry point / total number of healthcare associated or community associated *Staphylococcus aureus* bacteraemia.

Percentage of each ECB primary infection (%) = count of healthcare associated or community associated ECB with a specific source / total number of healthcare associated or community associated *Escherichia coli* bacteraemia.

Due to rounding percentages may not add up to 100%.

MRSA Clinical Risk Assessment (CRA) Uptake (%) = number of patients where CRA undertaken / all patients in audit sample *100.

Carbapenemase-producing Enterobacterales (CPE) CRA Uptake (%) = number of patients where CRA undertaken / all patients in audit sample *100.

Count of carbapenemase-producing Enterobacterales per year. Incidence rate of carbapenemase-producing Enterobacterales per 100,000 population per year.

Total number of reported incidents and outbreaks.

Number of reported incidents and outbreaks by HIIAT category.

Number of incident and outbreak reports where one or more patient cases where reported.

Number of incident and outbreak reports where two or more pathogens were reported.

Number of incident and outbreak reports where the causative pathogen was unknown.

Number and percentage of incident and outbreak reports from key organism types (%) = Number of incident and outbreak reports from a key organism type / Total number of incident and outbreak reports * 100. Note: some incidents included multiple organisms so total percentages may not add up to 100%.

Number and percentage of incident and outbreak reports from a key organism type where ARHAI has been notified of a multi-drug resistant organism (%) = Number of incident and outbreak reports from a key organism type where ARHAI has been notified of a multi-drug resistant organism / Number of incident and outbreak reports from corresponding key organism type * 100.

Disclosure

The PHS protocol on **Statistical Disclosure Protocol** is followed.

Abstract

Background

We used genome-based typing data with the aim of identifying the routes of acquisition of *Pseudomonas aeruginosa* (PA) by patients hospitalized in a medical intensive care unit (MICU) over a long period in a non-epidemic context.

Methods

This monocentric prospective study took place over 10 months in 2019 in a 15-bed MICU that applies standard precautions of hygiene. Lockable sink traps installed at all water points of use were bleach disinfected twice a week. We sampled all sink traps weekly to collect 404 PA environmental isolates and collected all PA isolates (n = 115) colonizing or infecting patients (n = 65). All isolates had their phenotypic resistance profile determined and their genome sequenced, from which we identified resistance determinants and assessed the population structure of the collection at the nucleotide level to identify events of PA transmission.

Results

All sink traps were positive for PA, each sink trap being colonized for several months by one or more clones. The combination of genomic and spatiotemporal data identified one potential event of PA transmission from a sink trap to a patient (1/65, 1.5%) and six events of patient cross-transmission, leading to the contamination of five patients (5/65, 7.7%). All transmitted isolates were fully susceptible to β-lactams and aminoglycosides.

Conclusions

Genome-based typing revealed the contamination of patients by PA originating from sink traps to be infrequent (1.5%) in a MICU with sink trap-bleaching measures, and that only 7.7% of the patients acquired PA originating from another patient.

Introduction

P. aeruginosa (PA) is an opportunistic Gram-negative bacillus that can thrive in a wide variety of niches. Hence, PA is widespread in soil and water and frequently found in the environment, including in the wastewater evacuation network of hospitals (1). PA is also one of the most frequent species responsible for nosocomial infection in Europe and the USA (2, 3). In intensive care units (ICUs), 10 to 15% of healthcare-associated infections are attributed to this pathogen (1). Such infections consist mostly of ventilator-associated pneumonia or bacteremia, associated with high mortality (4). A high number of such infections are nosocomial, especially among mechanically ventilated patients (5). The PA genome can also readily acquire genetic material and thus gain new antibiotic resistance (6).

The rate of colonization by PA is low (2.3%) among healthy humans, more frequent among patients admitted to ICUs (4.1 to 11.6%), and can reach higher rates (57.8%) during hospitalization (7–10). ICU patients can acquire PA from their environment and other patients, directly or via the hands of healthcare workers (8, 11). Hence, PA can contaminate respiratory equipment, endoscopes, and sections of the hospital water network, such as faucets, shower drains, and sink traps (also known as U-bends or P-traps) (12–16). The proportion of sink traps contaminated with PA varies from 15 to 50% in European ICUs and studies have reported that 7 to 50% of patients acquire PA from water points of use (17, 18). In addition, investigations of hospital outbreaks have identified the water supply system as the source of the PA outbreaks (19). This has led to infection control departments to recommend sink trap disinfection or sink removal or redesign in high-risk wards, such as ICUs and hematology units (20, 21).

The distribution of the sources of PA (endogenous, environmental, other patients) varies greatly between studies because of differing infection control procedures (contact precautions, sink trap disinfection). In addition, discrepancies in study conclusions may also result from differences in sampling protocols and bacterial typing methods. Hence, genome-based typing identifies

transmission routes of pathogens with a higher accuracy than older typing methods, which probably overestimate the number of transmission events (22, 23).

We aimed to identify the acquisition pathways of PA by patients in a medical ICU (MICU) in which patients positive for PA were managed according to the recommendations of the French Society of Infection Control and, additionally, in which sink traps were disinfected with bleach twice a week. We sampled patients and sink traps for 10 months to collect 519 PA isolates, for which the genomes were entirely sequenced and compared at the nucleotide level. Such analysis elucidated the precise network of PA transmission in this MICU and identified the routes of PA acquisition by the patients.

Methods

Study characteristics. This prospective monocentric study took place in a 15-bed MICU between January and November 2019 in a university hospital in France. This MICU has 11 individual rooms distributed within three subunits (A, B, and C) with one water point of use and a four-bed room with two water points of use (Fig. 1). The MICU admits ~ 700 patients/year and all 549 patients admitted during the time of the study were included. Each patient received care from ~ 10 members of the healthcare staff per day. Healthcare workers were dedicated to a subunit but could help in another subunit when needed. We conducted this study in the absence of an identified outbreak of PA.

Infection control procedures. All 13 water points of use were equipped with a lockable sink trap (Geberit, France) that was bleach-disinfected twice a week and at patient discharge. Briefly, locked sink traps were treated 15 min with 20 ml 2.6% liquid bleach and then rinsed with tap water. This unit systematically applies standard precautions of hygiene according to the recommendations of the French Society of Infection Control (24).

Bacteriological methods. Patients admitted to the MICU were screened for PA carriage upon admission and twice a week thereafter using nasal swabs, rectal swabs, and tracheal aspirates when intubated. In parallel, we collected all PA isolates retrieved from diagnostic samples. All sink traps were sampled every week for PA detection by collecting 50 ml sink-trap content with a suction catheter and a syringe. The sample was centrifuged 5 min at 5000 x *g* at room temperature and the supernatant discarded. Swabs and pellets were streaked on PA-selective cetrimide agar plates (Bio-Rad) and incubated 48 h at 35°C. All colony phenotypes were identified using a MALDI-TOF mass spectrometer (Maldi Biotyper, Bruker). We assessed the activity of 13 antipseudomonal agents (listed in Supplemental Table 1) from three classes (β-lactams, aminoglycosides, fluoroquinolones) by the agar diffusion method as recommended by the EUCAST (www.eucast.org). Morphologically different colonies of PA recovered from the same sink trap sample were retained for further analysis when they showed distinct resistance profiles. The resistance profile of isolates susceptible to all tested antibiotics was considered to be wildtype. Acquired genes encoding β-lactamases (including carbapenemases) were sought within the genomic data against the ResFinder database (25).

Data. Each isolate collected was associated with its date of isolation, its patient or sink trap of origin, and its antibiotic resistance profile. See Supplemental Material and Methods for details on bacteriological and sequence analysis. We sequenced the full genome of all PA isolates (Supplemental Table 1). Sequencing data are available in the NCBI BioProject PRJNA788732. We first identified the sequence type (ST) of each isolate by MultiLocus Sequence Typing (MLST) (26). Then, isolates for which the genome contained ≤ 30 different genes were clustered into groups with Core Genome MLST (cgMLST) using 3,867 core genes (27). We further measured the genetic relatedness of isolates within each group by the number of single nucleotide polymorphisms (SNPs) between genomes. See Supplemental Fig. 1 for the justification of the threshold.

Definitions. *(i)* Isolates from a given group were defined as clonal when their genomes clustered with a threshold of seven SNPs. (*ii*) Cross-contamination was defined by the identification of clonal isolates in two sampling points (patient or sink trap). (*iii*) In cases of cross-contamination between two sampling points ≥ 7 days apart, we defined the older one as the source. (*iv*) Infections were defined according to Sepsis-3.

Statistical analysis. The data were analyzed with R Studio (v 1.4) using the circlize and vegan libraries. Differences between the distributions of resistance profiles of the two PA reservoirs (patients and sink traps) were tested using Fisher's exact test at a threshold of 0.01.

Results

Contamination of sink traps and patients by **P. aeruginosa.** During the 10 months of the study, the 13 sink traps of the MICU were sampled 42 times each, for a total of 546 samples, of which 282 (51.6%) were positive for one or more isolates of PA. This led to the collection of 404 environmental isolates. All sink traps were positive for PA at some point of the study and could be contaminated with multiple STs (mean: 5, min: 2, max: 10), with clones persisting in each sink trap for long periods of time (mean: 242 days, max: 286 days). Among the 549 patients included, 65 (11.8%) were positive for PA. We collected 115 clinical isolates from these patients during their hospitalization. Three patients (3/65, 4.6%) were infected with PA.

Population structure of **P. aeruginosa**. The 519 isolates were distributed within 62 different STs, with five STs accounting for 54.9% of the entire collection. Hence, the high-risk clones ST253, ST308, ST298, and ST244 were represented by 90 (17.3%), 69 (13.3%), 39 (7.5%), and 32 (6.2%) isolates, respectively, and ST309 was represented by 55 isolates (10.6%) (Supplemental Table 1). Isolates from sink traps and patients were distributed within 27 and 48 different STs, respectively, with 13 STs in common. We then compared the clonal diversity of the population of isolates retrieved from the sink traps with that of the clinical isolates and found that the community of clinical PA was 4.1-times richer and 2.6-times more diverse than that retrieved from the sink traps (Supplemental Fig. 2).

Transmission routes of **P. aeruginosa**. The routes of transmission of PA within the MICU were accurately identified by comparing the genomes of all isolates with a pipeline that allowed variant calling. This method clustered the isolates into 36 groups (Supplemental Fig. 3). We combined these genomic data with spatiotemporal data to identify intra- and inter-reservoir transmission events (Table 1, Fig. 2).

Table 1
Details of the transmission of *P. aeruginosa* isolates involving patients in the medical intensive care unit at Besançon University Hospital (France) between January and November 2019.

Type of transmission	Isolate (ST, group)	Resistance phenotype	Reservoir 1	Room	Date (2019)	Direction of transmission[a]	Reservoir 2	Room	Date (2019)
Patient-to-patient									
	ST198, group34_1	FQs[b]	Patient43	A1	Apr. 14	Unknown	Patient49	A1	Apr. 18
	ST274, group30_1	Wild-type	Patient49[c]	C2	Apr. 12	Unknown	Patient32[c]	C2	Apr. 18
	ST1197, group25_1	Wild-type	Patient1	C1	Aug. 7	Unknown	Patient13	C2	Aug. 12

	ST671, group32_1	Wild-type	Patient19	A2	Mar. 30	→	Sink trap	A2	Apr. 8

[a] In cases of transmission between two sampling points ≥ 7 days apart, we defined the older one as the source.

[b] Isolated low-level resistance to fluoroquinolones.

[c] Patient32 and Patient49 shared both isolates ST274, group30_1 and ST3218, group15_1.

[d] ST3218, group15_1 was shared by Patient32 and Patient49 and transmitted from Patient8 to Patient39.

Most of the links occurred within a given sink trap, showing that such niches were contaminated with a signature flora that was stable over time. However, we identified 22 cross-transmission events between sink traps of different rooms, with 10 between sink traps of different subunits (Fig. 2A).

We identified six events of PA cross-transmission between patients, four involving one clonal isolate and one involving two (Table 1, Fig. 2B). These events involved five non-high-risk clones (ST198, ST274, ST1197, ST1238, ST3218) and nine patients. Isolate ST198 group34_1 was shared by two patients hospitalized in room A1 during the same week, but whose hospitalization

period did not overlap. Isolates ST1197 group25_1 and ST1238 group27_1 were transmitted between patients hospitalized during the same week in different rooms (C1 and C2 for ST1197, A1 and B5 for ST1238). Two patients from room C2 shared two isolates (ST274 group30_1 and ST3218 group15_1). The temporal proximity of the finding of these isolates prevented the identification of the source of contamination. In one case, we could document the direction of contamination of a patient of room C2 with the isolate ST3218 group15_1 from a patient hospitalized in room A3 (Table 1, Fig. 2B). Overall, four patients shared the isolate ST3218 group15_1: two patients were hospitalized in April 2019 in room C2 and two others six months later in rooms C2 or A3 (Table 1). We never retrieved this isolate from any sink trap (Supplemental Table 1).

In terms of environment-to-patient contamination, only one transmission of a PA isolate occurred from a sink trap to a patient. A high-risk ST253 clone, repeatedly found in the sink trap of rooms B2 and B3 from January to September 2019, was isolated from a patient hospitalized in May in room A3 (Table 1, Fig. 2B). In addition, we identified six transmission events of PA from patients to the sink traps of their rooms (Fig. 2B). The six STs involved (ST27, ST234, ST253, ST308, ST309, ST671) were transmitted in rooms A1, A2, A5, B2, and B3 (Table 1). Overall, among the 65 patients infected or colonized with PA, one patient (1.5%) acquired a PA isolate from a sink trap and five other patients (7.7%) were contaminated with a PA isolate from another patient.

Resistance profiles of **P. aeruginosa.** The proportion of isolates susceptible to all antibiotics tested was higher for the PA of human origin (74.8%; 86/115) than the PA found in the sink traps (48.0%, 194/404) (Fisher's exact test, $p = 2.8x10^{-7}$; Supplemental Table 1). The only clone that produced extended-spectrum β-lactamase (VEB-1) belonged to ST357 and was represented by eight isolates found in the sink trap of room B1. Isolates non-susceptible to carbapenems were more frequently found in sink traps (152/404, 37.6%) than in patients (19/115, 16.5%) (Fisher's exact test, $p = 1.6x10^{-5}$). The 13 isolates resistant to all antibiotics tested (Supplemental Table 1) were exclusively retrieved from sink traps and clustered within two clones belonging to ST111 (room C2) and ST357 (room B1).

Four of the five PA isolates transmitted between patients (ST274 group30_1, ST1197 group25_1, ST1238 group27_1, ST3218 group15_1) displayed wildtype resistance profiles. Of note, isolate ST3218 group15_1 was transmitted on two occasions involving four patients. The fifth isolate (ST198 group34_1) displayed an isolated low level of resistance to ciprofloxacin. Finally, the isolate ST253 group0_6 transmitted from a sink drain to a patient had a wildtype resistance profile to antibiotics (Table 1, Supplemental Table 1, Supplemental Fig. 3).

Discussion

We investigated the cross-transmission of PA between patients and sink traps over 10 months in the MICU of a university hospital in France in the absence of a recognized outbreak. Among the 65 patients infected or colonized with PA, one (1.5%) was contaminated with a clone originating from a sink trap and five (7.7%) from one originating from another patient.

The proportion of patients contaminated with a PA isolate previously found in a sink trap (1.5%) was lower than that previously reported (7–50%) (17, 18). Such a discrepancy could be due to the more accurate typing method used here relative to older typing techniques based on DNA restriction, such as pulsed-field gel electrophoresis (PFGE). Although PFGE can detect local outbreaks caused by PA, comparison at the nucleotide level is required to identify contamination routes of the pathogens (22, 23, 28). The implementation of infection control procedures, with improved hand hygiene, presumably accounted for the low transmission rate from the environment to patients. In addition, we identified five patients from among the 65 (7.7%) who acquired PA from another patient (Table 1, Fig. 2B). This is the first quantification of the rate of patient cross-contamination in a non-epidemic context. For each cross-contamination event, the genomes of the PA isolates retrieved from the two patients were completely identical (Supplemental Fig. 3). Three transmission events involved patients hospitalized in different rooms, indicating transmission by healthcare workers (Fig. 2B). Of note, the six cross-transmission events between patients were concentrated in the geographically close rooms A1 (two events) and C2 (four events), which frequently shared healthcare workers (Table 1, Fig. 1). Hence, the proximity of the beds and the sharing of sinks in the four-bed room C2 could enhance the risk of cross-contamination with PA. All clinical PA transmitted to the sink traps originated from patients occupying the room (Table 1), probably during their bathing.

Among the 65 patients positive for PA, 29 (44.6%) tested negative at admission. Only two (2/29; 6.9%) acquired a PA isolate from another patient. In other words, the vast majority of patients who became positive with PA during their hospitalization acquired an

isolate not previously found in the other patients or sink traps. Other studies have reported higher proportions (50.0-93.6%) of patients contaminated with an exogenous isolate in ICUs with no detectable PA outbreak and no bleach-disinfection of sink traps (22, 25). Although we cannot rule out contamination with PA isolates originating from unexplored sources (*e.g.* healthcare workers, invasive devices), our data show that endogenous sources (*i.e.* patient flora) predominate over exogenous sources in a non-epidemic context (22).

Overall, we can assume that the cleaning and disinfection procedures, together with infection control procedures, applied in this MICU limit the risk of PA transmission. Sinks were cleaned daily and sink traps were disinfected twice a week with 2.6% bleach. Disinfection procedures using bleach, acetic acid, electrochemically-activated solutions, or self-disinfecting sink drains fail to sterilize sink traps because bacterial biofilms in wastewater plumbing systems resist disinfectants and are not easy to access. However, such procedures likely limit the inoculum size, which, in turn, reduces the risk of contamination of the surrounding sink area and further transmission (29). Additionally, other mechanisms may limit the transmission of PA from sink traps to patients. Hence, sub-inhibitory concentrations of bleach can promote horizontal gene transfer (30), thus favoring the adaptation of pathogens to a harsh environment. Such adaptation, illustrated here by the stability and low diversity of PA populations in sink traps (Fig. 2A, Supplemental Fig. 2), could impair the ability of PA to colonize patients (31).

Our study focused on PA, but other pathogens (*Klebsiella pneumoniae*, *Acinetobacter baumannii, Elisabethkinga meningoseptica*) have already been retrieved from sink traps (32–34). One can assume that disinfection also limits the risk of outbreaks with these pathogens. However, the implementation of sink bleaching alone has not been shown to be systematically associated with the cessation of outbreaks and the implementation of a bundle of measures is recommended for infection control (35, 36).

Outbreaks of multidrug-resistant bacteria specifically linked to drains or sinks are overrepresented in the literature (35). We found all PA isolates transmitted from and to patients to be fully susceptible to β-lactams and aminoglycosides. Clinicians and microbiologists should not neglect the potential spread of strains with unspectacular resistance profiles (37).

This monocentric study was not designed to assess the effect of infection control procedures on the transmission of PA. Hence, the absence of a comparable ICU using different hygiene practices prevented assessment of the efficacy of sink trap disinfection in preventing the transmission of PA to patients. Instead, our design focused on breadth and depth sampling to identify the contamination routes of PA to patients. We isolated PA from both sink traps and patients over 10 months, collecting the largest dataset yet used for an epidemiological study (38). As we were aware of the complex flora of the sink traps (20), we sampled all sink traps weekly and analyzed all colonies with various colony phenotypes and resistance profiles in each sample to obtain a complete picture of the PA population in this environmental niche. The use of isolates collected over 10 months increased the chance of finding clonal isolates that overlapped among patients and sink traps. The genomes of all isolates were fully sequenced and compared at the nucleotide level. This contrasts with typing methods previously used in epidemiological studies (25, 39). We circumvented the absence of a consensus threshold for clonal isolate identification from genome-based data by performing a two-step analysis of the genomes. First, we clustered the isolates with cgMLST and grouped all isolates using a threshold (30 alleles of difference) higher than that found in the literature (15 alleles of difference) to avoid missing any clonal isolates (27). Second, we called variants between isolates within a group and performed a second clustering to access clonal strains with a threshold of seven SNPs of difference (Supplemental Fig. 3). This threshold was experimentally optimized (see Supplemental Fig. 2), consistent with previous studies (6–10 SNPs), and is fully compatible with the evolution rate of the bacterial pathogen (40).

Conclusions

Genome-based typing revealed the contamination of patients by PA isolates originating from sink traps to be rare (1.5%) in a MICU with sink trap bleaching measures and that 7.7% of the patients acquired PA from cross-contamination.

Figures

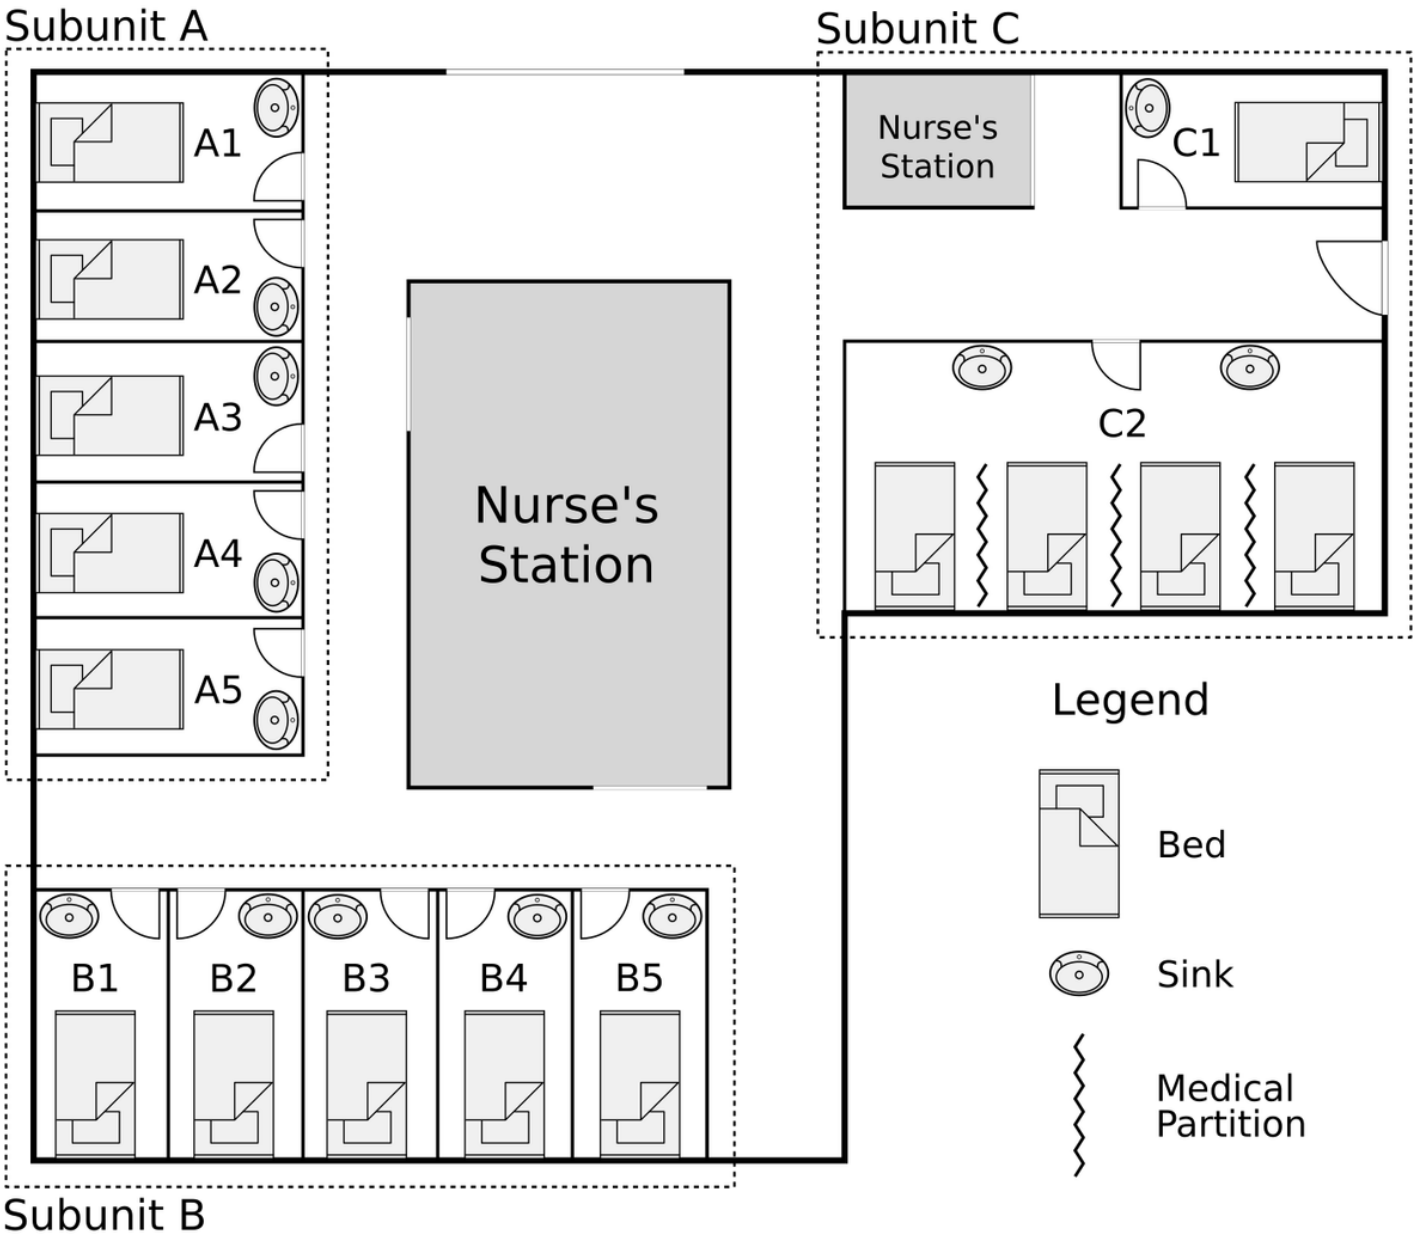

Figure 1

Layout of the medical intensive care unit at Besançon University Hospital (France). Subunits A and B are each composed of five rooms, with each room containing one bed and one water point of use. Subunit C is composed of two rooms, room C1 containing one bed and one water point of use and room C2 containing four beds and two water points of use.

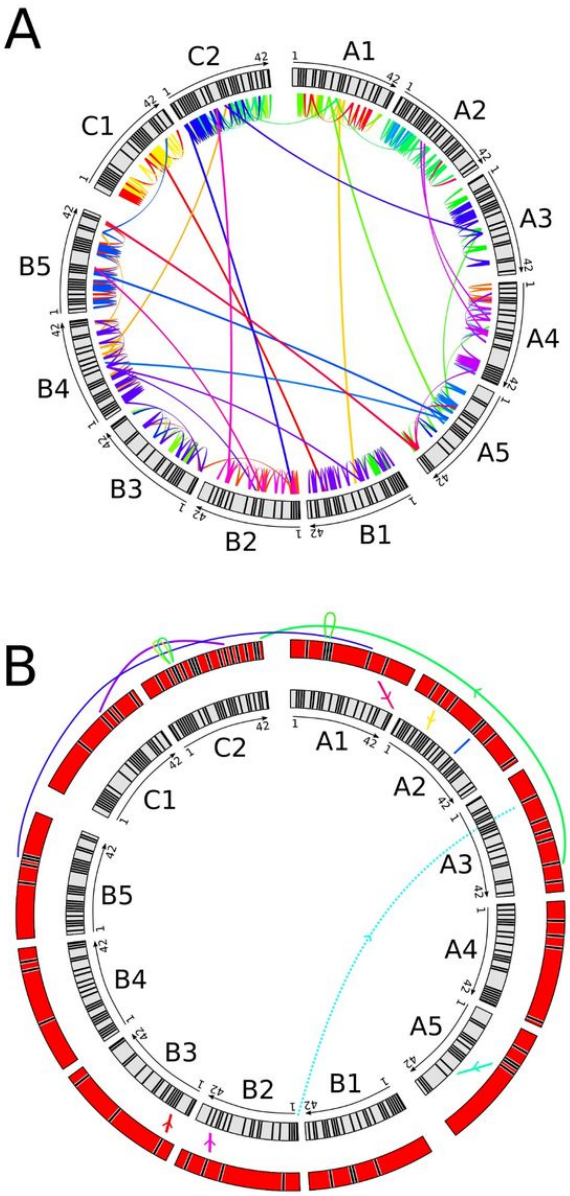

Figure 2

Representation of the transmission routes of *P. aeruginosa* between sink traps and patients in the MICU. Each sector represents a room with the chronology of PA isolation from week 1 to week 42 in a clockwise direction, with the black bars showing PA-positive samples in a given week. The gray circle represents the sink trap isolates and the red circle the human isolates. Each colored link connects two isolates for which the genomes clustered at a threshold of seven SNPs. Isolates from the same cgMLST cluster are connected with a link of the same color. The arrow in the link shows the orientation of the transmission, when determined. When a clone was repeatedly found in a sink trap, we only considered its first appearance to identify the potential links of transmission. (A) Transmission of PA within and between sink traps. (B) Transmission of PA from and to patients. The dotted link between the inner grey and outer red circles indicates the contamination of a patient in room A3 with a PA from the sink trap of room B2. The six links between the outer red and inner grey circles indicate sink traps contaminated with PA of human origin.

Association of Secondary and Polymicrobial Nosocomial Bloodstream Infections with Higher Mortality

D. Pittet[1]*, N. Li[3], R.P. Wenzel[2]

The objective of this study was to characterize microbiological factors independently associated with higher mortality rates following nosocomial bloodstream infection. All patients admitted to the University of Iowa Hospitals and Clinics between 1 July 1989 and 30 June 1990 who developed a nosocomial bloodstream infection were included. The crude in-house mortality for the 364 patients with nosocomial bloodstream infections was 33 %. These deaths accounted for 25 % of all in-hospital deaths. Significant risk factors for death from bloodstream infection included diagnoses of cancers and diseases of the cardiovascular and respiratory systems ($p < 0.01$). Neither previous surgery nor neutropenia was associated with higher mortality rates. Whereas the crude mortality rates associated with gram-negative (33 %) and gram-positive (31 %) bloodstream infections were similar, that associated with fungemia was higher (54 %, $p < 0.02$). The mortality associated with secondary bloodstream infections (46 %) was higher than that associated with primary bloodstream infections (28 %, $p < 0.001$). Furthermore, polymicrobial infections had a worse prognosis than infections from which a single pathogen was isolated ($p < 0.05$). A multivariate, logistic regression model identified four variables that independently predicted mortality ($p = 0.025$): age (OR 1.01 per year; CI95 1.00–1.02); cancer (OR 2.35, CI95 1.26–4.37) or diseases of the cardiovascular or respiratory systems (OR 2.20, CI95 1.04–4.67); polymicrobial infection (OR 2.34; CI95 1.21–4.53); and secondary bloodstream infection (OR 2.46; CI95 1.50–4.02). The last variable was the strongest independent predictor. Our study demonstrates the importance of microbiological factors in the outcome of nosocomial bloodstream infections.

Bloodstream infections are associated with a crude mortality that approximates 35 %, ranging from 30 to 45 % in the largest series (1–7). In studies comparing the mortality rates associated with community-acquired versus hospital-acquired bacteremia, the latter was associated with the higher rates (5, 8–12). Surely, the underlying diseases contribute importantly to the crude mortality from bloodstream infection. The concept of attributable mortality has been applied to nosocomial bloodstream infections to define the mortality rate directly attributable to the infection and apart from the underlying diseases. The attributable mortality of bloodstream infection has averaged 27 % in six specifically designed studies, with point estimates ranging from 14 to 38 %, depending on the offending species (13).

Several studies have reported that the mortality of bacteremia also varies with the source of infection (1, 7, 14, 15); in most series, bacteremia complicating lower respiratory tract or intraabdominal infections has been shown to be more frequently associated with a fatal outcome than bacteremia secondary to other sites. Furthermore, polymicrobial bloodstream infections have been associated with higher mortality rates than monomicrobial infections (5, 7, 8, 16), even in series including only cancer patients (10, 17) or those examining specific organisms (18, 19).

Although most studies have suggested that distinct microbiological factors may influence the outcome of the infection, few have attempted to

A53210128

define the respective role of such factors after controlling for confounders, particularly underlying diseases or other demographic variables that may affect the prognosis. The results of our study demonstrate that microbiological factors independently affect the outcome of nosocomial bloodstream infection.

Patients and Methods

Setting. The University of Iowa Hospitals and Clinics (UIHC) is a 900-bed tertiary health care center serving Iowa and the border areas of surrounding states. Approximately 25,000 patients are admitted annually for a mean hospital stay of seven days. Prospective hospital-wide surveillance for nosocomial infections began in 1976 at UIHC. There is one infection control practitioner per 200 beds. Recent studies using standard methods have indicated the sensitivity and specificity of this hospital-wide reporting of nosocomial infections to be 81 and 97 %, respectively (20).

Methods. All patients admitted to the UIHC between 1 July 1989 and 30 June 1990 who developed a nosocomial bloodstream infection were included in the study. Patients with bloodstream infections were identified through the nosocomial infection surveillance program according to standard definitions (21). These definitions combine specific clinical and laboratory findings (21): positive blood cultures are always associated with significant signs of sepsis, thus blood culture contaminants were excluded. Additional chart reviews were performed for data completion when necessary.

The objective of the study was to characterize the microbiological factors predictive of in-hospital mortality. The demographic variables studied were age, sex, underlying disease and surgery (defined as admission to the operating room). The underlying disease was defined as the primary diagnosis on admission based on the International Classification of Diseases (ICD-9) classification. Five groups of diseases were categorized as follows: cancer patients; burn and trauma patients; diseases of the cardiovascular or respiratory system; diseases of the digestive or urogenital system; and other diseases. Neutropenia was defined as ≤ 500 granulocytes/mm^3.

Microbiological Characteristics and Definitions. The microbiological variables studied were the type of infection (primary vs. secondary bloodstream infection), the nature of the bloodstream infection (monomicrobial vs. polymicrobial) and the class of microorganism involved (gram-positive bacteria, gram-negative bacteria, fungi). Primary bloodstream infection refers to bacteremia for which there was no documented distal source (21). The term includes those episodes resulting from intravenous or arterial line infections. Secondary bloodstream infection defines an infection that develops subsequently to a documented infection with the same microorganism at another body site (21). Polymicrobial bloodstream infection refers to infections in which more than one microorganism was recovered from the blood culture within a 48 h period (2). Roberts (22) has recently proposed the use of this definition. Most of our patients with polymicrobial infection (44/48) had positive blood cultures on the same day. We defined subsequent episodes of bloodstream infection as those occurring more than 48 h after the initial positive blood culture.

Outcome Variable. In-hospital mortality was used as the measure of outcome. In the event that the same patient developed more than one episode of bloodstream infection, only the first episode was considered in the analysis, except when death occurred more than 30 days after bacteremia. In the latter situation, mortality of the subsequent episode was considered. We excluded from the analysis patients whose blood cultures were obtained post-mortem.

Statistical Analysis. Characteristics of patients who died but survived bloodstream infection were compared in a univariate analysis, using two-sample tests for binomial proportions. We used the Yates-corrected chi-square test. Odds ratios (OR) and 95 % confidence intervals (CI95) were based on the method proposed by Miettinen (23). The value for alpha (p) was set at ≤ 0.05 to be considered statistically significant. The model for the binary response variable (death) was built by using logistic regression with seven independent variables (age, sex, underlying disease, neutropenia, primary/secondary bloodstream infection, class of microorganism and uni/polymicrobial infection); two of the variables had either three (class of microorganism) or five (underlying disease) categories. All statistical analyses were carried out using the procedure Logist in the Statistical Analysis System (SAS, version 6).

Results

Type of Infection and Microbial Etiology. Three hundred sixty-four patients developed 412 episodes of bloodstream infections at UIHC in 1989–1990. In the same period, 20,274 patients were admitted. Thus, the rate of bloodstream infection was 1.8 per 100 patients admitted or 1.99 episodes per 1,000 patient-days of care. There were 283 episodes of primary bloodstream infection, accounting for two-thirds of the infections (69 %). Of these, 45 episodes were polymicrobial (16 %). Secondary bloodstream infections constituted a third (31 %) of the total number of bloodstream infections, and 10 % of them were polymicrobial.

Overall, gram-positive organisms were involved in 271 (66 %) and gram-negative organisms in 158 (38 %) of the 412 infectious episodes (Table 1). Fungi were involved in 9.7 % of all infections (40/412); candidemia alone accounted for two-thirds of those, or 6.5 % of all bloodstream infection episodes. Overall, coagulase-negative staphylococci constituted the leading nosocomial pathogens, responsible for 33 % of all bloodstream in-

A53210128

Table 1: Leading pathogens responsible for 412 episodes of nosocomial bloodstream infections at the University of Iowa Hospitals and Clinics, 1989–1990.

Primary bloodstream infections (n = 283 episodes, 324 isolates)	Percent	Secondary bloodstream infections (n = 129 episodes, 145 isolates),	Percent
Coagulase-negative staphylococci	35	Staphylococcus aureus	18
Staphylococcus aureus	12	Coagulase-negative staphylococci	16
Escherichia coli	8	*Serratia marcescens*	14
Enterobacter spp.	6	*Escherichia coli*	11
Klebsiella spp.	6	*Candida albicans* and *Candida* spp.	10
Enterococci	6	*Pseudomonas aeruginosa*	10
Streptococci (non enterococci)	5.5	*Klebsiella* spp.	6.5
Candida albicans and *Candida* spp.	4.3	Streptococci (non enterococci)	6
Pseudomonas aeruginosa	2.5	Enterococci	4.8
Serratia marcescens	2	*Enterobacter* spp.	3.8

fection episodes. *Staphylococcus aureus* was the second most common pathogen, causing 16 % of the infections, followed in order of importance by *Escherichia coli* (9.5 %), *Klebsiella* spp. (6.8 %), non-enterococcal streptococci (6.5 %), *Enterobacter* spp. (6 %), *Serratia marcescens* (6 %), enterococci (5.8 %) and *Pseudomonas aeruginosa* (5 %). The stratification highlights the relative importance of several microorganisms responsible for secondary bloodstream infections (Table 1). For example, the relative proportions of *Serratia marcescens* (14 %) and *Pseudomonas aeruginosa* (10 %) secondary bacteremia were seven and four times higher, respectively, than those of primary bacteremia (2 and 2.5 %, respectively).

The three leading sources of 114 episodes of secondary bloodstream infection were lower respiratory tract infections (24 %), surgical wounds (24 %) and urinary tract infections (19 %). Importantly, among urinary tract infections 19/22 (86 %) were related to the presence of a Foley catheter. Finally, among the 283 episodes of primary bloodstream infection, at least 49 (17 %) were related to a documented infection at the skin insertion site of an intravenous or arterial line.

Factors Associated with Mortality. Among the 364 patients who acquired a nosocomial bloodstream infection within the study period, 121 (33 %) died. Importantly, the overall hospital mortality at the UIHC was 2.38 per 100 admissions: 483 patients of the 20,274 admitted. Thus, the crude mortality of nosocomial bloodstream infection accounted for 25 % of the total hospital mortality.

The crude mortality associated with nosocomial bloodstream infection varied with age (Table 2). In this study the odds ratio for dying from the infection was 1.016 (CI95 1.01–1.02) per year of age with the corresponding parameter estimate: 0.01587 ± 0.005. The formula to translate the odds ratio to a definite age is $e^{0.01587 \times age \pm 1.96\,(0.005)}$, with the translation for a 10-year-old vs. a 70-year-old patient as follows: $e^{0.01587 \times 10 \pm 1.96\,(0.005)}$ and $e^{0.01587 \times 70 \pm 1.96\,(0.005)}$, i.e. 1.17 (CI95 1.16–1.18) and 3.03 (CI95 3.00–3.06), respectively. Sex did not affect the prognosis of bloodstream infection. A total of 108 patients had surgery before the episode of bloodstream infection, of whom 28 died (26 %). Surgery before the development of nosocomial bloodstream infection was not associated with an increased risk of death in this study (OR 0.62, CI95 0.37–1.01).

We stratified the patients according to the primary diagnosis to account for the effects of underlying disease in the analysis (Table 2). One-third (31 %) of our population had cancer, with an associated crude mortality in those who acquired a nosocomial bloodstream infection of 40 % (46/114). This rate was different from that of patients without cancer (75/250, 30 %) but did not reach the statistical threshold ($\chi^2 = 3.32$, $p = 0.07$). Importantly, the mortality rates were similar for leukemics and non-leukemics among cancer patients. Eighty-one of 114 cancer patients (71 %) had neutropenia before or at the time bloodstream infection occurred, compared to 13 patients with non-malignant conditions. The mortality rate among neutropenic cancer patients (38 %) was similar to that among non-neutropenic cancer patients (45 %, $p = 0.63$) as well as that among neutropenic (44 %) and non-neutropenic patients without cancer (29 %, $p = 0.45$). Considered separately, the estimated odds ratios for cancer patients and for patients suffering from diseases of the cardiovascular or respiratory system were significantly higher than those of

A53210128

Table 2: Factors associated with the mortality of nosocomial bloodstream infections as determined by univariate analysis.

	Total no. of patients (n = 364)	No. (%) of deaths (n = 121)	Odds ratio	CI95	p value
Age	364	121 (33)	1.016	1.01–1.02	< 0.001
Sex					
Male	195	65 (33)	1.00		
Female	169	56 (33)	0.99	0.64–1.53	0.97
Underlying disease					
Cancer	114	46 (40)	2.31	1.28–4.16	0.005
Leukemia	63	25 (40)			
Non-leukemia	51	21 (41)			
Trauma / burns	30	7 (23)	1.04	0.40–2.71	0.32
Diseases of the cardiovascular and pulmonary systems	67	29 (43)	2.61	1.34–5.06	0.005
Diseases of the gastrointestinal and urogenital systems	47	15 (32)	1.60	0.74–3.44	0.96
Other	106	24 (23)	1.00		
Surgery					
No previous surgery	256	93 (36)	1.00		
Previous surgery	108	28 (26)	0.62	0.37–1.01	0.07
Type of infection					
Primary bloodstream infection	250	69 (28)	1.00		
Secondary bloodstream infection	114	52 (46)	2.20	1.39–3.49	< 0.001
Class of microogranism					
Gram-positive bacteria	214	66 (31)	1.00		
Gram-negative bacteria	122	40 (33)	1.09	0.68–1.76	0.98
Fungi	28	15 (54)	2.59	1.17–5.74	0.019
Type of bacteremia					
Monomicrobial	316	99 (31)	1.00		
Polymicrobial	48	22 (46)	1.85	1.00–3.43	0.049

CI95 = 95 % confidence interval.

patients with other underlying conditions (OR = 2.31 and 2.61, respectively; Table 2).

We reviewed the microbiological variables associated with mortality after nosocomial bloodstream infections. Whereas mortality rates associated with gram-positive and gram-negative bacteremia were similar (31 % and 33 %, respectively), fungemia was associated with a significantly higher mortality (54 %, $\chi^2 = 4.70$, $p = 0.03$). The exposure odds ratio for fungemia was 2.59 (CI95 1.17–5.74, $p < 0.02$). The mortality associated with secondary bloodstream infections (46 %) was significantly higher than that associated with primary infections (28 %, $p < 0.001$). Among the former, bloodstream infections associated with the higher mortality rates were those complicating lower respiratory tract infections (67 %) and gastrointestinal tract infections (73 %). Secondary bacteremia complicating wound infections was associated with a lower mortality rate (15 %).

Thirty-one percent of the patients (99/316) with monomicrobial bloodstream infections died, whereas 46 % of the patients (22/48) with polymicrobial infections died. Thus, the mortality associated with polymicrobial bloodstream infection was significantly higher than that associated with monomicrobial infection (OR = 1.85, CI95 1.00–3.43, $p < 0.05$). Moreover, although not statistically significant, secondary polymicrobial bloodstream infections had a higher mortality (55 %) than primary polymicrobial infections (43 %).

A53210128

Microbiological Factors as Independent Predictors of Mortality. A model predicting mortality from nosocomial bloodstream infection was derived from the multiple logistic regression procedure. This analysis indicated that the best predictor of bloodstream infection mortality in the population studied was a model composed of four of the seven variables entered. Those variables were age ($p = 0.011$), underlying disease, and secondary ($p < 0.001$) and polymicrobial ($p = 0.013$) bloodstream infection. Among underlying diseases, cancer (OR = 2.35, CI95 1.26–4.37, $p = 0.007$) and diseases of the cardiovascular or respiratory system (OR = 2.20, CI95 1.04–4.67, $p = 0.039$) were the two conditions that independently affected the outcome of nosocomial bloodstream infection. The estimated odds ratios for the two microbiological factors that independently predicted mortality were 2.46 (CI95 1.50–4.02) for secondary bloodstream infection and 2.34 (CI95 1.21–4.53) for polymicrobial infection. The class of microorganism causing the infection did not appear as an independent predictor of fatality.

The application of the logistic equation derived from the model in the following example illustrates the importance of the microbiological factors for the outcome of nosocomial bloodstream infection. For example, with our model, the probability of death for a 60-year-old cancer patient with a single organism in a primary bloodstream infection would be 36 % (Pr(death) = log (p/1–p) = -2.1653 + 0.8988(0) + 0.8524(0) + 0.0126(60) + 0.8547(1)). In the event the same individual developed a polymicrobial secondary bloodstream infection, the probability of death would be 77 % (Pr(death) = log (p/1– p) = -2.1653 + 0.8988(1) + 0.8524(1) + 0.0126(60) + 0.8547(1)).

Discussion

In our study population the crude mortality associated with nosocomial bloodstream infection was 33 %, accounting for 25 % of the total hospital mortality. Our data were confirmed with data independently examined over a three-year period (1987–1990) at our institution, during which time nosocomial bloodstream infections accounted for 22 % of the total hospital mortality (D. Pittet et al., 31st ICAAC, Chicago, 1991, Abstract A800). In the present study the crude mortality of bloodstream infection varied with age, underlying disease and microbiological variables. Cancer and diseases of the cardiovascular or respiratory system were the only underlying disease conditions that significantly affected the outcome of nosocomial bloodstream infection. Importantly, both secondary and polymicrobial bloodstream infections proved to be independent predictors of mortality.

Several authors have recently reviewed the topic of polymicrobial bacteremia (6–9, 24, 25). Although comparison across these studies is difficult because of the diversity of methods and definitions used (22), the proportions of polymicrobial bacteremia varied from 6 to 22 %, ranging from 6 to 18 % in the largest series (2, 7, 9, 26). Higher rates have recently been reported in the geriatric population (27, 28) as well as in infants in neonatal intensive care units (25 %) (16). In the present study 58 episodes (14 %) of bloodstream infection were polymicrobial; among them, 45 (78 %) developed in the setting of a primary and 13 (22 %) in the setting of a secondary bloodstream infection.

Both early and more recent series suggested that polymicrobial bacteremia has a higher mortality than monomicrobial bacteremia (7, 10, 11, 26, 29). In the study by Weinstein and colleagues (8, 26), polymicrobial bacteremia was significantly more likely to be hospital-acquired than monomicrobial infection ($p < 0.005$) and was associated with higher mortality (63 % vs. 38 %, $p < 0.05$). Deaths directly related to bloodstream infection were two-fold higher in polymicrobial versus monomicrobial episodes. Polymicrobial bacteremia is a significant problem in patients with malignancies (10, 17, 19, 30, 31) and is associated with higher mortality rates (19, 31). In the study by Whimbey and colleagues (31), the overall mortality of single-organism bacteremia was comparable in non-neutropenic (37 %) and neutropenic (29 %) patients. In contrast, neutropenic patients with polymicrobial bloodstream infection had an extremely high mortality rate (80 %). In the present study mortality was similar in neutropenic and non-neutropenic cancer patients but was significantly higher in patients with polymicrobial (67 %) vs. monomicrobial (33 %, $\chi^2 = 4.64$, $p < 0.05$) bloodstream infections. Noteworthy, neutropenia was not an independent predictor of mortality in the logistic regression analysis, underscoring the role of microbiological factors in the outcome of bloodstream infections.

In a recent analysis of 1,972 positive blood culture episodes over a three-year period (1984–1987) at the Vancouver General Hospital (7), organisms

A53210128

associated with lower mortality (*Escherichia coli*, coagulase-negative staphylococci) in monomicrobial bacteremia were associated with higher mortality in polymicrobial bacteremia, similar to the crude mortality associated with virulent organisms. Overall, polymicrobial sepsis was always associated with higher mortality, even after stratification for the type of microorganism (7). In the present study patients with polymicrobial infections had a two-fold increase in the risk of dying from the infection, independent of their underlying disease or of the class of causal microorganism. Our results extend previous observations by using an appropriate statistical approach that controls for other confounders of mortality from bloodstream infection.

Secondary bacteremia was associated with a higher mortality rate, independently of the class of microorganism involved. Among the three leading sources of infections, infections of the lower respiratory tract and urinary tract were associated with mortality rates as high as 67 and 45 %, respectively, if complicated by secondary bloodstream infection. Krieger and colleagues (32) previously provided direct estimates of the risk for secondary bloodstream infections among patients with nosocomial urinary tract infections; importantly, patients with infections due to *Serratia marcescens* were more likely to develop secondary bacteremia compared to those with infections due to other organisms; the median interval between urinary tract infection and bacteremia was 24 days. Our study did not include a sufficiently large number of secondary infections to allow a valid statistical analysis of the role of each separate source of infection as potential independent predictors of mortality in cases of secondary bloodstream infection. Such an analysis would have required a minimum of 380 episodes of secondary infections.

Several studies have previously suggested that the mortality of secondary bloodstream infection might be higher than that associated with primary infections (7, 15, 26, 27, 33). As recently suggested (7), both the sources of infection and the class of microorganisms causing the infection need to be considered in analyzing the mortality from bacteremia. In the study by Roberts and colleagues (7), striking differences in mortality rates were apparent when the source of secondary bloodstream infection was considered. Pneumonia, gastrointestinal tract and multiple sources of infection were associated with the highest mortality rates, ranging from 43 to 55 %. This study, however, included both community- and hospital-acquired bloodstream infections and did not attempt to control for underlying conditions in the analysis. In the study by Gatell and colleagues (15), bacteremia arising from high-risk sources, defined in their study as intraabdominal, lower respiratory tract or primary bloodstream infection not related to intravenous lines, was shown to predict independently a poor outcome in the logistic procedure performed (OR 2.7). Our findings confirm this observation: patients who developed secondary versus primary bloodstream infections had odds ratio of death of 2.46 after correcting for other microbiological variables.

Secondary bloodstream infections, accounting for one-third of all bloodstream infections, are potentially preventable (12). The proportion of secondary bacteremia varied from 47 to 80 % in three recent studies focused on nosocomial bloodstream infections (15, 27, 33), urinary tract infection being the leading source. Infections related to the use of urinary catheters were not specified but certainly accounted for most of these infections, as reported in our series. Secondary bloodstream infections complicating catheter-related urinary tract infection constitute a target for prevention, and data presented here should prompt infection control practitioners to study ways to improve their management. In the present study the time between the documentation of primary-site infections and secondary bloodstream infection averaged 6.4 days, ranging from two to 42 days. Studies need to readdress the question of the appropriateness of the management of nosocomial infections, particularly those associated with high rates of secondary bloodstream infection. Our results suggest that optimal management of distal sources may constitute an effective way to prevent the development of secondary infections and would thus reduce the cost, morbidity and mortality of nosocomial bloodstream infections. As a result, total hospital mortality would be reduced.

ABSTRACT

The incidence and spectrum of infections in pediatric leukemia patients vary depending on the type of leukemia. AML, which involves intensive chemotherapeutic regimes, leads to profound and prolonged neutropenia, making children more susceptible to infection. The intensity of chemotherapy, the duration of neutropenia, and antimicrobial prophylaxis implementation all affect the risk of life-threatening infections. In AML studies have shown that during intensive treatment, children experience more than one episode of infection, with majority being bacteremias. Viridans group *Streptococci* comprises around 20% of all isolates. Infection related deaths range from 5.4% to 7.3% during chemotherapy being more frequent on intensive phase. Invasive fungal infections (IFI) were highly associated with mortality specially caused by *Aspergillus* spp. In ALL induction and consolidation phases posing a higher risk for infections due to severe neutropenia. Infection related mortality in ALL is 2–4%, and infections are the main cause of treatment related deaths. IFI are significant concern with risk factors including age and treatment intensity. High risk include older children, delayed response during early induction therapy and corticosteroid administration. In summary, while survival rates for childhood leukemia have improved, the risk of infections, particularly bacterial and fungal infections, remains a significant concern, especially during intensive treatment phases. Ongoing research is needed to better understand and manage these infections in pediatric leukemia patients

1. Introduction

Survival rates for childhood leukemias have been on a consistent upward in high-income countries (HICs), trend primarily due advances in cancer treatment, risk assessment, and support care [1,2]. Overall survival rates of approximately 83% to 94% have been achieved for pediatric acute lymphoblastic leukemia (ALL) [3] and 65% to 70% for pediatric acute myeloid leukemia (AML) [4]. It is important to mention that the chance of a cure is lower low-income countries (LICs) probably due to more advanced stage at diagnosis, differences in population biology, higher rates of relapse, abandonment of therapy, and higher rates of death from toxicity [5].

However, the intensification of combination chemotherapy for purposes of eliminating leukemic cell populations leads to substantial immunosuppression increasing the rates of infections complications.

Infections are an important cause of morbidity and mortality for children and adults with hematological malignancies especially acute leukemia. These patients are at particularly high risk of infection, likely related to the intensity of their therapy resulting in repeated episodes of prolonged and profound neutropenia. Infections not only lead to increased mortality but also extend hospital stays, hinder the administration of chemotherapy, impact the quality of life, and raise healthcare resource utilization. The majority of microbiological documented infections in children with hematological malignancies are bacterial, the most frequent being bacteremias. Limited data exists on documented systemic viral infections in children undergoing therapy for acute lymphoblastic leukemia (ALL) or acute myeloid leukemia (AML). Sung et al., in their analysis of 492 children with AML, reported that 7.5% to 8.8% of virus infections were associated with the treatment phase, with a higher prevalence during the consolidation phase. Similar findings were observed in other series. With advancements in diagnostic techniques, there has been an observed increase in viral infections, as demonstrated in a recent study by Zawitkowska, which reported an incidence of 18.4% in patients with ALL. [6–8]. Virus infections can be very serious and can be complicated by secondary bacterial and fungal pathogens.

2. Incidence and spectrum of infections according with hematological malignancy

The occurrence of severe infectious complications in pediatric leukemia patients has been notably linked to the leukemia type, with AML displaying a higher incidence in comparison to ALL [9]. Nevertheless, as advances in treatment, including target therapies, with the aim of enhancing survival rates, it becomes imperative to reevaluated the risk of life-threatening infections. This reassessment should be predicated on several factors, including the intensity of chemotherapy, the duration of neutropenia, corticosteroids use and the implementation of antimicrobial prophylaxis.

a) Acute Myeloid Leukemia (AML):

Despite advances in therapy over the past decades, overall survival for children with acute myeloid leukemia has not exceeded 70%. In relation to the host and the disease, advances in cytogenetics and molecular profiling, as well as improvements in detection of minimal residual disease after induction therapy, have informed risk stratification. The treatment of childhood AML continues to be based primarily on intensive, conventional chemotherapy. However, recent trials focus on limiting treatment-related toxicity through the identification of low-risk subsets who can safely receive fewer cycles of chemotherapy, allocation of hematopoietic stem-cell transplant to only high-risk patients and optimization of infectious and cardioprotective supportive care.

In understanding the impact of different lines of treatment, during the last two decades, the intensification of antileukemic treatment has improved the long-term survival of both children and adults with AML. The cumulative doses of cytarabine were successively increased, and more effective anthracyclines such as idarubicin were given in the Acute Myeloid Leukemia-Berlin-Frankfurt-Muenster (AML-BFM) clinical trials. In this retrospective analysis the AML-BFM protocols between 1987 and 2012, the contribution of intensified first-line treatment, supportive care and salvage therapy were fundamental to this success. The BFM group used cranial radiotherapy until 2009 and maintenance therapy until the BFM 2012 protocol, obtaining results comparable to the groups that did not use these two components of therapy [10,11].

Therapy for AML targets the myeloid cell lineage, producing profound and prolonged neutropenia and it is therefore one of the most intensive chemotherapeutic regimens used in pediatric oncology. Consequently, many children experience one or more infectious complications during AML treatment [7,12].

The incidence and severity of infections are contingent upon the treatment protocol employed and the specific phase of treatment. Studies have been conducted with the objective of establishing the incidence and the risk of infection, subsequently informing more effective management strategies.

There was a significantly reduced infectious related mortality in AML-BFM 04 compared to historic data of the AML-BFM 93 e 98 studies, especially in the first 42 days (early deaths group) or after achieving clinical remission (CR).

On BFM-93, 295 episodes of infection were documented among 285 children receiving first induction therapy and 85/285 (29%) experienced a microbiologically documented infection, Viridans group *Streptococci* (VGS) comprised 56/252 (22%) of all isolates [13].

Lately in a multi-institutional clinical trial AML-BFM 2004, study by Bochennek et al., 405 patients experienced 1326 episodes of suspected or confirmed infection during intensive treatment, averaging 3.3 infectious complications per patient. These infections included fever of unknow origin (56.1%), clinically and microbiologically documented infections (17.5% and 32.4%, respectively). Among microbiologically documented infections 71.6% were bacteremia, with Viridans group *Streptococci* (VGS) responsible for over 30% of these cases. Invasive fungal infections occurred in just 3% of cases, and 1.5% of patients died due to infections, mainly from Gram negative pathogens or invasive aspergillosis [6].

The incidence of infectious complications was slightly higher compared to a previous study (AML-BFM 93). However, infection-related mortality was significantly lower (1.5% versus 5.4%) [6].

Reducing infectious-related mortality, particularly in non-responsive patients, enables the consideration of second-line therapy. This means that severely ill patients are now eligible for hematopoietic stem cell transplantation (HSCT), thereby enhancing the overall outcomes for these individuals [11].

Prospective trials of transplantation in children with AML suggest that overall, 60% to 70% of children with HLA-matched donors available who undergo allogeneic HSCT during their first remission experience long-term remissions with the caveat that outcome after allogeneic HSCT is dependent on risk-classification status [14].

The better supportive care contributed to reduce the early death rate and partly infectious-related deaths. These findings have important implications for the future, because intensification of anthracycline- and cytarabine-based chemotherapy will most likely not result in a major reduction of relapse or nonresponse. Although standard treatment of AML usually includes high-dose induction therapy, recent genomic studies have shown that applying regimens with reduced-intensity inductions can achieve long-term remissions with less treatment-related toxicity. Thus, the strategy of administering a minimally myelosuppressive regimen for the first induction remission and risk-adapted therapy for subsequent courses has, as its main objective, to avoid treatment-related early mortality [15].

On CCG 2961 protocol, 297/492 (60%) children experienced at least one microbiologically documented infection during induction (phase 1); 300/407 (74%) on phase 2 and 176/248 (71%) on phase 3. In induction, 191/297 (64%) of microbiologically documented infection were Gram positive organism, with 91/ 191 (18%) being Coagulase negative Staphylococci and 51/297 (17%) due to VGS. The rate of VGS bacteremia was higher in the fludarabine based regimen compared with idaDCTER (idarubicin, daunomycin, cytarabine, thioguanine, etoposide, and dexamethasone) [7]. On 2009, 872 children with AML on CCG 2891 protocol were evaluated. Of these 872 patients, 678 were randomized to intensive versus standard timing induction and 452 were allocated or randomized to chemotherapy, autologous SCT or allogeneic SCT in Phase 2. The results were similar with more infections on intensive phase of treatment and a significance increase in VGS infections associated with intensive timing induction [16]. It is noteworthy in both studies with large number of patients that the prevalence of infection varies depending on type of treatment with high risk of infections consisting in intensive time induction. (Table 1).

Gram negative infections were less common, the two most common Gram negative bacteria on both BFM-93 and CCG 2961 were *Escherichia coli* and *Pseudomonas aeruginosa*. In AML BFM 2004 *E. coli* and *Klebsiella pneumoniae* were more prevalent, while *Pseudomonas aeruginosa* ranked as the third most common agent. This suggest that maintaining anti-pseudomonal coverage remains a vital element of empirical antibacterial therapy in this population [6,12,16].

AML BFM 2004 Gram-negative pathogens were significantly more often isolated in consolidation and intensification as compared with induction [6].

It is crucial to highlight the observed disparity in the incidence of fungal infections between two studies using the AML-BFM 93 protocol and CCG 2961 protocol 3% vs 21% (Sung 2007 and Bochennek 2016). This difference could be attributed, at least partially, to the administration of antifungal prophylaxis in 47% of the chemotherapy cycles on Bochenneck study. This prophylaxis primarily involved the use of antifungal agents with activity against molds, such as amphotericin B, voriconazole, or posaconazole [6,17].

Polymicrobial invasive infections in pediatric AML are more related to infection-related mortality than that caused by a single pathogen [7].

Sung et al. in 2012 conducted a systematic assessment of the severity of infections in AML, aiming to identify organisms deemed life-

threatening or fatal. They explored whether the intensity of induction or the type of intensification therapy influenced the proportion of such infections. The study revealed a significant increase in life-threatening or fatal infections during intensive timing (60.3%) compared to standard timing (37.3%) in phase 1 induction ($p < 0.0001$). Infections caused by Gram-positive bacteria, Gram-negative bacteria, and fungi were more likely to be classified as life-threatening or fatal during intensive timing. Specifically, infections caused by VGS, Pseudomonas spp, and Escherichia coli had a higher likelihood of being life-threatening or fatal during intensive timing. Molds were considered life-threatening or fatal irrespective of whether they occurred during standard or intensive timing induction [18].

In an attempt to reduce infections rates and, consequently, decrease morbidity and mortality in these children, several authors have sought to demonstrate the effectiveness of antibiotic prophylaxis. However, further studies are necessary to estabilish the true benefits. Long-term monitoring is essencial to assess the emergence of multiresistant pathogens, *Clostridioides difficile* infection, invasive fungal infection and impact on children's [19,20].

Castagnola E, 2010, performed a retrospective, multi-center study on the epidemiology of bacteremias and invasive fungal infections (IFI) in 240 children with AML and showed that more than half of them developed at least one episode of severe infection. Bacteremias were significantly more frequent than IFI. The epidemiology of IFI alone was influenced by the status (first diagnosis or relapse) of AML, and cumulative risk of the IFI were significantly higher during treatment for relapsing AML [21].

Invasive fungal infections (IFI) were highly associated with mortality specially caused by *Aspergillus* spp [7,16]. The true incidence of IFI in AML children is probably underestimated once the diagnostic is difficult to be made the majority of studies were done in adult populations [22].

A recent publication evaluated a total of 298 episodes of febrile

neutropenia in 78 patients with AML revealing IFI rates of 3% for proven, 2.6% for probable and 9.4% for possible. Aspergillosis accounted for the majority of IFI cases. Importantly patients with relapsed AML had higher risk of developing IFI and in multivariate analysis it was the most substantial risk factor associated to mortality. This highlights the crucial role of fungal infections in AML and underscores the potential benefits of antifungal prophylaxis in mitigating their occurrence [23].

Infectious deaths are relatively common in this population, with an infection-related mortality rate between 5.4% and 7.3% during chemotherapy [12].

There are limited studies assessing the infection rate in children with AML in Latin America. A recent study conducted in Mexico evaluated the incidence of IFIs in children with ANL and demonstrated a high IFI incidence compared with literature (11.6% vs 8.2%) [24,25].

It is of utmost importance to understand the local epidemiology and further studies on IFIs in this population are necessary.

In Brazil, whose data are still under analysis, there is an open prospective study, by the Childhood Acute Myeloid Leukemia Study Group – LMA Protocol 2021, with the proposal of two induction cycles with low doses of citrarabine, with lower toxicity and expectation of complete remission without loss of dose intensity by reducing the incidence of severe infections at diagnosis.

b) **Acute Lymphoid Leukemia (ALL):**

Acute lymphoblastic leukemia (ALL) occurs ~5 times more frequently than acute myeloid leukemia (AML), accounting for 75% of all childhood leukemia. [26]

The treatment related mortality in currently published studies is 2-4% mainly due to infections. [3,27]

The risk for infections varies by phase of ALL therapy during induction, and consolidation phases, the duration and depth of neutropenia are more severe than in maintenance. During the first two phases, patients are usually hospitalized, and bacterial and fungal infections are more frequent, often originating from the patients' own flora or nosocomial settings. The incorporation of genomic and molecular data in pediatric ALL will allow for additional refinements in risk stratification to enable the tailoring of treatment intensity. These data will also dictate the incorporation of target therapies into frontline treatment, as immunotherapies, in the hope of improving survival while decreasing treatment-related toxicity.

Medical Research Council (MRC) Working Party on Leukemia in Children UK National Acute Lymphoblastic Leukemia (ALL) Trial, UKALL2003, the 5-year cumulative incidence of infection-related mortality was 2.4% and accounted for 30% of all deaths and 64% of treatment-related deaths. [26]

A retrospective multicenter study in Poland analyzed 1363 patients with ALL treated under the ALL IC-BFM 2002 and 2009 protocols. The incidence of microbiologically documented infections was 53% (726/1363), with 36.4% (497/1363) being bacterial infections, predominantly Gram-positive (57.5%, 298/497). Fungal infections comprised 406 episodes (probable 42; proven 28; possible 337), ranging from 1 to 7 per person. In terms of patients, fungal infections were observed in 20% (278/1363) of the children. Among the 726 patients with documented infections, twenty children (2.75%) died due to sepsis, and eight children (2.9%) died due to fungal infections. [8]

Other study performed by Christensen et al. analyzed 1652 children with ALL who were treated according to the NOPHO-ALL92 protocol between 1991 and 2001. Out of 1652 patients, 56/1652 (3.4%) died due to complications of therapy, being 68% (38/56) caused by infections. [28]

The largest cohort of pediatric ALL related sepsis deaths was documented in a 2016 study involving 3126 patients from MRC UKALL 2003 trial. Out of a total of 249 deaths, sepsis emerged as the leading cause of treatment related mortality (TRM), accounting for 75 deaths, or 2.4% of all trial patients. Sepsis was prominently observed in both the induction and post-induction phases, with 48% of infection related deaths occurring during induction, 9.3% during consolidation; 22.6% during delayed intensification and 20% during maintenance. Notably an identifiable pathogen was found in 75% of infection related mortality (IRM) with bacterial infections (68%) being the most common, followed by fungal (20%) and viral (12%) infections. The 5-year cumulative incidence of IRM on UKALL 2003 (2.4%) was comparable to other trials in which IRM has been reported (1.7–2.3%) [26]

It is noteworthy to mention that while infections can occur at any point during the treatment for ALL, the risk is higher during the induction chemotherapy, particularly before achievement remission. This elevated risk is thought to be associated with the use of central venous catheters, mucositis, neutropenia and immunodeficiency induced by chemotherapy specially use of corticosteroids and bone marrow disease.

In Latin America, a recent retrospective cohort study was conducted, involving 259 children and adolescents diagnosed with ALL and treated with the Brazilian Cooperative Group of Treatment of Lymphoblastic Leukemia in Childhood -GBTLI–LLA 2009 protocol. Blood stream infection (BSI) were documented in 19.3% (50/259) of the patients, with the isolated microorganisms comprising 39 Gram negative bacteria (*Pseudomonas aeruginosa* and *Escherichia coli* more prevalent), 21 Gram positive bacteria and four fungi. Among the isolated microorganisms, there was resistance in 17/64 of cases (26.5%). [29]

To mitigate the incidence of bacterial infections in this population, a potential strategy involving antibacterial prophylaxis has been emerging. However, this approach encounters limitations due to concerns about antibiotic resistance. Data on this practice in children are scarce, with few observational studies and two published randomized trials in children with ALL. Wolf et al.'s study (2017) evaluated 344 newly diagnosed ALL patients, comparing infection-related outcomes with no prophylaxis, levofloxacin prophylaxis, or other prophylaxis during induction therapy in the XVI study. Levofloxacin prophylaxis reduced infections but also lowered exposure to cephalosporins, aminoglycosides, and vancomycin, thereby decreasing the odds of *C. difficile* infection by over 95%. No increase in antibiotic-resistant organism infections was observed. Similarly, in Brazil, Dufrayer et al. (20 patients) demonstrated that its use did not elevate cephalosporin enterobacteriacae colonization rates or lead to *C. difficile*-associated diarrhea [19,30]. More studies are necessary to do any recommendation

Invasive fungal diseases need to be highlighted as a significant cause of infection in this group.

The risk of IFD can be influenced by various factors, including age and treatment intensity. An extensive analysis was conducted involving 6136 patients enrolled in the AIEOP-BFM ALL 2009 Phase III clinical trial. Among the 419 reported serious adverse events related to IFI, the incidence of proven/probable IFI was 3.8%. Through logistic regression, it was determined that children aged 12 years or older and those with more than 10% bone marrow blasts on day 15 were at significantly higher risk for IFD (both $p < 0.0001$). [31]

It is well reported that higher treatment intensity increases IFD risk, but notably in this study insufficient treatment response during induction therapy emerged as an independent risk factor for IFD, and corticosteroid administration during the first 6 weeks of treatment, impacting neutrophils and macrophages, should be considered. [31]

All these factors emphasize the need for a reassessment of the infection risk in ALL, and, in certain cases, the consideration of prophylactic measures, including those against bacterial and fungal infections. [19,20,25]

Risk-based treatment assignment is a key therapeutic strategy utilized for children with ALL, and protocols are designed for specific patient populations that have varying degrees of risk of treatment

failure. This approach allows children who historically have a very good outcome to be treated with less intensive therapy and to be spared more toxic treatments, while allowing children with a historically lower probability of long-term survival to receive more intensive therapy that may increase their chance of cure. The use of bortezomib was based on compelling biologic rationale, strong preclinical data, and encouraging safety and efficacy in relapsed T-ALL/T-LL in COG AALL07P1. [32]

The advent of effective immunotherapy is now changing therapeutic paradigms, providing options for patients in whom cytotoxic chemotherapy has proven ineffective or intolerable. Immunotherapies can be exquisitely target-specific, conferring more limited toxicity to normal tissues than traditional chemotherapy. Blinatumomab is a bispecific monoclonal antibody with one site for CD3 (T cells) and the other site for CD19 (present on most B-ALL cells). Thus, blinatumomab promotes the binding of the patient's own cytotoxic T cells to B lymphoblast. After initial reinduction chemotherapy, the use of blinatumomab instead of intensive cytotoxic chemotherapy as pre-HSCT consolidation has been shown to be associated with superior outcomes. [33]

c) **Down Syndrome and Leukemia**

Children with Down syndrome (DS) constitute a distinct genetic population who has a greater risk of developing acute lymphoblastic leukemia (ALL) and acute myeloid leukemia (AML) compared to their non-Down syndrome counterparts. In addition to a higher risk of relapse, patients with DS have been shown to have an increased risk of treatment-related mortality with traditional induction and consolidation chemotherapy, such that they have here to fore often been excluded from clinical trials in ALL or have received adapted treatment elements with reduced intensity Approximately 2% to 3% of childhood ALL cases occur in children with Down syndrome. ALL in pediatric patients with Down syndrome is characterized by a lower incidence of both favorable (e.g., ETV6::RUNX1 and high hyperdiploidy with favorable trisomies) and unfavorable (e.g., BCR::ABL1, KMT2A rearrangements, low hypodiploidy, t(9;22)(q34;q11.2) or t(4;11)(q21;q23)) biology and a near absence of T-cell phenotype [34].

Patients with Down syndrome have an increased risk of developing toxicities from treatment, including infections, mucositis, and seizures. In some studies, outcomes of children with Down syndrome and ALL and AML [35].

Because of the well-established increase in toxicity experienced by patients with Down syndrome, some ALL protocols (such as those of the COG) have de-intensified risk-based treatment for patients with Down syndrome and ALL to minimize exposure to the morbid components of therapy. While this treatment reduction strategy reduces the frequency and severity of toxicities, its impact on antileukemic outcomes is not yet known [35].

3. Prophylaxis in patients with Acute Leukemia (AML and ALL)

3.1. Bacterial prophylaxis

Antibiotic prophylaxis consists in an important strategy in reducing bacterial infections and associated complications in pediatric patients with acute leukemia (AL) [20,36]. Quinolones, notably due to their efficacy in adults, have been widely used in this group. However, concerns exist regarding their true efficacy, toxicity, and the emergence of antibiotic-resistant strains. The recommendation for pediatric use is based on limited evidence, emphasizing the need for a careful risk-benefit assessment [20]. A comprehensive 2022 meta-analysis encompassing diverse risk classes, chemotherapy protocols, and leukemia phases suggests that quinolone prophylaxis effectively reduces bloodstream infections (BSIs) and may decrease febrile episodes in AL settings. However, conclusive evidence on mortality impact is lacking, warranting further research [37].

While quinolone prophylaxis may contribute to reduced hospitalization and healthcare costs, its role in preventing *Clostridium difficile* infections and antibiotic exposure remains inconclusive [30,36,38]. Discrepancies in study findings suggest a potentially nonsignificant role for quinolones in these aspects, underscoring the need for validation in larger cohorts. The prophylaxis's positive impact on febrile episodes may enhance patient quality of life by shortening hospital stays, potentially contributing to cost-effectiveness.

A noteworthy consideration is the potential impact of quinolones on gut microbiota. Margolis et al.'s study highlights resistome modifications, indicating that levofloxacin (LVX) may elevate the risk of colonization with resistant bacteria. However, recent evidence also emphasizes the detrimental role of antibiotic-mediated dysbiosis, emphasizing the need for a nuanced understanding of these dynamics in future research [39].

The ECIL-8 (European Conference on Infectious in Leukemia) group does not recommend routine antibacterial prophylaxis for paediatric patients with AL (recommendation 1; grade D, level of evidence III) [40].

3.2. Fungal prophylaxis

Systemic antifungal prophylaxis is a vital strategy in the reduction of invasive fungal disease (IFD). An array of pediatric studies, encompassing both retrospective and prospective analyses, has delved into the efficacy of various mold-active and mold-nonactive agents. In a pivotal multicenter randomized trial involving 517 AML patients, caspofungin exhibited a noteworthy reduction in the incidence of proven or probable IFD in comparison to fluconazole (3.1% vs. 7.2%; HR 0.37 [95% CI 0.15–0.94]; p = 0.03). and proven or probable invasive aspergillosis (0·5% vs 3·1%, HR 0·16 [95% CI 0·02–1·27]; p = 0·046) There were 23 proven or probable invasive fungal disease events (6 caspofungin vs 17 fluconazole) included 14 molds, 7 yeasts, and 2 fungi not further categorized. It is crucial to note that this study's interpretation is constrained by premature termination arising from an unplanned interim analysis, precluding observations on overall survival impact [41].

Paediatric guidelines strongly recommend primary antifungal prophylaxis in patients who are at high risk of developing invasive fungal diseases to reduce disease related morbidity and mortality (invasive fungal diseases with an incidence of ≥10% are usually considered of high risk) Patients receiving intensive chemotherapy for acute myeloid leukaemia, highrisk acute lymphoblastic leukaemia, and recurrent acute leukaemia, especially during prolonged courses of glucocorticosteroids or phases of long lasting and profound granulocytopenia are in this group A strong recommendation was made in this guideline to administer a mould active agent with an echinocandin or a mould active azole when systemic antifungal prophylaxis is warranted [40,42,43].

4. Conclusion

AML and ALL present varying infections risks. AML's intensive chemotherapy leads to prolonged neutropenia, making patients more susceptible to infections. Recent studies have highlighted the importance of antimicrobial prophylaxis and tailored treatments in managing AML related infections. Similary ALL patients, particularly during induction and consolidation phase, face a significant infection risk with mortality rate of 2–4%. IFI are a major concern influenced by factors like age, treatment intensity, responses to induction therapy and corticosteroids administration. Further research is necessary to understand the full scope of the problem and develop strategies for reducing infection-related morbidity and mortality in young leukemia patients. Despite progress in childhood leukemia treatment, addressing infection challenges remains a crucial area for ongoing study and improvement.

Looking ahead 5 to 10 years, advancements in leukemia research and treatment are expected to bring transformative changes to infection management. The new monoclonal and bispecific antibodies and CAR-T,

besides offering new perspectives in the overall survival and disease-free survival of patients, may also transform the epidemiology of infections in ALL by improving the toxicity of treatments. On the other hand development on the tools for early diagnose and target therapy will lead to a significant reduction in infection-related mortality rates.

ANALYSIS

Systematic analysis of infectious disease outcomes by age shows lowest severity in school-age children

Judith R. Glynn[1]✉ & Paul A. H Moss[2]

The COVID-19 pandemic has ignited interest in age-specific manifestations of infection but surprisingly little is known about relative severity of infectious disease between the extremes of age. In a systematic analysis we identified 142 datasets with information on severity of disease by age for 32 different infectious diseases, 19 viral and 13 bacterial. For almost all infections, school-age children have the least severe disease, and severity starts to rise long before old age. Indeed, for many infections even young adults have more severe disease than children, and dengue was the only infection that was most severe in school-age children. Together with data on vaccine response in children and young adults, the findings suggest peak immune function is reached around 5–14 years of age. Relative immune senescence may begin much earlier than assumed, before accelerating in older age groups. This has major implications for understanding resilience to infection, optimal vaccine scheduling, and appropriate health protection policies across the life course.

Introduction

A striking feature of the COVID-19 pandemic is that disease and death are both much less common in children than in adults[1]. This unexplained phenomenon has renewed interest in age patterns of disease. Before COVID-19, most contemporary discussion focussed on vulnerabilities at the extremes of age, due to the immature immune system in infants, and immune deterioration or 'immunosenescence' in the elderly[2]. There has been little investigation of the comparative response to infection in between theses extremes: indeed, it is generally assumed that the response is broadly constant over this period and that immune function remains stable until around 60 years of age[2].

Infections which have been noted to increase in severity in young adults, such as Spanish influenza and tuberculosis, are typically discussed as outliers, and explanations sought. However the medical literature a century ago noted that the case fatality rate (deaths/cases) by age is J-shaped for a number of infections, with a 'honeymoon period' in school-age children and rising fatality throughout adulthood[3,4]. This pattern, which has never been systematically examined, appears to have been largely forgotten, and the explanation for it is unknown.

We present a systematic analysis of severity of infectious disease by age, concentrating on the age at which severity starts to rise after childhood. We investigated case fatality rates and other measures of severity for a wide range of viral and bacterial infections. We are interested in the effect of age on the outcome of infection, so do not include population mortality rates, as they would be influenced by different exposures to infection by age. For infections for which there are effective treatments or vaccines, older studies were sought, as the interest is in the natural host response. We have included all studies identified by our search that fit our inclusion criteria.

We find that for almost all infections, school-age children have the lowest severity, severity starts to rise well before old age, and for many infections, severity is already higher in young adults than in children.

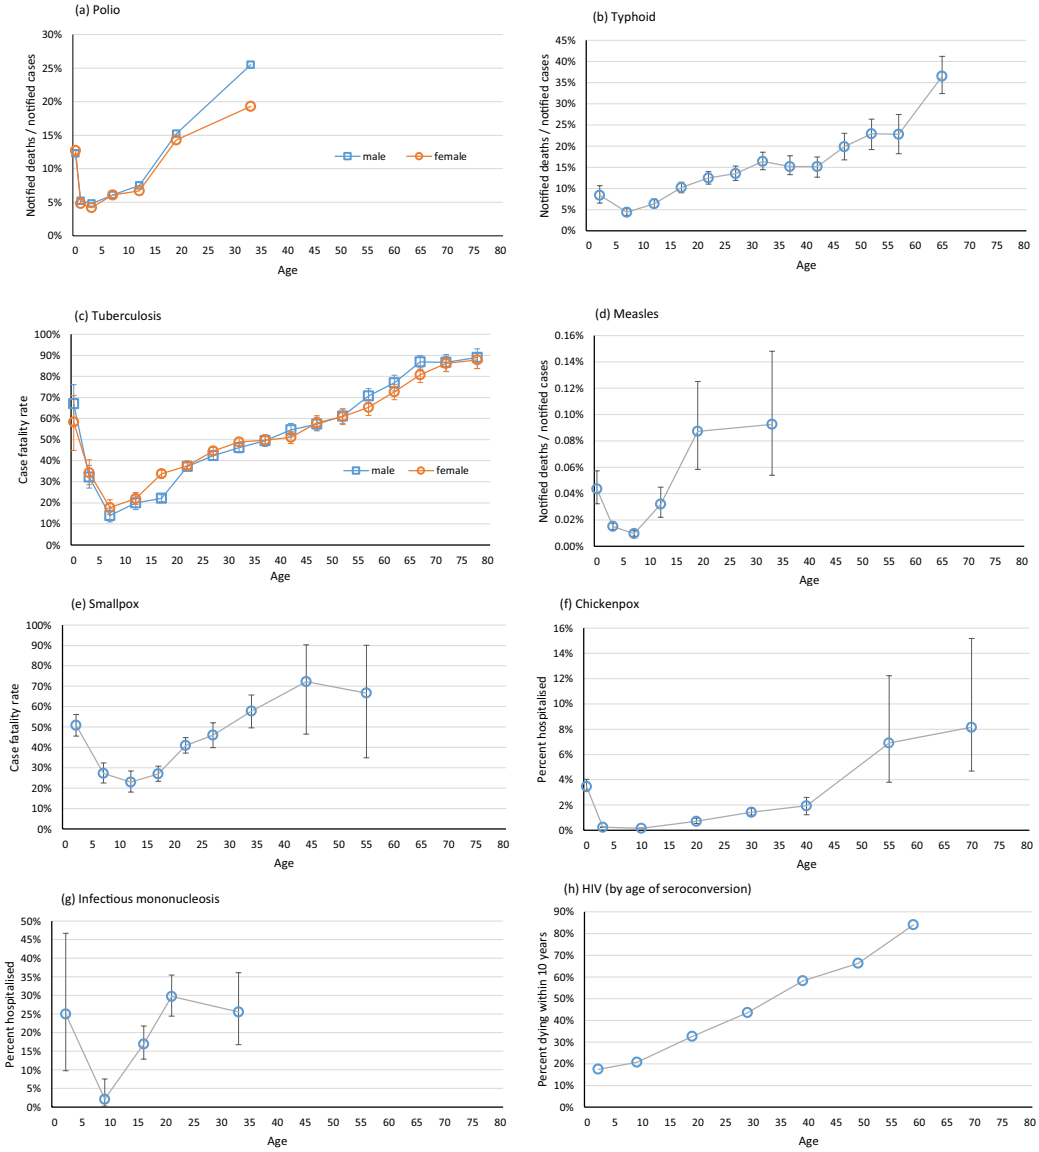

Fig. 1 Severity of infectious disease by age for polio, typhoid, tuberculosis, smallpox, chickenpox, measles, infectious mononucleosis and HIV. The 95% confidence intervals on the estimates are shown where they are known or could be calculated. (**a**) Polio in England and Wales 1947–50, notified deaths/notified cases (23,143 cases)[12]; (**b**) Typhoid in small towns in New York State, US, 1915–24, notified deaths/notified cases[13]; (**c**) Pulmonary TB in Denmark, 1925–34, percent of notified cases dying by 31st December 1934[21]; (**d**) Measles in England and Wales, 1970–88, notified deaths/notified cases[29]; (**e**) Smallpox in London Smallpox Hospital, UK, 1836–51, case fatality rate among unvaccinated patients[35]; (**f**) Chickenpox in France 1997–9, estimated hospitalisation rates based on national databases and surveillance[40]; (**g**) Infectious mononucleosis in Rochester, Minnesota, US, 1950–69, percent hospitalised[43]; (**h**) HIV in Europe, North America and Australia, 1983–1996, percent dying within 10 years, mother-to-child infections excluded (12,910 cases, survival estimated from graph)[44].

Results

Information on at least one measure of severity in at least one study was found for 32 infections. Severity is measured as case fatality rate, or the proportion of cases with severe disease (e.g. the proportion hospitalised), or as the proportion with symptomatic disease among those with infection or known exposure. For ease of comparison, a figure from the largest dataset for each infection is presented in Figs. 1–4. Details of all identified studies for each infection are given in the Supplementary Material[1,5–143], together with figures, including the number of cases in each age group, where known, and 95% confidence intervals where these could be calculated. Results are shown separately by sex when this was available and the sample size was sufficient.

For most infections clinical severity is relatively high in infancy, drops in early childhood and rises in adulthood and more steeply into old age. Figures 1–4, Supplementary Figures S1–32 and online-only Table 1 are arranged in order of the age at which the severity starts to rise.

A53210128

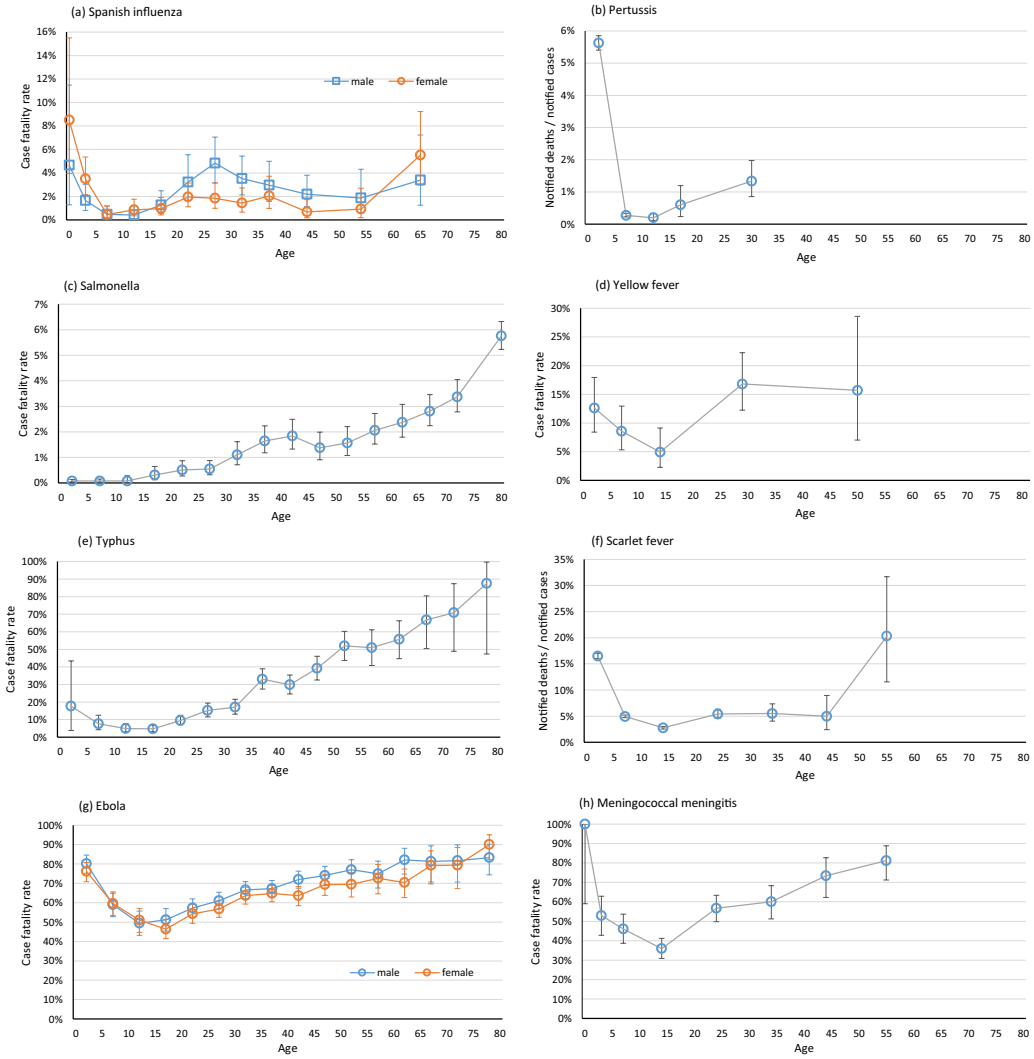

Fig. 2 Severity of infectious disease by age for influenza, pertussis, Salmonellosis, yellow fever, typhus, scarlet fever, Ebola, and Meningococcal meningitis. The 95% confidence intervals on the estimates are shown where they are known or could be calculated. (**a**) Influenza in Maryland, US, 1918–19, case fatality rate from household surveys[47]; (**b**) Pertussis in small towns in New York State, US, 1915–24, notified deaths/notified cases[13]; (**c**) Salmonellosis in Spain 1997–2006, case fatality rate among hospitalised patients (numbers estimated from graph and population data)[55]; (**d**) Yellow fever in New Orleans, US, 1878, case fatality rate[63]; (**e**) Typhus in London Fever Hospital 1848–57, case fatality rate[15]; (**f**) Scarlet fever in Pennsylvania, US, 1907–12, notified deaths/notified cases[9]; (**g**) Ebola in Guinea, Liberia and Sierra Leone, 2013–15. case fatality rate[66]; (**h**) Meningococcal meningitis in Cyprus, 1908–9, case fatality rate[70].

For many infections the rise in severity is apparent by age 20 years. For polio, typhoid, tuberculosis and measles (Fig. 1a–d, Supplementary Figures S1–4) some datasets suggest that the case fatality rate is already higher by age 10–14 years than in younger children[9,11–13,21,29]. A rise in severity by age 15–19 or 15–24 years is seen clearly in large datasets for case fatality rates for smallpox[35], HIV[44], Spanish influenza[47,48], pertussis[13], and Salmonella[55], for hospitalisation rates for chickenpox[40], and in smaller datasets for hospitalisation for infectious mononucleosis[43], and case fatality rate for Yellow fever[63] (Figs. 1d–h, 2a–d, Supplementary Figures S5–12).

A slightly later rise, from around 20 years, is seen for case fatality rates for typhus[15], scarlet fever[9], Ebola[66], meningococcal meningitis[70], and Japanese encephalitis[73] (Figs. 2e–h, 3a, Supplementary Figures S13–17). For cholera, case fatality rates were lowest around 10-24 years in a number of datasets (Supplementary Figure S18)[75,76], but mortality rates in the large 19th century waterborne outbreaks, in which all age groups would have been exposed, were lowest at 5-14 years[88,89]. For Lassa fever, case fatality rates in Nigeria[91,92] increased with age from 20–30 years but no particular pattern with age was seen in Sierra Leone (Supplementary Figure S19)[93,94].

For most of the remaining infections for which information was available, the severity rises with age from 30 years (seasonal influenza[48], brucellosis[96], plague[102], probably hepatitis B acute infection[99], Fig. 3d–f, Supplementary Figures S9c, S20–22), 40 years (Hepatitis A[111], SARS[114], COVID-19[117], MERS-CoV[124,125], St Louis encephalitis[126], Figs. 3g,h 4a–c, Supplementary Figures S23–27) or 50 years (Campylobacter[57], Western equine encephalitis[134], Fig. 4c,d Supplementary Figures S28, 29).

A53210128

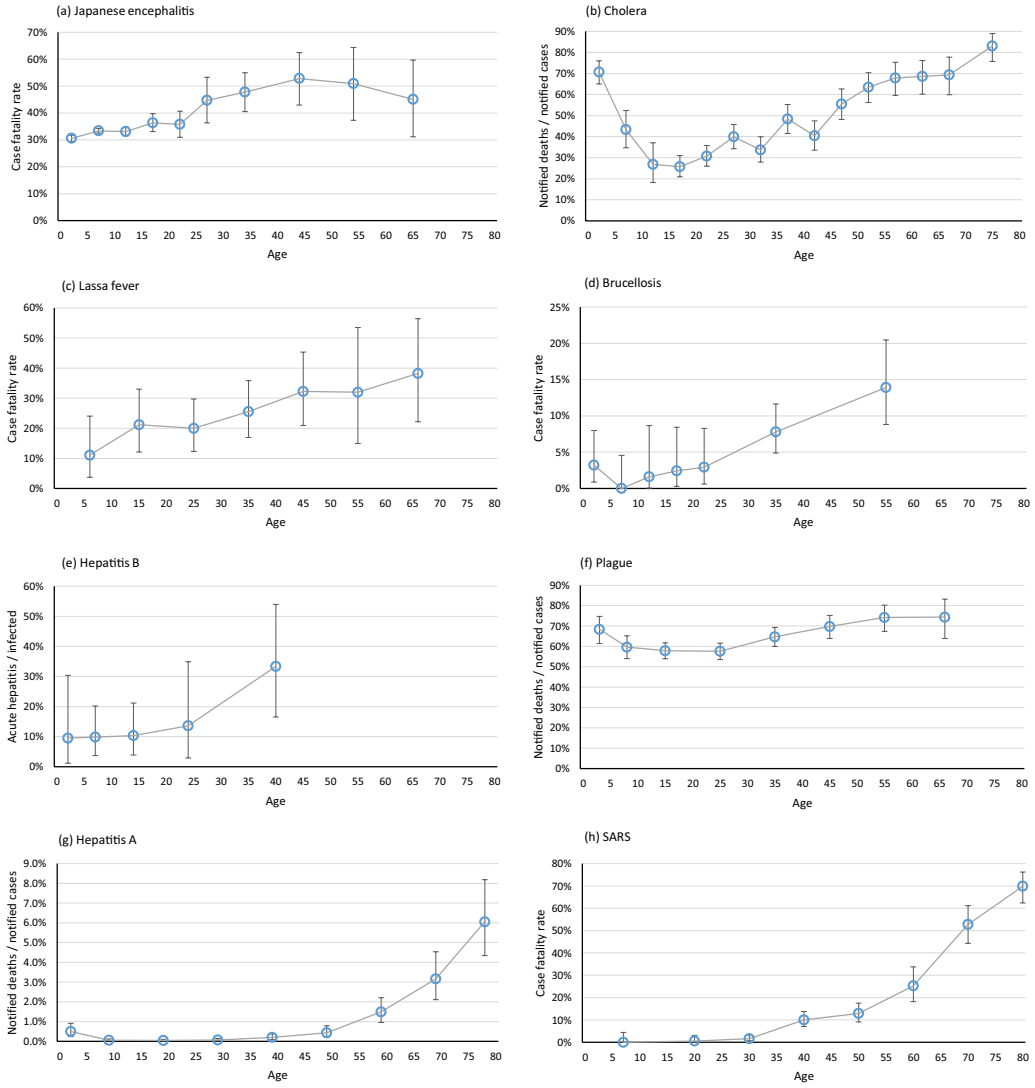

Fig. 3 Severity of infectious disease by age for Japanese encephalitis, cholera, Lassa fever, brucellosis, hepatitis B, plague, hepatitis A, and SARS The 95% confidence intervals on the estimates are shown where they are known or could be calculated. (**a**) Japanese encephalitis in Korea, 1955–66, notified deaths/notified cases[73]; (**b**) Cholera in Munich, Germany, 1873–4, notified deaths/notified cases[76]; (**c**) Lassa fever in Nigeria, 2018, case fatality rate in laboratory confirmed cases[91]; (**d**) Brucellosis in Malta, 1936, case fatality rate[96]; (**e**) Hepatitis B in Alaska, 1971–6, proportion of new infections with symptomatic hepatitis[99]; (**f**) Plague in 75 villages in Jalandhar District, India, 1897–8, notified deaths/notified cases[102]; (**g**) Hepatitis A in England and Wales, 1979–85, notified deaths/notified cases[111]; (**h**) SARS in Hong Kong, 2003, case fatality rate (numbers estimated from incidence and population data)[114].

Three infections show different patterns, with greater severity in children than in young adults. The case fatality rate from diphtheria drops steeply with age in childhood, and continues to fall during adolescence, so the lowest case fatality rate is in the 20 s and 30 s, before rising from age 40 years (Fig. 4f, Supplementary Figure S30)[9,135]. The proportion of people with Shiga-toxin producing *E coli* who develop the haemolytic uraemic syndrome follows a similar pattern, with a drop during childhood, and the lowest proportion in the 40 s and 50 s before rising from age 60 years (Fig. 4g, Supplementary Figure S31)[138,139]. For Dengue the proportion with more severe disease (measured as the proportion with haemorrhagic or any complications or the proportion hospitalised) is greatest in school-age children, dropping to a nadir in the 20–30 s before rising again (Fig. 4h, Supplementary Figure S32)[142].

Discussion

Our findings show that the severity of most infectious diseases is at its lowest in school-age children. Strikingly, the severity was higher among young adults than among school-age children for polio[12], typhoid[13–15], tuberculosis[21,22], measles[29], smallpox[34,35], chickenpox[40,41], infectious mononucleosis[43], HIV[44], influenza[47,48], pertussis[13], Salmonella[55], Yellow fever[62,63], typhus[15], scarlet fever[9,65], Ebola[144], meningococcal meningitis[70], Japanese

A53210128

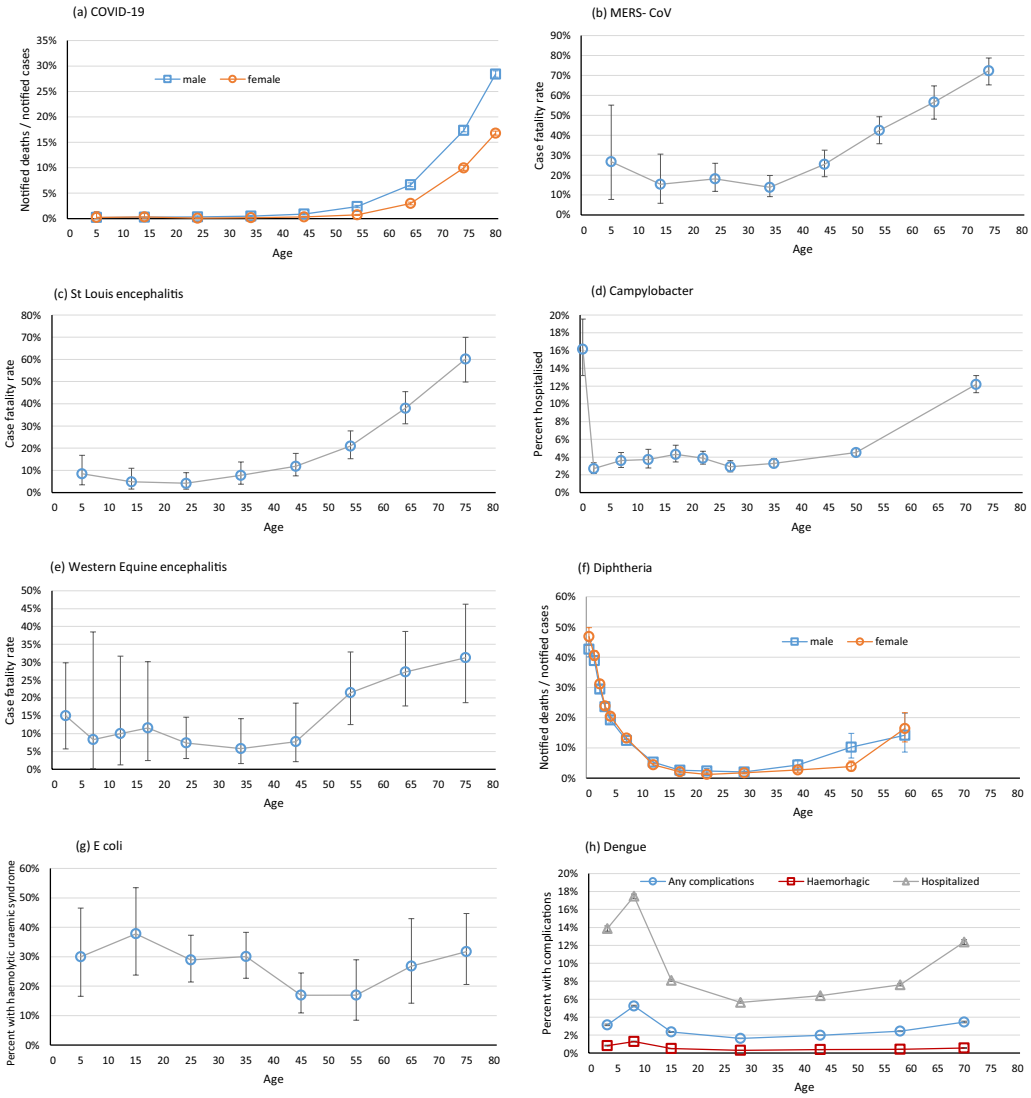

Fig. 4 Severity of infectious disease by age for COVID-19, MERS-CoV, St Louis encephalitis, Western equine encephalitis, diphtheria, Escherichia coli, and dengue. The 95% confidence intervals on the estimates are shown where they are known or could be calculated. (**a**) COVID-19 in Spain 2020, notified deaths/notified confirmed cases, as of 11 May 2020[117]; (**b**) MERS-CoV in Saudi Arabia June 2012-July 2014 and 2017–18, case fatality rate[124,125]; (**c**) S Louis encephalitis in St Louis, US, 1933, case fatality rate[126], (**d**) Campylobacter in Canada, 2001–4, percent hospitalised[57]; (**e**) Western equine encephalitis in Mannitoba, Canada, 1941, case fatality rate[134]; (**f**) Diphtheria in London, UK, 1894–1903, notified deaths/notified cases[135]; (**g**) *E coli* 0104/H4 Hamburg, Germany, 2011, proportion developing haemolytic uraemic syndrome[138]; (**h**) Dengue in Brazil 2000–2014, proportion haemorrhagic, with any complications, and hospitalised[142].

encephalitis[73] cholera[76], and perhaps Lassa fever[91]. Some infections show a slower rise of severity with age after childhood (brucellosis[96], plague[102], coronavirus infections[113,115,117,124,125], acute hepatitis B[99] and hepatitis A[111], St Louis encephalitis[126], Campylobacter[57], and Western equine encephalitis[134],) but for most this rise begins well before old age. For Diphtheria[9,135] and Shiga toxin-producing E coli[138,139] severity remains raised in childhood and adolescents compared to young or middle-age adults, and for Dengue[142] the greatest severity is in school-age children.

Since exposure may vary for children and adults we examined case fatality rates and other measures of severity, not mortality rates. Many reports relied on clinical diagnoses or were based on surveillance data or were limited to hospitalised patients, and it is possible that diagnoses, notifications and hospitalisations differ for children and adults. In order to measure outcomes that are unaffected by vaccination or effective treatments, some of the included studies are old. But even some older studies were carefully conducted. House-to-house surveys of smallpox[34] and influenza[47,48] ensured mild cases and all ages are included. Direct estimates of fatalities in well-characterized outbreaks of Yellow fever[62,63], meningococcal meningitis[70], and viral encephalitides[73,126] avoid any strain differences or notification differences by age. Long-term follow-up studies of patients with

tuberculosis[21,22] ensured all deaths are included. For each infection the different datasets tell a consistent story. The general pattern is remarkable, and unlikely to be explained by biases in the data.

A number of factors may explain these observations. The severity of infectious disease depends on the virulence of the infecting organism, the dose or route of infection, and the response of the host. Variation in strain virulence by age is unlikely, and many of the studies reported outbreaks of single strains (e.g. Spanish influenza, Ebola, smallpox, typhoid, cholera). Most infections have a single route or mode of infection, and for HIV the mode of infection does not explain the age pattern[44].

Adolescents and adults may be exposed to higher doses of infectious agents than are younger children, through caring responsibilities or because they eat more. Greater exposure often increases the risk of acquiring an infection, but the relationship with disease severity is less consistent. An association between infecting dose and severity of disease has been suggested for measles[145] and perhaps chickenpox[146,147], and for Salmonella food-poisoning but not typhoid[148–150]. Fatal cases of SARS and MERS had a slightly shorter incubation period, consistent with a higher infectious dose, but this was not found for influenza[151–153], and an association between severity and incubation period could be explained by host susceptibility. For Ebola, infecting dose (as estimated by degree of exposure to people with Ebola virus disease and their bodily fluids) is strongly associated with the risk of disease, but did not influence the case fatality rate[67,69]. Infectious dose cannot explain the continued rise in severity throughout adulthood.

The J-shaped pattern of severity, high in infancy, dropping in early childhood to a minimum around age 10 years, and rising in adolescence and through adulthood, with a steep increment in old age mirrors that seen for all-cause mortality across populations[154,155]. It is also seen for many of the more frequent causes of death including respiratory disease, diarrhoeal disease, and tuberculosis[154], consistent with a changing age-specific host response.

Co-morbidities tend to increase with age but are generally low in young adults. Interestingly, in a large study of trauma in the US, the case fatality rate, adjusted for severity of injury, only rose from age 55 years onwards[156], suggesting that the change in resilience to infection at younger ages is immunological, not dependent only on co-morbidities or physiological changes.

Further support comes from the immunological response to vaccine challenge by age. In clinical trials of human papilloma virus vaccine, the antibody levels to 9 different component vaccine sub-types measured 7 months post-vaccination decreased with each year increase in age from 9–26 years, with the steepest decline between ages 10 and 16 years[157]. A similar profile was seen in responses to Hepatitis B vaccine in China, with antibody titres in subjects vaccinated at ages 15–24 years half of those vaccinated at 5–14 years;[158] and in bacteriocidal antibody responses to Meningococcal group A conjugate vaccine in West Africa, with lower titres in those aged 18–29 years at vaccination than in those aged 2–10 or 11–17 years[159]. However this is not universal: responses by age to the Meningococcal B vaccine varied by vaccine strain[160].

Humoral responses to natural infection also indicate that immune function may be optimised in children and adolescents. Antibody titres against persistent herpesviruses such as cytomegalovirus and varicella zoster increase in response to recurrent episodes of viral reactivation so higher titres indicate less effective immune control, or re-infection. In the Gambia, where most people are infected with cytomegalovirus in infancy, cytomegalovirus-specific antibody levels show a 'J-shaped' pattern with age, with the lowest levels (suggesting optimal control) in adolescents, rising after age 20 years[161]. Similarly, Varicella zoster is ubiquitous where there is no vaccination, and studies in different settings suggest that antibody levels in seropositive individuals are at their lowest (suggesting optimal control) at 8–9 or 15–19 years[162,163].

The immune system changes in infancy and old age are well described[2]. After birth the weak innate immune system of neonates strengthens rapidly, and the adaptive immune system develops an expanded repertoire of memory B and T cells triggered by infections (and vaccinations), the microbiome, and allergens in food and the environment[2]. With ageing, there is a decline in naïve T-cell numbers and T-cell receptor diversity, cytokine production by CD4 and CD8 T-cells is impaired, the CD4 to CD8 ratio is inverted, and the cells of the innate immune response function less well[164]. It is likely that the majority of the data presented here reflect the response to initial pathogen exposure, as those who are already fully protected by acquired immunity will not be included as cases, and those who are partially protected may have mild disease and not be diagnosed. The primary immune response may be particularly affected by ageing. The very high case fatality rates in elderly people observed in response to novel pathogens such as COVID-19, MERS, SARS, St Louis encephalitis, and Ebola, may result from restriction of the naïve T-cell repertoire.

Studies of immune senescence have focussed largely on those over 60 years, but our data indicate that important changes in immune function are apparent at a much younger age. This could be explained by relative 'senescence' of the immune system starting in young adulthood or even earlier[165,166]. Peak immune function in childhood and adolescence, at around age 5–14 years, might represent the intersection of improved function due to maturity and increasing antigenic exposure, and decreasing function due to early senescence. This is supported by assessment of immune parameters, some of which change almost linearly over the lifespan[167], and by changes in the thymic cortex and medulla which peak in size at age 4–11 years[168], or earlier[169].

The severity of infectious disease depends not only on the control of the infectious agent but also on pathological damage arising from the immune response. Dengue is an example where strong immune responses in childhood are associated with increased clinical complications due to antibody dependent enhancement[170]. It has been suggested that the balance between an insufficient immune response and an over-active immunopathological response is generally more favourable in children[4]. However it seems surprising that a similar balance would be required for the wide range of viral and bacterial infections with similar age-severity patterns presented here, including infections in which protection is mainly antibody-mediated (e.g. smallpox) and those in which it is predominantly cell-mediated (e.g. tuberculosis).

The increase in infectious disease severity during adolescence suggests that puberty could have a role. Sex hormones influence immune responses (reviewed in[171,172]) but in different ways and with inconsistent findings

between studies. Overall, testosterone tends to suppress and oestrogens to enhance the immune response[172,173]. These associations may contribute to the generally higher mortality rate from infectious disease in males and higher incidence of autoimmune disease in females[173,174]. Numerous differences in immune marker concentrations and response to infection have been described between males and females, and these increase after puberty[175]. However, where data are available, the increase in severity of disease in young adults compared to children and adolescents was seen in both males and females (e.g. Ebola, tuberculosis, Spanish influenza, polio). The decreased immune response to human papilloma virus vaccine with age, and the profile of cytomegalovirus-specific immunity with age, are also similar in males and females[157,161,176].

Environmental exposures and heterologous infections may modulate the magnitude and quality of the immune response at different ages. For tuberculosis it has been argued that not only HIV but some (unknown) sexually and parenterally transmitted virus might trigger progression to disease and explain the age distribution[177].

Persistent infections, such as herpesviruses, may establish early in life, or increase with age, especially with the changing social contact patterns of adolescence. Cytomegalovirus seropositivity has been associated with immunosenescent changes, including a reduction in the naïve T-cell pool and commensurate increase in CD8 + memory T-cells with a reduced CD4:CD8 ratio[165,166,178–181], as well as with increased risk of mortality in older age[182,183]. However, the functional consequence of persistent cytomegalovirus infection appears to vary with age and cytomegalovirus may enhance responses to heterologous infections in younger people[166,184–186]. In most countries (and probably everywhere at the time when some of the data we present were collected) almost everyone is infected with cytomegalovirus in early childhood[161,187], and continuing exposure and multiple infections are likely. So if cytomegalovirus has a role in explaining the age-pattern of severity, it may reflect immunological attrition due to the burden of persistent infection or reinfection rather than simple presence or absence of infection[188].

The age pattern of severity suggests that natural selection has acted to optimise immune function in childhood and adolescence with a subsequent decline during adulthood. Peak function before reproduction seems counter-intuitive, but according to life history theory there is a trade-off between the energy required for immune response and that required for other functions, such as reproduction and growth[189,190]. Whilst the energy costs of innate immunity are spread throughout the lifetime[189,190] the adaptive immune system has high upfront but lower running energy costs. Thymic involution conserves energy when sufficient naïve T-cells have been generated[189], facilitating the metabolic demands of the adolescent growth spurt and secondary sexual development[191], but leaving the elderly more vulnerable.

SARS-CoV and SARS-CoV-2 appear to have more extreme variation in severity by age than other infections, with predominantly mild disease in children, and very high case fatality rates in the elderly. Unusually, there is no evidence of higher severity in infants. The reasons for this extreme variation are not yet known, but should be considered in the context of the findings of this review.

Appreciating how responses to infections vary by age outside the extremes of age can have major implications. Understanding the prevalence and transmission of SARS-CoV-2 in children, and how this differs from influenza, is crucial in predicting the role of school closures in the response[192]. Vaccination programmes that increase the average age of infection, can paradoxically increase the numbers of people with severe disease[193]. This has led to targeted vaccination of older children for measles and rubella. The higher vaccine response of younger children to human papilloma virus vaccine may lead to a shift in target age groups.

The finding that many infectious diseases are least severe in school-age children suggests that relative immune ageing starts far earlier than has previously been recognised. Improved understanding of the mechanisms underlying this observation may provide novel opportunities for intervention strategies. Children tend to have lower mortality than adults from sepsis, and comparison of their responses is being used in drug discovery[194]; similar approaches could be used for other infections. Comparison of immune response to infections which increase in severity in young adults and those that only increase later may give clues to drug and vaccine design. In the midst of a pandemic and with increasing antimicrobial resistance, new approaches such as these are desperately needed.

Methods

We sought information on severity of infectious disease by age for a wide range of different infections.

Defining outcome measures. The focus of this study is the host response to infection by age. We are interested in the outcome of infections or exposure. We have therefore used:

- Case fatality rates estimated directly from cohorts of individuals
- Case fatality rates estimated from surveillance data, comparing numbers of deaths and numbers of cases
- Proportion of cases with severe disease (e.g. the proportion hospitalised)
- Proportion with symptomatic disease among those with infection or known exposure

Note that mortality rates, though more readily available, would be misleading, as exposure is likely to vary by age.

Sources of data and possible biases. The most accurate data come from situations in which there is active case ascertainment to ensure mild cases are not missed, and active follow-up to ensure outcomes are recorded, ideally proving infection through serology or microbiology. But such studies are rare, and imposing such strict criteria would leave very little data.

Hospital-based data exclude mild cases, and admission criteria may vary with age, but outcomes are likely to be accurately recorded.

Surveillance data provide some of the largest studies but interpreting the age patterns assumes diagnosis and notification are not influenced by age group. Case fatality rates measured from surveillance data can also be biased because of the lag between incidence and death. This is a particular problem in ongoing epidemics, and for diseases with long duration, but will not necessarily bias the age pattern.

Strains of different virulence could affect different sections of the population. Although it is unlikely that strains would differ systematically by age group, studies of single outbreaks of disease avoid this theoretical problem, but are only available for some infections.

For infections for which effective vaccines or treatments are available there may be very few cases or few severe cases, and differential access to or efficacy of vaccines and treatment by age could influence the results. For these infections estimates from the older (e.g. pre-antibiotic or pre-vaccine) literature can be helpful.

For endemic infections leading to life-long immunity, disease in adults may be rare or atypical, so estimates from isolated (e.g. island) populations are most informative. Similarly, newly-emerged infections, or infections in areas where they have not been seen before, will not be affected by partial immunity in older individuals.

Search strategy. Finding sufficiently detailed age-specific information for different diseases is not straightforward and a conventional systematic review is not possible. Very few studies are done to look at the effect of age on disease outcomes. Most outbreak or surveillance reports do not include enough detail, giving age only as a median and range, or giving the age breakdown only for deaths or only for cases. Relevant data are occasionally included as background information in studies on other topics.

Information on different infections was found in different ways. PubMed was used to find reports on specific infections, searching with "case fatality" or "severity" or "hospital*"and "age", or looking at reports of large outbreaks. Outbreak reports were also searched through the *Morbidity and Mortality Weekly Report (MMWR)* produced by the US Centers for Disease Control.

To find suitable studies in the older literature, the journal *Public Health* was hand-searched from volume 1 (1888) to volume 59 (1946), the *Public Health Bulletin* from 1904–1949 and the issues of the *Journal of Tropical Medicine and Hygiene* available on-line (1915–19, 1921, 1923). All pamphlets and reports in the London School of Hygiene & Tropical Medicine library open shelves and books in the Wellcome collection library open shelves relating to infectious diseases were hand-searched. These include reports from the 19th century onwards. We also searched books and reports available electronically from the United States Public Health Service, US National Library of Medicine Digital Collections, the London School of Hygiene & Tropical Medicine, or Google on plague, cholera and yellow fever. The authors' literature collection was searched, and relevant references followed (snowball searching).

All identified studies that gave information on the age-pattern of severity were included if they satisfied the following criteria:

- Included children and adults
- Data stratified in 10-year age groups or less
- At least 100 cases included
- Source of data given

All eligible studies were included whatever age-severity pattern they showed. Where the number of cases and outcomes was presented, or could be derived, by age group, binomial exact 95% confidence intervals were calculated for the proportions. For each infection, the relative risk of the outcome (death or other measure of severity) in adults was compared to that in children using the largest dataset with information on numbers of individuals in the relevant age groups.

Data availability

All datasets are available in an Excel file[195]. This links to the supplementary material, and includes the origin of each dataset.

Code availability

There was no custom code for this analysis

Summary:

Various isolation strategies are used to prevent infections during bone marrow transplantation; data on their efficacy are lacking. We studied whether use of high efficiency particulate air filtration (HEPA) and/or laminar airflow (LAF) units affect transplant-related mortality (TRM) or survival in the first year after allogeneic transplantation. 5065 patients with leukemia receiving bone marrow transplants from an HLA identical sibling ($n = 3982$) or alternative related or unrelated donors ($n = 1083$) between 1988 and 1992 were reported to the International Bone Marrow Transplant Registry by 222 teams. Two types of isolation were considered: (1) conventional protective isolation with single patient room and any combination of hand-washing, gloves, mask and gown; and (2) HEPA and/or LAF. Cox proportional hazards regression models were used to determine the relative risks (RRs) of transplant-related mortality (TRM) and of deaths from any cause in patients treated in HEPA/LAF units compared to patients treated in conventional isolation. HLA-identical sibling and alternative donor transplants were analyzed separately. Risks of TRM and overall mortality in the first 100 days post-transplant were significantly lower among patients treated in HEPA/LAF units than in those treated conventionally. RRs of TRM were 0.76 ($P = 0.009$) for recipients of HLA-identical sibling transplants and 0.65 ($P = 0.003$) for recipients of alternative donor transplants. Correspondingly RRs of overall mortality were 0.80 ($P = 0.02$) and 0.65 ($P = 0.0006$). Decreased risks of TRM and of death in the first 100 days post-transplant resulted in significantly higher 1-year survival rates in patients treated in HEPA/LAF rather than in conventional isolation units. Use of HEPA and/or LAF to prevent infections decreases TRM and increases survival after allogeneic bone marrow transplants for leukemia.

Keywords: allogeneic bone marrow transplantation; infection prophylaxis; protective isolation

Correspondence: Dr MM Horowitz, International Bone Marrow Transplant Registry, Medical College of Wisconsin, 8701 Watertown Plank Road, Milwaukee, WI 53226, USA
Received 14 March 1997; accepted 6 January 1998

Bone marrow transplant recipients have a high risk of infections early after transplant. Data from the International Bone Marrow Transplant Registry (IBMTR) indicate that infections are the primary cause in about 15%, and a contributory cause in another 35%, of deaths occurring in the first post-transplant year.

Several strategies are used to prevent infections during transplants including physical barriers to infectious agents (protective isolation) and prophylactic antibiotics.[1–17] Approaches differ in costs and psychosocial effects on patients.[18,19] There is controversy whether these strategies effectively decrease infections. This study focused on whether use of high efficiency particulate air filtration (HEPA) and/or laminar airflow (LAF) units rather than conventional isolation techniques influenced transplant outcome.

Patients and methods

Population

The study included 5065 patients receiving allogeneic bone marrow transplants between 1988 and 1992 and reported to the IBMTR with the following: (1) chronic myelogenous leukemia (CML), acute myelogenous leukemia (AML) or acute lymphoblastic leukemia (ALL); (2) graft-versus-host disease (GVHD) prophylaxis with cyclosporine with or without other drugs or T cell depletion. We excluded patients treated without protective isolation ($n = 63$) or with isolation strategies other than the categories described below ($n = 193$), those receiving other types of GVHD prophylaxis ($n = 246$), those with insufficient HLA data to determine donor–recipient histocompatibility ($n = 153$), and

A53210128

those without information on pretransplant disease state or age ($n = 77$). Patients were reported by 222 teams.

Isolation strategies

Two isolation strategies were studied: (1) conventional protective isolation using single rooms, and any combination of hand-washing, gloves, mask, and gown to prevent infection transmission (conventional isolation, $n = 827$); and (2) protective isolation in rooms designed to lower exposure to airborne infectious agents using HEPA filtration systems with or without LAF equipment (HEPA/LAF, $n = 4238$).

Outcomes

Transplant outcomes analyzed included acute and chronic GVHD, fungal pneumonia, 1-year transplant-related mortality (TRM), and 1-year survival. Acute GVHD was defined as moderate to severe (grade II–IV) disease using published criteria;[20] patients surviving $\geqslant$21 days with engraftment were considered at risk. Chronic GVHD was determined by clinical criteria in patients surviving $\geqslant$90 days with engraftment.[21] TRM was defined as death in patients without leukemia relapse, with censoring at time of relapse or last follow-up.[22] Follow-up to 100 days post-transplant was available for 100% of patients; follow-up to 1 year was available for 84%.

Statistical methods

Patient-, disease- and transplant-related variables of the two study groups were compared using the χ^2 statistic for categorical and the Mann–Whitney U test for continuous variables. Probabilities of transplant outcomes were calculated using the Kaplan–Meier estimator; the log-rank test was used for univariate comparisons. Associations of isolation-type with TRM and survival were evaluated using Cox proportional hazards regression.[23] Since recovery of immune function differs after HLA-identical sibling and alternative donor transplants, these cohorts were analyzed separately. Potential confounding variables considered in the analysis were: donor–recipient relationship and histocompatibility, recipient age, donor–recipient sex-match, donor and recipient cytomegalovirus (CMV) serology, pretransplant Karnofsky performance score, disease, remission state, white blood cell count (WBC) at diagnosis, conditioning regimen, GVHD prophylaxis, year of transplant and the prophylactic use of systemic antibiotics, oral nonabsorbable antibiotics, cotrimoxazole, acyclovir, intravenous immune globulins, hematopoietic growth factors including G-CSF and GM-CSF, transplant center size (number of transplants done annually) and transplant center site. Forward stepwise variable selection at a 0.05 significance level was used to identify covariates associated with outcome. In each step of the analysis, the covariate for isolation type was included in the model. For each model the assumption of proportional hazards was tested using a time-dependent covariate; this indicated a differential effect of isolation type in the early and late post-transplant period. Models were therefore constructed breaking the post-transplant course into two time periods using the maximized partial likelihood method to find the most appropriate breakpoint. First order interactions between type of isolation and all significant covariates were considered.

Results

Patient-, disease- and transplant-related variables are shown in Tables 1 and 2. Among patients receiving HLA-identical sibling transplants, there were statistically significant differences between those treated in conventional *vs* HEPA/LAF isolation in patient age, pretransplant performance score, year of transplant, conditioning regimen, GVHD prophylaxis, use of systemic and oral nonabsorbable antibiotics, use of cotrimoxazole, hematopoietic growth factors and transplant center site (Table 1). Among those receiving alternative donor transplants, the cohorts differed for disease, disease state, pretransplant performance score, CMV status, year of transplant, conditioning regimen, GVHD prophylaxis, use of cotrimoxazole, acyclovir, intravenous immune globulins and transplant center site (Table 2).

Table 3 shows actuarial probabilities ($\pm$ 95% confidence interval) of acute and chronic GVHD, fungal pneumonia, TRM and 1-year survival by donor type and isolation technique in univariate analysis. Rates of acute or chronic GVHD were similar in patients treated in conventional *vs* HEPA/LAF isolation. Among patients receiving alternative donor transplants, the probability of fungal pneumonia was lower in the HEPA/LAF cohort. TRM was lower and 1-year survival higher for patients treated with HEPA/LAF isolation, whether the transplant was from an HLA-identical sibling or alternative donor (Table 3, Figure 1).

Table 4 shows the relative risk of TRM for patients treated in HEPA/LAF *vs* conventional isolation in multivariate analyses, adjusting for the effect of other significant variables. The relationship between isolation and TRM is time-dependent. Patients treated with HEPA/LAF had lower risks of TRM in the first 100 days post-transplant with no effect thereafter.

Table 5 shows the relative risk of mortality in the first post-transplant year for patients treated in HEPA/LAF *vs* conventional isolation. Again, HEPA/LAF isolation decreased overall mortality in the first 100 days post-transplant. There were no interactions between the effect of isolation and prophylactic use of antibiotics, cotrimoxazole or immune globulins in either model. Transplant center site, categorized as high or low geographic latitude, but not transplant center size, was significantly associated with TRM and mortality in the first post-transplant year. HEPA/LAF decreased TRM and mortality regardless of transplant center site.

There were no significant differences in the primary causes of death, for patients dying within 1 year post-transplant, between patients treated in HEPA/LAF *vs* conventional isolation.

Discussion

Isolation techniques used for allogeneic bone marrow transplant recipients vary.[3,6,12,17] Several studies comparing

different techniques are reported with contradictory results.[24–31] This study represents the largest group of patients analyzed for associations between isolation technique and outcome.

Our major finding is that survival is higher in patients treated in HEPA/LAF units than in those treated with conventional isolation. This benefit persists after adjusting for other differences in patient-, disease- and transplant-related variables. Higher survival results from less TRM in the first 100 days post-transplant. The effect is seen in both HLA-identical sibling and alternative donor transplants and appears to be stronger in the latter. This effect of isolation technique is independent of use of prophylactic antibiotics or immune globulins.

Previous studies of isolation techniques analyzed small and/or heterogenous patient groups,[24–26] but three prospec-

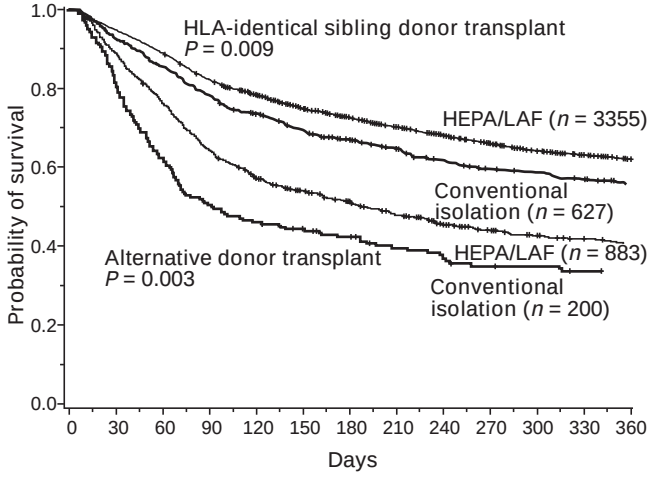

Figure 1 Probability of survival in the first year post-transplant after HLA-identical sibling transplant and alternative donor transplant by type of protective isolation.

tive studies from one single center are reported.[27,30,31] Two studied patients with leukemia. The first, involving 99 recipients of HLA-identical sibling transplants between 1981 and 1984, compared conventional to LAF isolation;[30] both groups received prophylactic systemic antibiotics. The second study, done between 1984 and 1987, included 342 recipients of HLA-identical sibling and alternative donor transplants and compared four strategies: conventional isolation, conventional isolation and prophylactic systemic antibiotics, LAF isolation, and LAF isolation and prophylactic systemic antibiotics.[31] Both studies evaluated events up to the time of engraftment and showed lower probabilities of bacteremia and other clinically significant infections with more intensive isolation; there was no survival benefit. A third study analyzed 100 patients with aplastic anemia treated with conventional isolation, conventional isolation and granulocyte transfusions or LAF isolation.[27] Compared to patients in conventional isolation, patients in LAF isolation had less bacteremia and other documented infections, less and delayed acute GVHD and higher probabilities of 100-day survival. Differences in GVHD and survival were of borderline statistical significance. Overall, results from the above studies are similar in direction and magnitude as those in the current IBMTR analysis. Although survival advantages in the prospective studies cited were not statistically significant, the large numbers of patients analyzed and longer follow-up in this study substantially increased our power to detect such differences. Our study did not elucidate the reasons for improved survival of patients in the HEPA/LAF cohort. In patients receiving transplants from donors other than an HLA-identical sibling, who are at high risk of invasive infections,[32,33] we found fewer fungal pneumonias in the HEPA/LAF cohort. We lacked sufficient data to examine relative rates of bacterermia and other bacterial infections. Distribution of causes of death did not differ by isolation technique for either HLA-identical sibling or alternative donor transplants. We did not detect any difference in incidence or severity of GVHD. Experimental data show that GVHD may be reduced by a strictly sterile environment[34] but this is rarely attained in the clinical setting.

Our study found an inverse association between distance from the equator, ie geographic latitude, and TRM and 1-year mortality independent of the effect of isolation. Patients treated in warm climates may be at higher risk of exposure to airborne fungal spores.[35] However, the effect of HEPA/LAF was similar at warm and temperate latitudes.

The data analyzed have several limitations. First, we were unable to compare HEPA with LAF. This would be desirable since costs of these two techniques differ. We also did not have data on duration of isolation and insufficient data to assess influence of gut sterilization. However, neither oral nonabsorbable nor systemic antibiotics other than cotrimoxazole, both of which decrease gastrointestinal flora, seemed to impact TRM or survival. Finally, this was a non-randomized study. Although we carefully considered

potential confounding by a large number of patient and treatment variables, it is possible that the observed effects are due to other unmeasured factors. The effects noted, however, are sufficiently strong to merit further study.

In conclusion, HEPA and/or LAF isolation appears to decrease TRM and increase survival after allogeneic bone marrow transplant. This benefit is stronger in patients receiving transplants from donors other than HLA-identical siblings. Further study is needed to determine whether HEPA and LAF differ, and to better define impact of prophylactic antibiotic regimens. As centres come under increasing pressure to control costs by eliminating costly supportive care measures, it is important to study carefully the impact of such changes on patient outcome.

Cystic Fibrosis Upper Airways Primary Colonization with *Pseudomonas aeruginosa*: Eradicated by Sinonasal Antibiotic Inhalation

To the Editor:

Chronic pulmonary infection with pathogens like *Pseudomonas aeruginosa (P. aeruginosa)* is the major cause of premature death in cystic fibrosis (CF). The sinonasal area has been discussed as a reservoir for lung infection. Since the upper airways (UAW) are not assessed microbiologically according to current CF standard care, evidence (1–4) of their role in disease progression remains scarce (5). Furthermore, therapeutic options have been insufficiently evaluated and sinonasal deposition of aerosols was not effective with common nebulizers.

A 12 1/2–year-old patient (genotype DeltaF508/CFTRdele17a-18) suffered from chronic mucopurulent rhinosinusitis as predominant CF symptom (6). Otorhinological assessment revealed abundant secretions and mucosal inflammation but no morphologic changes requiring surgery. He was treated with oral antibiotic courses, nasal topical steroids, and frequent therapeutic nasal lavages (NL), applying 250 ml of isotonic saline (6), to remove mucus and crusts. Routine sputum samples were taken every 1 to 3 months. In addition, we sampled UAW by diagnostic NL as described previously (3). In brief, 10 ml of sterile isotonic saline was applied to each nostril using a 10-ml syringe, with reclined head and occluded soft palate. Then, nasal material was drained into a cup by anteflection and any material from the mouth was discarded.

First evidence of nonmucoid *P. aeruginosa* of the head was found in the patient's NL in June 2006 (Figure 1). Despite a 2-week intravenous course of tobramycin and ceftazidime, *P. aeruginosa* was detected by NL again in August 2006.

The patient subsequently inhaled tobramycin (Gernebcin 80 mg/d) off-label for 4 weeks using the Pari Sinus nebulizer (Pari Corp, Starnberg, Germany). This device, which uses the new principle of superimposing 44-Hz vibration upon nebulization, has been shown by *in vitro* (7) and *in vivo* (8) experiments to deposit aerosol into paranasal sinuses. We recently published results of the first clinical trial with the device, a double-blind, placebo-controlled pilot crossover study, assessing sinonasal inhalation of dornase alpha in five patients with CF. Dornase alpha significantly improved Quality of Life assessed by the Sinonasal Outcome Test 20 (9).

Sinonasal inhalation was performed as described previously (9). In brief, patients inhaled into each nostril consecutively while occluding the soft palate and semi-occluding the contralateral nostril (duration 4 min/nostril). Therapy was well tolerated.

During the subsequent 4.5 years, more than 40 samples from the patient's upper and lower airways and serum antibodies remained negative for *P. aeruginosa*.

Discussion

The possibility of bacterial spread from the upper to the lower airways has been suspected (1), as in initially *P. aeruginosa*–free transplanted lungs the *P. aeruginosa* genotype of the explanted CF lungs was found, implying sinonasal persistence. Besides, *P. aeruginosa* biofilms were detected intraoperatively in paranasal sinuses of patients with CF who had only intermittent lower airway colonization (2). Concordantly, we found 96% identical genotypes of *P. aeruginosa* sample pairs in patients with colonization of both airway levels (3).

In our case the novel therapeutic approach of sinonasal antibiotic administration using Pari Sinus vibrating aerosol technology led to eradication of *P. aeruginosa*.

Conclusions

Current standards of CF care would not have detected first colonization with *P. aeruginosa* in our patient. Upper airway sampling by nasal lavage can facilitate detection of pathogen colonization, and its therapy may delay pulmonary infection with *P. aeruginosa*, the leading cause of mortality in patients with CF.

Author Disclosure: None of the authors has a financial relationship with a commercial entity that has an interest in the subject of this manuscript. However, we are now performing a prospective DBPC pilot study on sinonasal inhalation of tobramycin supported by InfectoPharm and Pari as well as a pilot study on sinonasal inhalation of Colistin supported by Gruenenthal, Germany.

original reports

A Population-Based Study of the Long-Term Risk of Infections Associated With Hospitalization in Childhood Cancer Survivors

Leena Chehab, MD, MS[1]; David R. Doody, MS[2]; Adam J. Esbenshade, MD, MSCI[3]; Gregory M.T. Guilcher, MD[4]; Christopher C. Dvorak, MD[5]; Brian T. Fisher, DO, MSCE, MPH[6,7]; Beth A. Mueller, MPH, DPH[2,8]; Eric J. Chow, MD, MPH[2]; and Jenna Rossoff, MD[9,10]

abstract

PURPOSE Infections pose a significant risk during therapy for childhood cancer. However, little is known about the risk of infection in long-term survivors of childhood cancer.

METHODS We performed a retrospective observational study of children and adolescents born in Washington State diagnosed with cancer before age 20 years and who survived at least 5 years after diagnosis. Survivors were categorized as having a hematologic or nonhematologic malignancy and were matched to individuals without cancer in the state birth records by birth year and sex with a comparator:survivor ratio of 10:1. The primary outcome was incidence of any infection associated with a hospitalization using diagnostic codes from state hospital discharge records. Incidence was reported as a rate (IR) per 1,000 person-years. Multivariate Poisson regression was used to calculate incidence rate ratios (IRR) for cancer survivors versus comparators.

RESULTS On the basis of 382 infection events among 3,152 survivors and 771 events among 31,519 comparators, the IR of all hospitalized infections starting 5 years after cancer diagnosis was 12.6 (95% CI, 11.4 to 13.9) and 2.4 (95% CI, 2.3 to 2.6), respectively, with an IRR 5.1 (95% CI, 4.5 to 5.8). The survivor IR during the 5- to 10-year (18.1, 95% CI, 15.9 to 20.5) and > 10-year postcancer diagnosis (8.3, 95% CI, 7.0 to 9.7) periods remained greater than comparison group IRs for the same time periods (2.3, 95% CI, 2.1 to 2.6 and 2.5, 95% CI, 2.3 to 2.8, respectively). When potentially vaccine-preventable infections were evaluated, survivors had a greater risk of infection relative to comparators (IRR, 13.1; 95% CI, 7.2 to 23.9).

CONCLUSION Infectious complications continue to affect survivors of childhood cancer many years after initial diagnosis. Future studies are needed to better understand immune reconstitution to determine specific factors that may mitigate this risk.

J Clin Oncol 41:364-372. © 2022 by American Society of Clinical Oncology

INTRODUCTION

In the past five decades, the 5-year survival rate for all pediatric cancer has steadily increased to exceed 80%.[1] This improvement in survival is primarily attributed to advancements in therapy, risk stratification, and supportive care.[2,3] Although these treatment protocols are lifesaving, they have undesirable consequences, including prolonged delays in immune reconstitution leaving patients vulnerable to infection well beyond completing chemotherapy.[4-6] The Childhood Cancer Survivor Study reported that survivors of all cancer were 1.6-2.7 times more likely to be hospitalized for infection > 5 years following the completion of therapy compared with age- and sex-matched individuals in the general population.[7] As a result, infection remains a significant cause of morbidity and mortality for the estimated 500,000 survivors of childhood cancer in the United States.[5,7,8]

Although prior studies highlight the overall infection risk for children after completing therapy for any cancer, there is a paucity of data documenting the incidence of specific infections in long-term cancer survivors, including potentially vaccine-preventable illnesses severe enough to require hospitalization.[9] In the absence of these data, clinicians, in particular, pediatricians in the community who care for these children following completion of therapy, are unable to have informed discussions regarding infection risk with parents and their patients in this post-treatment period. The aim of the current study is to describe the overall incidence rate (IR) of infections requiring hospitalization for survivors of childhood and adolescent cancers at least 5 years from initial cancer diagnosis. IRs will also be calculated for specific infection types and by subgroups of survivors of hematologic and nonhematologic malignancies. Evaluating infections separately in survivors of hematologic and nonhematologic cancers allows for a better understanding of malignancy-specific risks and addresses the specific knowledge gap of immune

CONTEXT

Key Objective

There is a paucity of data documenting the incidence of specific infections in long-term cancer survivors, specifically differentiating risk in patients with hematologic versus nonhematologic malignancies. This population-based retrospective observational follow-up analysis sought to determine whether survivors of pediatric cancer still have an elevated risk of infection > 5 years from initial diagnosis.

Knowledge Generated

Survivors of pediatric cancer remain at increased risk of infections associated with a hospitalization or death long after their initial diagnosis. This risk is elevated in survivors of both hematologic and nonhematologic malignancies for infections across most of the organ systems and pathogen groups assessed.

Relevance

It is vital for patients, caregivers, and their providers to appreciate this long-term infection risk assessment. This allows for better counseling by physicians and recommendations of care for survivors that will reduce the morbidity of infection throughout the survivorship period.

impairment after treatment in nonhematologic malignancies.[9] As therapeutic options improve and the number of childhood cancer survivors increases, it is important to define infection risk in the post-therapy period to guide counseling and encourage investigations aimed at developing effective preventative strategies.

METHODS

Study Design and Patient Population

We conducted a population-based retrospective observational follow-up analysis using linked cancer-birth-hospital discharge records from Washington State–born children and adolescents with and without cancer. We calculated IRs of infections associated with a hospitalization or death overall and during different follow-up time periods that each started 5 years after cancer diagnosis. These rates were separately calculated for children with hematologic and nonhematologic malignancies and compared with rates for children and adolescents without cancer.

Identification of Cancer Survivors

Cancer survivors were identified from two population-based cancer registries in Washington State: the Cancer Surveillance System (part of the National Cancer Institute's Surveillance, Epidemiology and End Results Program) and the Washington State Cancer Registry (part of the Centers for Disease Control and Prevention's North American Association of Central Cancer Registries). The former registry began in 1974 and includes > 70% of the state's population; the latter began in 1995. Cancer registry records of individuals age < 20 years at the time of primary cancer diagnosis were linked to Washington State birth records to identify those born in state (N = 5,605). Only children diagnosed between 1982 and 2008 and who survived at least 5 years from diagnosis were included in this analysis (N = 3,152), with last date of follow-up through December 2013. An index date of 5 years from initial cancer diagnosis was assigned to each survivor.

Comparator Subjects

Each cancer survivor was randomly matched by birth year and sex to 10 children identified in the remaining Washington State birth records. Comparator subjects representing the general population were not known to have died before the survivor's index date on the basis of further linkage to the state death records.

Outcome

Record linkage occurred in 2014-2015. Records of all subjects were linked to state hospital discharge and death records beginning at the index date, as described previously.[8] Subjects without a death or hospitalization record identified during this time were assumed to be alive and event-free through December 2013. The primary outcome was incidence of any infection associated with a hospitalization or death occurring 5 or more years after the cancer diagnosis through December 2013. Time to event was measured from index date, with median potential follow-up[10] of 9.3 years (interquartile range [IQR], 4.4-14.5 years) for both cases and comparators. Infections were defined using International Classification of Disease, Version 9 and 10 (ICD-9/-10), codes according to Medicare-Medicaid billing standards (Appendix Table A1, online only). State hospital discharge data include records of all inpatient discharges (full and observation admissions) at non-Federal facilities and contain up to 25 discharge diagnoses. State death records contain one underlying primary and up to 10 contributing causes of death. Death because of infection without an associated hospitalization was extremely rare, and thus the primary outcome is referred to more simply as infection associated with a hospitalization. As done previously, infections were classified by organism type (bacterial, fungal, or virus), by organ

A53210128

system/infection type (nervous system, respiratory, GI, genitourinary, musculoskeletal, skin, or sepsis), and by whether it is potentially vaccine-preventable (influenza A and B virus, varicella zoster virus, *H. influenzae*, hepatitis B, or *S. pneumoniae*).[11] Subjects may have had more than one hospitalization associated with infection.

Covariate Data

Race/ethnicity, birth year, and sex for cancer survivors and comparator subjects were available from the state birth records. Cancer-specific variables including International Classification of Diseases for Oncology (ICD-O) morphology and topography codes, date of diagnosis, and age at diagnosis were available from the cancer registries. Cancer types were classified per the International Classification of Childhood Cancer, 3rd edition.[12] Cancer treatment duration and relapse status were not available from these registries.

Statistical Analysis

IRs of infection associated with a hospitalization per 1,000 person-years (PY) were calculated. Poisson regression was used to estimate the incidence rate ratios (IRR) and associated 95% CIs comparing infection rates between children with and without cancer.[13] For each infection type, the count of infections (ranging from 0 to 15) was the dependent variable, with years under observation included as an offset term in the Poisson model. Birth year (continuous) and sex were included as covariates. Survivors were categorized as having a hematologic (n = 1,244) or nonhematologic (n = 1,908) malignancy, with calculation of respective IRs and IRRs. We examined the infection-related IRs and IRRs overall for 5+ years after diagnosis, and more specifically during 5 to < 10 years after diagnosis, and ≥ 10 years after diagnosis. IRs and IRRs for infections associated with a hospitalization were also calculated by infection type, organ system, and status as potentially vaccine-preventable. We used Stata version 17 (College Station, TX) for all analyses.[14]

RESULTS

The assembled cohort included 3,152 cancer survivors: 1,244 (39.5%) survivors of hematologic malignancy and 1,908 (60.5%) survivors of nonhematologic malignancy (Table 1). Leukemia (25.9%), CNS tumors (19.8%), and lymphoma (13.6%) were the most common cancers. Sex and age distribution of cancer survivors and comparators were similar by design. Each group consisted of 48.1% females and 51.9% males. The median age at cancer diagnosis was 7 years (range, 0-19 years). Median follow-up after index date was 8.8 years (range, 0.05-27.0 years; IQR, 4.1-14.2 years) for cancer survivors and 9.3 years (range, 0.1-27.0 years; IQR, 4.4-14.5 years) for age- and sex-matched comparators.

Overall and Specific Inpatient Infection Rates

In the follow-up period, there were 382 infections diagnosed during a hospitalization among 3,152 cancer survivors and 771 infections diagnosed in the inpatient setting among 31,519 comparators. This resulted in an IR of 12.6 inpatient infections per 1,000 PY (95% CI, 11.4 to 13.9) in cancer survivors and 2.4 inpatient infections per 1,000 PY rate (95% CI, 2.3 to 2.6) in the comparator subjects. Among survivors of hematologic and nonhematologic malignancy, the IR for all infections associated with a hospitalization was 18.5 (95% CI, 16.2 to 21.1) and 8.7 (95% CI, 7.5 to 10.2), respectively. Among infection types, bacterial was the most common in both survivors of hematologic and nonhematologic malignancy (IR, 7.3; 95% CI, 5.9 to 9.0; and IR, 2.7; 95% CI, 2.1 to 3.6, respectively). By organ system, respiratory infections were most common in survivors of hematologic malignancy (IR, 4.1; 95% CI, 3.5 to 4.9), whereas survivors of nonhematologic malignancy had a very similar incidence of genitourinary and respiratory infections (IR, 2.6; 95% CI, 2.0 to 3.5; and IR, 2.6; 95% CI, 1.9 to 3.4, respectively). Sepsis was also among the most frequent inpatient infection in both survivors of hematologic and nonhematologic malignancy (IR, 2.2; 95% CI, 1.5 to 3.2; and IR, 0.8; 95% CI, 0.5 to 1.4, respectively; Table 2).

The incidence of infections associated with a hospitalization per 1,000 PY declined for cancer survivors, both of hematologic and nonhematologic malignancy, in the > 10-year postdiagnosis follow-up period (IR, 8.3; 95% CI, 7.0 to 9.7) as compared with 5- to 10-year follow-up period (IR, 18.1; 95% CI, 15.9 to 20.5; Figs 1 and 2). However, these IRs were higher for cancer survivors in both follow-up periods relative to rates of infection associated with a hospitalization for age- and sex-matched comparators during the same follow-up windows (IR, 2.5; 95% CI, 2.3 to 2.8; and IR, 2.3; 95% CI, 2.1 to 2.6, respectively; Appendix Tables A2 and A3 [online only]).

Relative Risk of Infections Associated With Hospitalization

The IRR of infections associated with hospitalization in all cancer survivors was 5.1 (95% CI, 4.5 to 5.8). Although bacterial infections were more numerous in survivors of both hematologic and nonhematologic malignancy, the relative risk was highest for fungal infections in both groups (IRR, 25.2; 95% CI, 14.7 to 43.2; and IRR, 10.2; 95% CI, 5.5 to 18.9, respectively) followed by bacterial (IRR, 10.7; 95% CI, 8.3 to 13.7; and IRR, 4.0; 95% CI, 3.0 to 5.5, respectively). When evaluating organ systems, the IRR of survivors of hematologic malignancy relative to comparators was highest for infections of the nervous system (IRR, 13.9; 95% CI, 6.2 to 31.1) followed by respiratory infections (IRR, 10.1; 95% CI, 7.8 to 13.1), whereas relative risk for infections of the genitourinary followed by nervous system (IRR, 8.1; 95% CI, 5.7 to 11.4; and IRR, 5.0; 95% CI, 1.9 to 13.7, respectively) were the highest among survivors of nonhematologic malignancy (Table 3, Fig 3).

Both survivors and comparators experienced relatively low rates of inpatient vaccine-preventable infections associated with hospitalization (Table 2); however, rates were significantly higher in cancer survivors versus comparator

subjects. Specifically, survivors of both hematologic malignancy and nonhematologic malignancy have an increased risk of varicella zoster virus infections relative to comparator subjects (IRR, 69.7; 95% CI, 24.8 to 195.4; and IRR, 6.7; 95% CI, 1.3 to 34.5, respectively). Survivors of hematologic malignancy also had a significantly

increased risk of influenza A and B infection associated with hospitalization (IRR, 32.9; 95% CI, 8.8 to 122.7; Table 3).

DISCUSSION

In this observational comparative study, infections diagnosed in the inpatient setting were consistently and significantly higher in cancer survivors versus age- and sex-matched comparators. Although higher rates of infections diagnosed during a hospitalization were documented in the 5- to 10-year period, the increased risk for such infections persisted for survivors of hematologic malignancy and nonhematologic malignancy > 10 years from cancer diagnosis. These results are consistent with prior literature. In 2011, Lorenzi et al found that pediatric cancer survivors in a British Columbia registry had an increased risk of infections diagnosed during hospitalization for up to 5 years after their diagnosis. This risk was particularly evident among the leukemia survivor subgroup.[15] A separate Canadian study from Pelland-Marcotte et al[6] leveraged administrative data from the Pediatric Oncology Group of Ontario Networked Information System to show that leukemia survivors had an increased relative risk of infections diagnosed in the inpatient and outpatient settings at 5 years and > 5 years after the completion of chemotherapy compared with a control group. Data from our US-based study, in conjunction with these Canadian reports, highlight the potential long-lasting impact that cancer therapy has on infection risk.

Although survivors of hematologic malignancy tended to have higher risk of infection than survivors of nonhematologic malignancy relative to comparators, both groups had significantly increased relative risks for inpatient infections across most of the organ systems and pathogen groups assessed. Given that the increased risk for infections associated with hospitalization existed across most infection subtypes, clinicians caring for pediatric cancer survivors need to remain vigilant for a wide range of infections in these patients compared with their healthy counterparts. This is particularly true for bacterial infections, which were the most numerous. However, it is also important to maintain awareness for fungal infections, which yielded the highest IRR of all infection types, as they were far less common in the comparators. Among organ systems, the increased risk of infections of the respiratory tract, nervous system, and genitourinary system, and sepsis were particularly profound. This higher index of suspicion may warrant lower thresholds for bringing patients into the clinic for evaluation, pursuing diagnostic testing, or referring to subspecialists for additional evaluation. Furthermore, it is imperative that patients and their caregivers are appropriately counseled about this long-term risk so that they may seek timely medical attention for infectious symptoms, rather than assuming that their infectious

symptoms can be managed with a similar approach used for otherwise healthy children and adolescents.

Survivors of both hematologic and nonhematologic malignancy also had significantly increased risk for vaccine preventable illnesses diagnosed during a hospitalization. The magnitude of risk relative to comparators was noted be higher among the survivors of hematologic malignancy. Varicella zoster virus was the most common vaccine-preventable illness reported followed by influenza. It is important to note, however, that many of these patients (approximately 70%) were born before incorporation of the varicella vaccine into the routine childhood vaccination series, and thus may not represent a failure of prior vaccine receipt. The increased risk of influenza infections in the

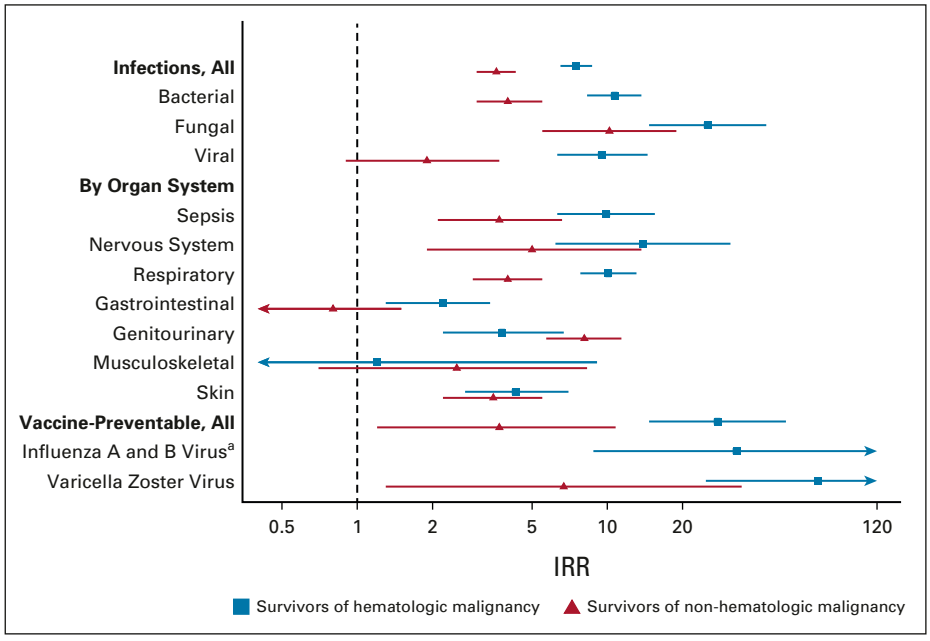

FIG 3. IRRs (Poisson regression) of infections by organism and organ system for survivors versus comparators. [a]No influenza hospitalizations in nonheme survivors. IRR, incidence rate ratio.

A53210128

survivors of hematologic malignancy underscores the importance of annual immunization for this population. Further investigation is necessary to determine whether revaccination after completion of chemotherapy would prevent some of these vaccine-preventable illnesses that present in the immediate years after completing chemotherapy. Importantly, there were few diagnosed vaccine-preventable infections associated with hospitalization in the period beyond 10 years from cancer diagnosis suggesting that the increased risk of infection from these pathogens declines with time. At present, international guidelines from the Children's Oncology Group recommend that all survivors of childhood cancer make up missed doses of regularly scheduled vaccines.[9] For survivors who have received all scheduled vaccinations, it is recommended that either (1) boosters be given or (2) titers be measured (if available) and a booster be given if a survivor lacks seroprotection for a given vaccine.[9] These guidelines generally align with practice in the United Kingdom and published recommendations from the European Conference on Infection in Leukemia, where boosters are recommended.[16-18]

Major strengths of this study include a large cohort of pediatric cancer survivors with a variety of cancer diagnoses and a large comparator group with a 10:1 ratio of age- and sex-matched subjects. Additionally, data came from robust and substantiated population-based data sources that are prospectively coded, thus helping to circumvent response bias.[19] Furthermore, this study contributes to a knowledge gap regarding long-term risk of infections diagnosed during hospitalizations in survivors of nonhematologic malignancy, specifically the high rates of fungal and genitourinary infections and significantly increased risk of sepsis relative to comparators, even > 10 years from cancer diagnosis. Overall, there is a paucity of published data reporting on late-onset (> 5 years and 10 years after diagnosis) inpatient infections in cancer survivors and a lack of results specific to certain organ systems and pathogen types, notably vaccine-preventable illnesses. The results from this study contribute to our knowledge regarding the extent of these types of late effects of treatment.

There are several limitations of this study. First, non-Hispanic Whites accounted for > 80% of the subjects in both groups. Although the population of Washington state is reported to have higher percentages of non-Hispanic White and Asian and a slightly lower percentage of Hispanic and Black people than the US population as a whole,[20] this cohort spans a diagnosis period dating back to the 1980s when the US population, especially children, was less diverse than today. Second, the data source for patients with cancer in this study did not identify whether additional treatment for relapse, secondary malignancy, or allogeneic hematopoietic cell transplantation occurred. It is possible that some of the identified infections were attributable to this additional immune suppression rather than residual effect of initial cancer therapy. However, this should be less of a concern among survivors analyzed > 10 years from initial cancer diagnosis, when significantly increased rates of infection were still observed. Third, given that this analysis only assessed inpatient infections and was dependent on diagnostic codes for infection event detection, we likely underestimated the burden of infections in the observed follow-up period. However, by restricting outcomes to those associated with hospitalization, our results should have captured the most clinically relevant serious infections.

Advancement in treatment protocols has yielded survival rates of > 80% at 5 years from diagnosis of childhood cancer; however, these patients are still at risk of significant long-term risk from infection secondary to their cancer diagnosis and therapy.[21,22] Our data show that the risk of an infection associated with hospitalization continues to be significantly increased in survivors of childhood cancer compared with age-matched controls many years to decades after initial diagnosis, with an even higher burden on survivors of hematologic malignancies. It is vital for patients, caregivers, and their providers to have an awareness of this longer-term infection risk to allow for better counseling by physicians and recommendations of care for survivors that will reduce the morbidity of infection during the survivorship period. Additional investigation is necessary to optimize strategies aimed at preventing these infections altogether.

In 1882, Robert Koch suggested four postulates that establish causation between an infectious agent and a particular disease: (1) the infectious organism must be found in abundance in all diseased, but not in healthy, organisms, (2) the infectious organism must be isolated from the diseased host and grown in culture, (3) the disease must be reproduced when the cultured organism is introduced into a healthy organism and (4) the same organism must be reisolated from the experimentally diseased host (Tabrah, 2011; Breitschwerdt et al., 2013). In **Figure 1** we suggest an adaptation to the original postulates of Koch to be used as a framework to assess the causation between intestinal *Pseudomonas aeruginosa* and intestinal disease in patients with cancer. In the following sections we describe the prevalence of *P. aeruginosa* in cancer and the immunosuppressive and stress-inducing conditions of cancer that facilitate the growth, dissemination and virulence of intestinal *P. aeruginosa*. In addition, we describe work showing that *P. aeruginosa* promotes intestinal epithelium cancer-related phenotypes when introduced in tumor prone model hosts.

CANCER AND OTHER IMMUNOSUPPRESSIVE CONDITIONS PROMOTE THE PREVALENCE OF *P. aeruginosa*

Bacteremia is a major cause of life-threatening complications in patients with cancer, especially those who receive anticancer chemotherapy. Cancer patients are more vulnerable to invasive infection, due to ulcerative lesions in mucosal surfaces and immune suppression secondary to chemotherapy (Safdar and Armstrong, 2001). Many studies associate bloodstream infections in cancer patients with Gram-negative bacteria (Oliveira et al., 2007; Bos et al., 2013; Montassier et al., 2013).

P. aeruginosa is a Gram-negative opportunistic bacterium that causes various infections. Common community-acquired infections with *P. aeruginosa* are skin and soft tissue infections, ulcerative keratitis and otitis externa, while hospital-acquired infections include bloodstream infections, pneumonias and urinary tract infections (Driscoll et al., 2007). Infections may be associated with a high rate of morbidity and mortality in immunocompromised hosts, such as those suffering from chemotherapy-induced neutropenia, patients with cystic fibrosis or severe burns and individuals who receive intensive care (Driscoll et al., 2007; Kerr and Snelling, 2009; Worth and Slavin, 2009; Stuart et al., 2010; Rafla and Tredget, 2011).

P. aeruginosa intestinal carriage increases from ∼3% in normal people to ∼20% in hospitalized patients (Stoodley and Thom, 1970). In a case-control study the intestinal colonization by *P. aeruginosa* in cancer patients was 10% before and 31% after hospitalization (Andremont et al., 1989). Studies conducted in oncology–hematology units, found an overall intestinal carriage of *P. aeruginosa* between 11.7 and 37% (Thuong et al., 2003). In another case-control study *P. aeruginosa* intestinal colonization was identified in 17% of controls and 60% of blood cancer patients (Vuotto et al., 2013). These epidemiology data suggest that intestinal colonization by *P. aeruginosa* is prominent among hospitalized cancer patients (Andremont et al., 1989; Vuotto et al., 2013).

The intestinal carriage of *P. aeruginosa* is likely a consequence of the opportunistic nature of this species. Most *P. aeruginosa* infections appear secondary to a breach in host defences. In addition to compromised host immunity, intestinal microbiota play a major role in intestinal defence to infection (Levison, 1973). Thus systemic exposure to antibiotics, which alters intestinal microbiota by reducing the abundance of certain microbes creates the opportunity for intestinal growth of *P. aeruginosa* and other pathogenic bacteria (Hentges et al., 1985).

INTESTINAL *P. aeruginosa* AS A SOURCE OF SYSTEMIC AND REMOTE INFECTIONS

The translocation of endogenous intestinal *P. aeruginosa* extraluminally is an important pathogenic phenomenon and a cause of systemic infections, especially in neutropenic patients with hematological malignancies (Okuda et al., 2010). During the translocation process, bacteria and their products cross the intestinal barrier by traveling between or through the cells of the intestinal epithelium, causing infection and massive inflammation (Alexander et al., 1990; Papoff et al., 2012). Lung infections caused by *P. aeruginosa* are frequent in patients and can occur by direct contamination of the lungs by gastrointestinal flora or through hematogenous spread from the intestine to the lungs. Sepsis and mortality in immunocompromised patients are the results of the presence of highly virulent strains of *P. aeruginosa* within the intestinal tract and the pathogen's ability to adhere to the

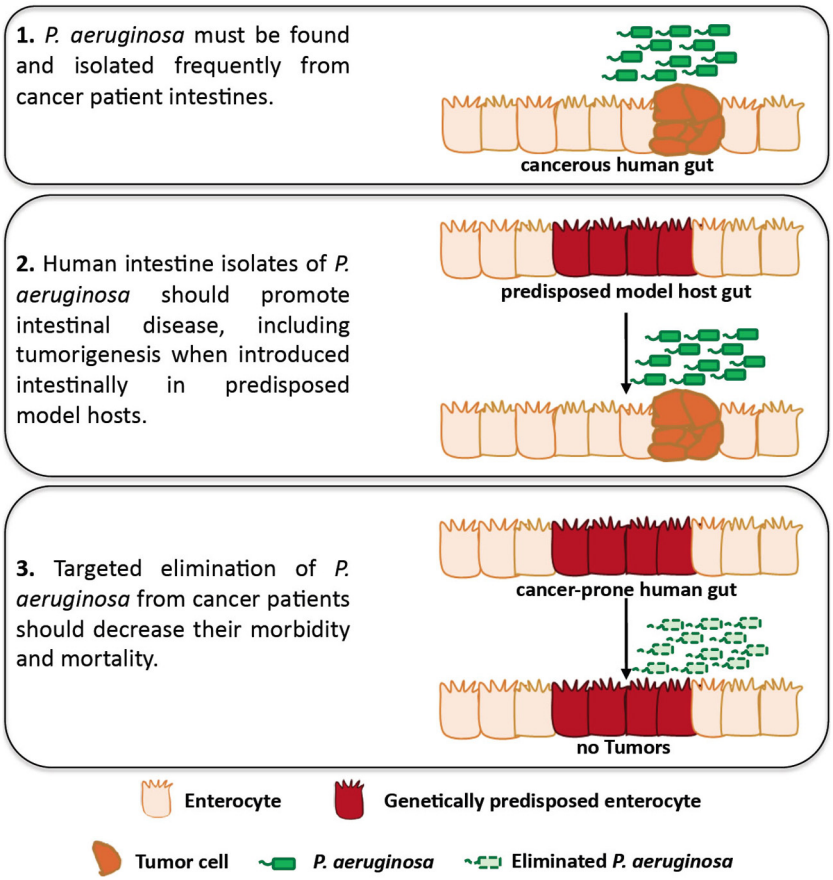

FIGURE 1 | An adaptation of Koch's postulates assessing causation between intestinal *P. aeruginosa* and disease in patients with cancer. Studies using *Drosophila* and mammalian hosts may assess the role of *P. aeruginosa* in facilitating intestinal disease, including intestinal *P. aeruginosa* growth, dissemination, virulence and tumorigenesis, in predisposed hosts. In addition, clinical studies can be designed to assess the presence of *P. aeruginosa* in cancer patients and its role in intestinal disease, including tumorigenesis for which clinical data are lacking.

intestinal epithelial barrier (Marshall et al., 1993; Alverdy et al., 2000; Osmon et al., 2004; Zaborina et al., 2006; Okuda et al., 2010).

P. aeruginosa uses different virulence factors that can damage epithelial cells, such as enzymes (proteases and elastases), toxins, adhesins, flagella and protein secretion systems (Sundin et al., 2004). The T3SS enables the injection of at least four effector proteins (ExoS, ExoT, ExoU, and ExoY) into the host cell. ExoS injected into the host epithelial cell migrates to the membrane where it binds to the mammalian factor FXYD3, expressed specifically in the colon and stomach (Okuda et al., 2010). Thus, ExoS may assist the penetration of *P. aeruginosa* through the intestinal epithelial barrier, impairing the defence function of tight junctions against bacterial penetration (Okuda et al., 2010). Moreover, gut inflammation and apoptosis–which can be initiated by the *Pseudomonas* quinolone signal (PQS)–lead to tight junction disruption and an increase of epithelial barrier permeability (Alverdy et al., 2005; An, 2008). Similarly, *P. aeruginosa* lectin PA-I, which is associated with adhesion to epithelial cell layer, is produced after intestinal ischemia and secreted into the intestinal lumen, causing tight junction interruption, epithelial barrier dysfunction and increase of its permeability (Seal et al., 2011).

INTESTINAL *P. aeruginosa* EXHIBITS ENHANCED VIRULENCE UPON STRESS, SURGERY, TRAUMA, AND MAYBE CANCER

Cohort studies show that infections are more frequent, severe and lethal among surgical patients (Craven et al., 1988; Sax et al., 2011). Surgical injury can shift the dynamics of the host-pathogen interaction leading to phenotype transformation or phase variation that develops as microbes adapt and respond to novel environments, causing morbidity and mortality (Babrowski et al., 2013). *P. aeruginosa* escalates its virulence and promotes systemic inflammation during various conditions of host stress (Seal et al., 2011). In patients colonized by *P. aeruginosa*, the prolonged surgical injury releases stress-related host factors that can trigger the otherwise dormant colonizers, making them invasive and lethal (Babrowski et al., 2013). Defence mechanisms such as degradative proteases and lipases, exopolysaccharide capsule and outer membrane-derived vesicles (OMVs), which serve as a secretion mechanism for virulence factors,

A532-10126

help the pathogen to survive in the host environment (Macdonald and Kuehn, 2013). OMVs are induced in response to physiological stressors and secreted during infection serving multiple roles in bacterial pathogenesis (Macdonald and Kuehn, 2013). In surgically stressed hosts interferon-gamma, endogenous opioids and the hypoxic end-products adenosine and inosine are released into the intestinal lumen where they bind bacteria and activate the expression of PA-I lectin and other virulence factors of *P. aeruginosa*. The PA-I lectin alters the tight junction permeability of the intestinal epithelium to exotoxin A, leading to lethal gut derived sepsis (Long et al., 2008). Moreover, local intestinal depletion of extracellular phosphate (hypophosphatemia), which occurs after surgical injury, can activate virulent pathways due to bacterial sensing of low phosphate, shifting the phenotype of *P. aeruginosa* to that of a lethal strain (Long et al., 2008). Because interferon-gamma, opioids and hypoxia are part of the host response and the therapeutic regiments administered to cancer patients (Dunn et al., 2005; Vaupel and Mayer, 2007), the conditions that accompany cancer may also provide the signals for *P. aeruginosa* virulence induction.

CAN *P. aeruginosa* SIMILARLY TO OTHER GASTROINTESTINAL BACTERIA FACILITATE CANCER?

Bacteria may initiate oncogenesis because they can induce inflammation and produce cell damaging toxins that facilitate tumorigenesis (Collins et al., 2011; Tjalsma et al., 2012). The characteristic single polar flagella and type 4 pili of *P. aeruginosa* function as initiators of inflammation and adhesins, respectively (Gellatly and Hancock, 2013). *P. aeruginosa* induces Toll-like receptors to activate cytokines, chemokines and COX-2 and recruit cells of the innate and adaptive immune system (Hussain et al., 2003; Holt et al., 2008; de Lima et al., 2012). Epithelial adherence is a property of various bacteria associated with gastrointestinal disease and cancer, such as *Bacteroides fragilis, Streptococcus bovis, Escherichia coli* and *Helicobacter pylori* (Toprak et al., 2006; Selgrad et al., 2008; Abdulamir et al., 2011; Arthur et al., 2012). Cell wall antigens of *S. bovis* induce overexpression of COX-2 and NF-κB *in vitro*, which promote cellular proliferation and angiogenesis (Tafe and Ruoff, 2007; Abdulamir et al., 2009).

E-cadherin, a cell adhesion molecule serves as an antagonist of invasion and metastasis and is found mutated in human carcinomas (Cavallaro and Christofori, 2004; Berx and van Roy, 2009). *B. fragilis* secreted factor BFT cleaves E-cadherin, which is usually bound inside the plasma membrane to β-catenin. The cleavage releases catenin in the cytosol leading to the transcription of the oncogene *c-myc* (Hardy et al., 2000). Similarly, *P. aeruginosa* secreted factor LasI can disrupt adherens junctions and reduce the expression and distribution of E-cadherin and β-catenin in the cell membrane, resulting in changes in cell junction associations and enhanced paracellular permeability (Vikström et al., 2009).

Interestingly, intestinal innate immune responses and stem cells may drive tumor initiation, maintenance and metastasis (Schwitalla et al., 2013). Cancer development is assisted by apoptotic programmed cell death in the tumor microenvironment (Evan and Littlewood, 1998; Lowe et al., 2004; Adams and Cory, 2007) and *P. aeruginosa* uses many virulence factors that induce epithelial cell apoptosis. Intestinal infection with *P. aeruginosa* in *Drosophila* activates the c-Jun N-terminal kinase (JNK) pathway, which causes apoptosis of enterocytes and leads to proliferation of intestinal stem cells (Apidianakis et al., 2009). Importantly, genetic predisposition via an oncogenic form of Ras1/K-Ras oncogene, can synergize with inflammatory signals to induce stem cell-originating tumors characterized by alterations in cell polarity and tissue architecture. Moreover, sustained intestinal infection with *P. aeruginosa* in *Drosophila* induces the Imd/NF-κB pathway, which synergizes with the oncogene $Ras1^{V12}$ to activate the JNK pathway. This leads to invasion and dissemination of oncogenic hindgut cells to distant sites (Bangi et al., 2012; Christofi and Apidianakis, 2013).

CONCLUSIONS

P. aeruginosa is a common colonizer of the human intestine upon hospitalization, immunosuppression, antibiotic treatment, surgery, severe trauma and other conditions that cancer patients may face. Not only is *P. aeruginosa* carriage increased in the aforementioned conditions, but also bacteria become more virulent and damaging to the intestinal epithelium upon surgery, injury, and severe stress. Moreover, human isolates of *P. aeruginosa* can induce intestinal pathology and cancer-related epithelial phenotypes in genetically predisposed model hosts. Thus, *P. aeruginosa* appears to have the opportunity and the ability to promote intestinal disease in predisposed hosts, although further proof on the ability of this bacterium to promote tumorigenesis in mammalian models of infection is needed. The lack of epidemiological data linking *P. aeruginosa* to intestinal disease and potentially tumorigenesis in cancer patients may reflect the lack of clinical studies assessing bacterial growth and virulence in relation to cancer recurrence. Because the titter, distribution and virulence of *P. aeruginosa* in the intestine may be very dynamic (Tjalsma et al., 2012), future studies should be designed to repeatedly assess intestinal *P. aeruginosa* abundance and virulence in cancer patients versus healthy individuals. Clinical samples can be assessed for the presence of *P. aeruginosa* via classical microbiology, and next-generation sequencing may offer the chance to assess *P. aeruginosa* transcriptome during infection. Importantly, definite proof of causation of *P. aeruginosa* in morbidity and mortality of cancer patients can only be achieved if targeted elimination of *P. aeruginosa* from these patients improves the outcome of their disease. In **Figure 1** we illustrate a roadmap to specifically assess the role of *P. aeruginosa* in intestinal disease and tumorigenesis. It is conceivable that similar principles can be used to assess causality between intestinal disease and many other opportunistic pathogens harbored by the human gut.

Surveillance Cultures Growing Carbapenem-Resistant *Acinetobacter baumannii* Predict the Development of Clinical Infections: A Retrospective Cohort Study

Rachel Latibeaudiere,[1] Rossana Rosa,[1] Panthipa Laowansiri,[1] Kristopher Arheart,[2,3] Nicholas Namias,[4] and L. Silvia Munoz-Price[5,6]

[1]Department of Medicine, [2]Department of Public Health Sciences, [3]Division of Statistics, and [4]Department of Surgery, University of Miami Miller School of Medicine, Florida; and [5]Institute for Health and Society, and [6]Department of Medicine, Medical College of Wisconsin, Milwaukee

Background. We aimed to determine the effect of the presence of carbapenem-resistant *Acinetobacter baumannii* in accordance with surveillance cultures on the subsequent development of clinical infections by this organism.

Methods. This retrospective cohort study was conducted at a tertiary hospital from January 2010 to November 2011. We included all consecutive patients admitted to the trauma intensive care unit, who had weekly surveillance cultures performed (from rectum, and if intubated, respiratory secretions), and without evidence of *A. baumannii* infections prior to the collection of the first surveillance culture. Univariable and multivariable analyses were performed using log-binomial regression. Survival analyses were performed using Cox proportional hazards.

Results. Three hundred sixty-four patients were included, of whom 49 (13.5%) had carbapenem-resistant *A. baumannii* on surveillance cultures. Patients with positive surveillance cultures had 8.4 (95% confidence interval [CI], 5.6–12.7; $P < .0001$) times the risk of developing a subsequent *A. baumannii* infection compared with patients who remained negative on surveillance cultures. Multivariable analysis showed significant associations between clinical infection and both positive surveillance cultures (relative risk [RR], 5.9 [95% CI, 3.8–9.3]; $P < .0001$) and mechanical ventilation (RR, 4.3 [95% CI, 1.03–18.2]; $P = .05$). On survival analyses, the only variable associated with the development of clinical infections was the presence of positive surveillance cultures (hazard ratio, 16.3 [95% CI, 9.1–29.1]; $P < .001$).

Conclusions. Presence of carbapenem-resistant *A. baumannii* on surveillance cultures is strongly associated with subsequent development of carbapenem-resistant *A. baumannii* infections. Prevention efforts should be focused at limiting the acquisition of this organism during hospitalization.

Keywords. *Acinetobacter baumannii*; carbapenem-resistant; surveillance cultures; clinical infections; intensive care unit.

Acinetobacter baumannii is a gram-negative coccobacillus, frequently identified as resistant to most commercially available antibiotics, including carbapenems [1–3]. In 2013, the Centers for Disease Control and Prevention (CDC) named carbapenem-resistant *A. baumannii* as one of the serious health threats for the US population. *Acinetobacter baumannii* is especially problematic in intensive care units (ICUs), and is associated with high morbidity and mortality as well as longer hospital stays [4,5]. Therefore, it is imperative to prevent the development of *A. baumannii* infections by identifying and modifying risk factors for these infections.

Patient-to-patient transmission of *A. baumannii* among hospitalized cases has been described in the literature and linked to contaminated hospital environment, suboptimal disinfection of communal objects,

and contaminated healthcare workers' hands [1, 6, 7]. Patients colonized with *Acinetobacter* carry this organism on their body surfaces and contaminate their immediate environment [8, 9]. Gowns, gloves, and hands of healthcare workers become contaminated after contact with either an *Acinetobacter*-positive patient or their contaminated environment [10]. Finally, being exposed to an environment contaminated with *A. baumannii* has been associated with a higher risk of acquiring this pathogen [11]. Therefore, interventions aimed at containing *Acinetobacter* outbreaks consist of a combination of surveillance cultures, hand hygiene, heightened environmental cleaning, and contact precautions [12].

In 2009, as part of a bundle of interventions designed to limit the spread of carbapenem-resistant *A. baumannii*, we implemented weekly surveillance cultures among consecutive admissions to our adult ICUs [12]. Subsequently, the trauma ICU (TICU) was identified as one of the units with the highest rates of acquisition of *A. baumannii* [13]. We used surveillance cultures to cohort *Acinetobacter*-positive patients, and the staff caring for them, within a section of an inpatient unit. However, we did not know the clinical implications of being an asymptomatic carrier of this multidrug-resistant pathogen. Thus, the primary aim of this study was to evaluate a cohort of patients admitted to TICU in order to characterize their differential risk of developing carbapenem-resistant *A. baumannii* infections based on the presence of this organism on surveillance cultures. Secondarily, we aimed to determine the effect of other covariates (comorbidities, antibiotic exposure, and invasive procedures) on the primary association, and explore the effect of time to positive surveillance cultures on primary and secondary associations.

METHODS

This was a retrospective cohort study conducted at a 1500-licensed-bed public teaching hospital in South Florida with a documented carbapenem-resistant *A. baumannii* endemicity [13]. Over the years, the unit with highest prevalence of this organism was the TICU, a 25-bed open-layout unit located in a freestanding trauma center. We evaluated all consecutive patients admitted to TICU from 1 November 2010 to 30 November 2011. During this period, the TICU had a monthly hospital acquired rate of carbapenem-resistant *A. baumannii* of 55.9 ± 8.95 cases per 10 000 patient-days [12]. This study was reviewed and approved, and informed consent was waived by the Institutional Review Board of the University of Miami Miller School of Medicine.

Since 2009, as part of a bundle of interventions, all adult ICUs performed surveillance cultures to rule out carriage of carbapenem-resistant gram-negative bacilli, including carbapenem-resistant *A. baumannii*. As previously described [14], surveillance cultures were performed on admission to the unit and weekly thereafter throughout ICU admission. Surveillance cultures included rectal swab cultures and, if mechanically ventilated, lower respiratory cultures. Samples were streaked in MacConkey agar plates with a 10-μg ertapenem disk and incubated overnight at 37°C. Colonies were selected based on color and morphology and final identification was performed using Vitek II [14].

A patient was considered to be *Acinetobacter*-positive on surveillance cultures if either rectal or respiratory secretions grew carbapenem-resistant *A. baumannii*. Patients excluded from the analysis included all subjects who failed to have at least 1 surveillance culture during their ICU stay or who failed to have surveillance cultures prior to the development of an *A. baumannii* infection. Carbapenem-resistant *A. baumannii* infections were defined using the CDC definitions [15]; these determinations were ascertained by 2 independent reviewers using the hospital's electronic medical records. Any discrepancy on determination of clinical infection was reviewed and discussed by the team to achieve a resolution. Additional information collected included demographics, comorbidities, and the use of mechanical ventilation.

Antibiotic exposures were obtained both as a composite of any antibiotic use ("any antibiotic") and as the exposure to individual antibiotic classes (eg, cephalosporins, carbapenems). For patients who remained negative on surveillance cultures, antibiotic exposures were collected from hospital admission until unit discharge, death, or development of first positive clinical culture, whichever occurred first. For patients with positive surveillance cultures, the initial exposure period expanded from admission to the hospital to the date of collection of first positive surveillance culture. The second period encompassed the time from first positive surveillance culture until unit discharge, death, or development of a carbapenem-resistant *A. baumannii* infection, whichever occurred first.

Statistical Analysis

This study was designed to test the association between surveillance cultures growing carbapenem-resistant *A. baumannii* (independent variable) and the subsequent development of clinical infections caused by the same organism (dependent variable). Baseline characteristics of the groups (age, sex, comorbidities, antibiotic exposure, invasive procedures) based on surveillance status were compared using χ^2 and Fisher exact tests for proportions, and Student *t* tests for continuous variables.

To obtain relative risks (RRs) rather than odds ratios, univariable and multivariable analyses were performed using log-binomial regressions. Variables included in the multivariable model were selected based on statistical significance obtained in univariable analyses ($P \leq .5$). The presence of multicollinearity

A53210128

Downloaded from https://academic.oup.com/cid/article/60/3/415/312715 by University of Edinburgh user on 02 June 2025

was explored for all significant antibiotic exposures prior to the building of multivariable models [16].

Cox proportional regression was used to include time-to-positive surveillance cultures. For these analyses, "time zero" was the time of admission to TICU. *Acinetobacter baumannii* infections were considered the "events." Patients who either died or were discharged from TICU before the development of the "event" were censored. Additionally, to account for the different risks of a patient to develop clinical infections during the periods before and after positive surveillance cultures, a time-dependent covariate was created using the date of first positive surveillance culture [17]. All analyses were performed using SAS software, version 9.3 (Cary, North Carolina).

RESULTS

During 13 months, 479 consecutive patients were admitted to TICU (Figure 1). Ninety-three patients were excluded due to lack of surveillance cultures; these 93 patients either failed to have orders for surveillance cultures or orders were entered incorrectly in the system (eg, "rule out vancomycin-resistant enterococci" rather than "rule out carbapenem-resistant gram-negative

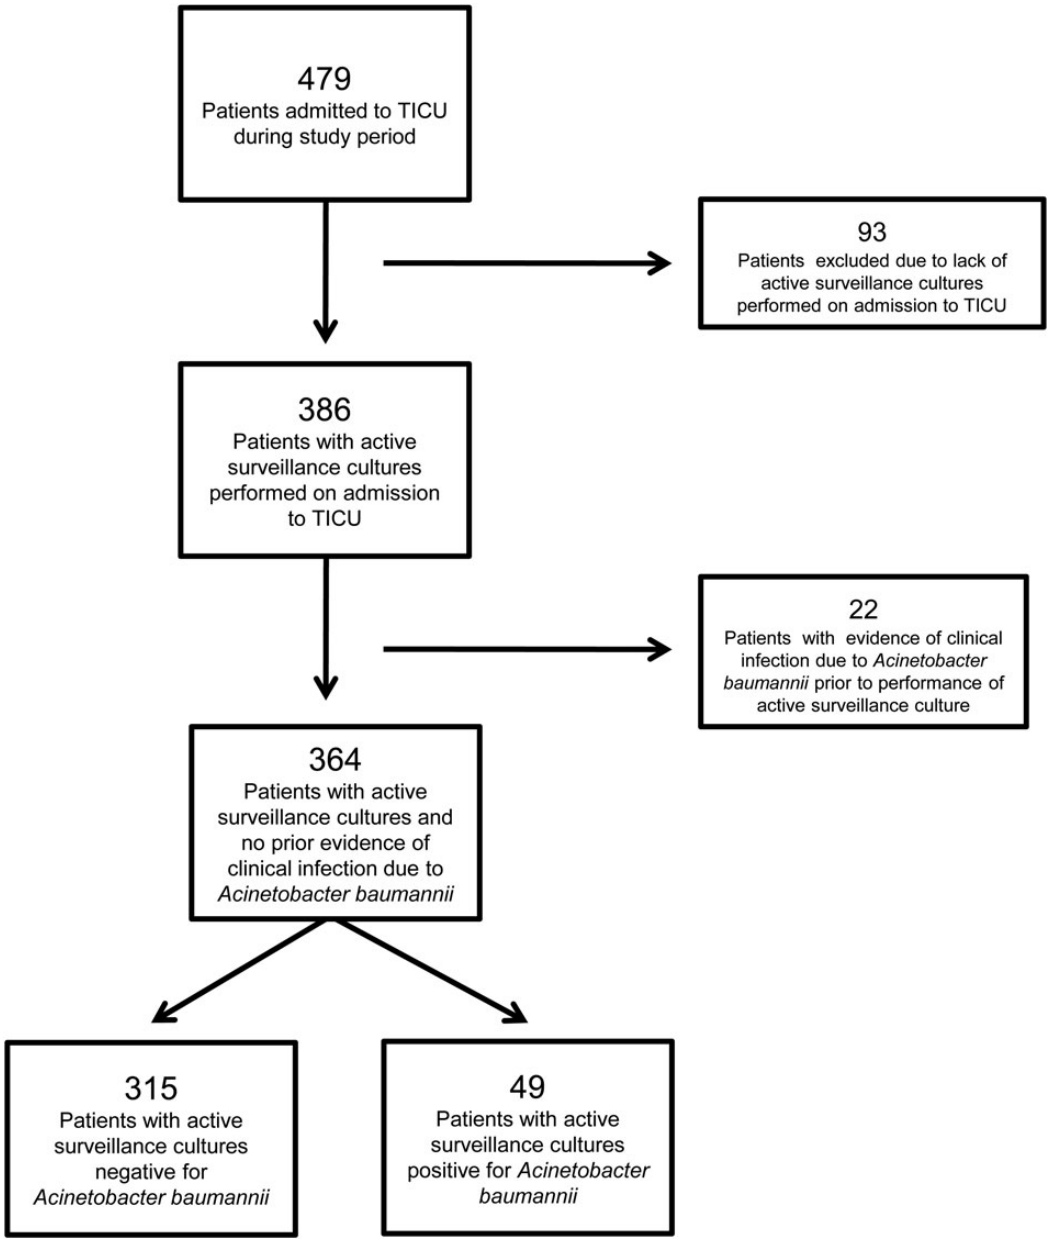

Figure 1. Patient selection flow algorithm. Abbreviation: TICU, trauma intensive care unit.

rods"). Twenty-two patients were excluded due to evidence of *A. baumannii* infections prior to their first surveillance culture. Three hundred sixty-four patients were included in the final analysis: 49 patients (13.5%) had positive surveillance cultures for carbapenem-resistant *A. baumannii*, and the remaining 315 patients (86.5%) had negative surveillance cultures throughout their ICU stay. Baseline characteristics of the groups based on the status of their surveillance cultures are displayed in Table 1. Variables found to be statistically different at baseline included sex (group with positive surveillance cultures had higher proportion of females; $P = .005$) and mechanical ventilation (all patients with positive surveillances were mechanically ventilated; $P < .0001$). Additionally, the group with positive surveillance cultures had greater exposure to antibiotics than the group that remained negative on surveillances ($P = .04$). In regard to specific antibiotic classes, the group with positive surveillance cultures had higher exposures to both vancomycin and carbapenems ($P = .003$ and $P < .0001$, respectively).

Carbapenem-resistant *A. baumannii* infections occurred in 60 of the 364 (16.5%) patients who underwent surveillance cultures. Twenty-eight patients (47%) developed ventilator-associated pneumonia, 22 (37%) had either primary or secondary bloodstream infection, 7 (12%) had urinary tract infection, 2 (3%) had intra-abdominal infection, and 10 (17%) had some combination of skin and soft tissue infection. Of the 60 patients with clinical infections, 34 (56.7%) had previously documented positive surveillance cultures. Table 2 describes the variables associated with the development of carbapenem-resistant *A. baumannii* infections. Patients with positive surveillance cultures had 8.4 times the risk (95% confidence interval [CI], 5.6–12.7; $P < .0001$) of developing carbapenem-resistant *A. baumannii* infections than patients who remained negative on surveillance cultures. Univariable analyses showed that sex, mechanical ventilation, and exposures to either carbapenem, aminoglycosides, vancomycin, or "any antibiotics" were associated with the development of clinical infection (Table 2). After controlling for other variables, only positive surveillance cultures (RR, 5.9 [95% CI, 3.8–9.3]; $P < .0001$) and being on mechanical ventilation (RR, 4.3 [95% CI, 1.03–18.2]; $P = .05$) were associated with the development of carbapenem-resistant *A. baumannii* infection (Table 2).

Cox proportional regression showed a high hazard for carbapenem-resistant *A. baumannii* infections among patients growing this organism on surveillance cultures (hazard ratio, 18.8 [95% CI, 10.8–32.8]; $P < .0001$; Table 3). Sex, mechanical ventilation, and exposure to cephalosporins were also significantly associated with the outcome. However, after adjusting for all significant variables, the only exposure that remained significant was the growth of carbapenem-resistant *A. baumannii* on surveillance cultures. At 30 days of admission to the unit,

Abbreviations: CI, confidence interval; DM, diabetes mellitus; RR, relative risk.

[a] Model for multivariable logistic regression included surveillance status, mechanical ventilation, sex, and exposure to any antibiotic (fit criteria Quasi-likelihood criterion [QIC] = 336).

[b] Patients with insufficient data to calculate a Charlson comorbidity score were removed for this analysis.

[c] Model for multivariable logistic regression included surveillance status, mechanical ventilation, sex, exposure to carbapenems, exposure to vancomycin, and exposure to aminoglycosides (fit criteria QIC = 336). In this model, surveillance status and mechanical ventilation remained significant ($P < .0001$ and $P = .05$, respectively).

the proportion of patients free of clinical infections among groups with positive and negative surveillance cultures was 0.50 (95% CI, .33–.76) and 0.89 (95% CI, .82–.97), respectively. Figure 2 shows the probability of remaining free of carbapenem-resistant *A. baumannii* infections based on results of surveillance cultures.

Table 3. Hazard Ratios for the Development of a Clinical Infection Due to *Acinetobacter baumannii*

	Univariable Analysis		Multivariable Analysis	
Variable	HR (95% CI)	*P* Value	HR (95% CI)	*P* Value
Surveillance culture, positive	18.8 (10.8–32.8)	<.0001	16.3 (9.1–29.1)	<.0001
Mechanical ventilation	6.1 (1.5–25.1)	.01	3.4 (.8–14.6)	.09
Charlson score >2	0.9 (.4–2.5)	.99		
Charlson score >5	1.5 (.4–6.1)	.58		
Male sex	0.6 (.3–.9)	.03	0.98 (.6–1.7)	.95
Age >50 y	0.9 (.5–1.6)	.79		
Exposure to penicillin	0.8 (.5–1.3)	.41		
Exposure to cephalosporins	0.5 (.3–.9)	.03	0.9 (.5–1.7)	.87
Exposure to quinolones	0.6 (.3–1.1)	.08		
Exposure to vancomycin	1 (.5–2.4)	.90		
Exposure to aminoglycosides	1 (.4–2.2)	.96		
Exposure to carbapenems	1.3 (.7–2.2)	.40		
Exposure to any antibiotic	0.7 (.2–2)	.52		

Antibiotic exposures spanned from hospital admission to development of clinical infection, discharge from unit, or death. Differential risks for development of clinical infections (ie, before and after positive surveillance cultures) were accounted for using a time-dependent variable within the model.

Abbreviations: CI, confidence interval; HR, hazard ratio.

DISCUSSION

This study characterizes the clinical implications of detecting carbapenem-resistant *A. baumannii* on surveillance cultures. We found that patients with positive surveillance cultures were 8 times more likely to develop carbapenem-resistant *A. baumannii* infections, even after controlling for other variables. Furthermore, among the group with positive surveillances, the median time for the development of carbapenem-resistant *A. baumannii* infections was approximately 30 days from ICU admission.

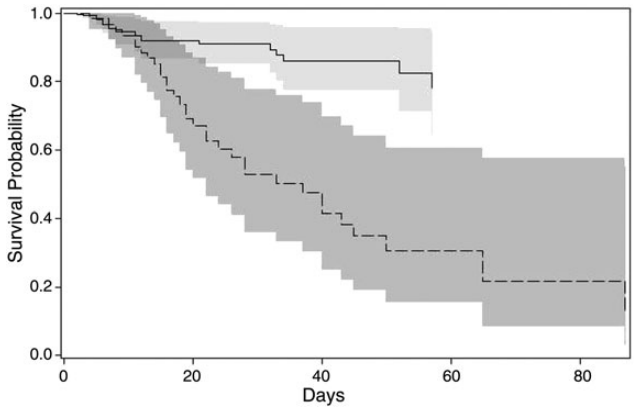

Figure 2. Survival curves with the probability to develop clinical infections with carbapenem-resistant *Acinetobacter baumannii* based on results of surveillance cultures. Curves represent the probability of staying free of clinical infection caused by carbapenem-resistant *A. baumannii*. Days represent the days from admission to the unit until the development of the outcome or censoring. Solid line represents the group that remained negative for carbapenem-resistant *A. baumannii* on surveillance cultures. Dashed line represents the group that became positive for carbapenem-resistant *A. baumannii* on surveillance cultures. Shaded area depict the 95% confidence intervals.

Prior studies have described the presence of colonization as a factor associated with the development of *A. baumannii* infections [18, 19]. Our results are in agreement with these conclusions; nevertheless, our findings are framed in the context of an active surveillance program within a retrospective cohort, thus ensuring that surveillance cultures, if positive, preceded the development of clinical infections.

Previously identified risk factors for the development of *A. baumannii* infections include mechanical ventilation [20], prior exposure to antimicrobials [20, 21], high Acute Physiology and Chronic Health Evaluation (APACHE II) score at the onset of infection [21], long duration of hospital stay, recent central venous catheter insertion [22], female sex [23], length of transducer catheter usage, and hyperalimentation [24]. In regard to antibiotic exposure, the definition of this variable is not unified across the literature, and its quantification differs across different studies [18, 19]. Our study collected antibiotic exposures as dichotomous variables across specified periods of time. Receipt of carbapenems, aminoglycosides, vancomycin, and the composite variable of any antibiotic exposure were associated with a greater risk of developing carbapenem-resistant *A. baumannii* infections. However, none of these variables were identified as independent risk factors on multivariable analyses. Previous

studies that found antibiotic exposures as risk factors for acquisition of *A. baumannii* quantified the use of antibiotics as either grams per time period [25], "unit pressure" [18], days of exposure [22], or dichotomous variables [20]. Additionally, severity of illness has been recognized as a risk factor for the development of *A. baumannii* infections [26], as well as a marker for poor prognosis [27, 28]. The Charlson comorbidity index was used in our cohort and failed to show an association with the development of clinical infections. In a previous study [11], higher Charlson comorbidity index was shown to be associated with lower risk of acquiring *A. baumannii* in ICU patients.

Limitations of this project include being a single-center study, where surveillance cultures were performed weekly rather than on a daily basis. Additionally, surveillance cultures are an insensitive method to detect carriage, predisposing to classification bias (high number of false negatives), although this would have skewed our results toward a nonsignificant association. Another caveat of our study is the lack of molecular typing of surveillance and clinical isolates; thus, we can only assume that surveillance and clinical isolates were related within individual patients. Moreover, antibiotic exposures were evaluated as dichotomous rather than continuous variables, lacking number of days and exact onset of exposure. This lack of time-dependent covariates for antibiotic exposures predisposes our analysis to immortal time bias [29], which could have overestimated the impact of antibiotics in our associations. Even though comorbidity index was used to categorize patients' comorbidities, acuity of illness (APACHE score) was not determined. APACHE II determination upon unit admission was not included given that the outcomes occurred many days after admission. Nevertheless, we admit that the lack of serial acuity of index scores for each individual patient is a major limitation of this study.

In conclusion, this study shows that positive surveillance cultures were strongly associated with the subsequent development of carbapenem-resistant *A. baumannii* infections. Furthermore, survival analyses demonstrated 16.3 times the risk to develop carbapenem-resistant *A. baumannii* infections among patients who grew this pathogen on surveillance cultures during their ICU stay. Surveillance cultures upon admission to ICUs are a valuable infection control tool [30] that should be used not only for cohorting patients but also as a signature marker for subsequent clinical infections. We now know that we should target prevention of acquisition of carbapenem-resistant *A. baumannii* (eg, infection control bundles, antibiotic stewardship, vaccination [31]) as well as focus our efforts on patients who are known to be colonized. The latter could include not only selective digestive decolonization [32] but, most importantly, manipulation of the gut or lung microbiome to prevent the progression of colonization to clinical infections [33]. Remaining questions that should be explored are the effect of antibiotic exposures treated as continuous variables and modeled as time-dependent covariates. The effect of timing of these exposures will allow us to establish the impact of antibiotics on the acquisition of *A. baumannii*, and also their subsequent effect on the development of clinical infections by this organism, especially among previously colonized patients. Establishing the timing of these associations is important, as it will further highlight the interdependence between acquisition of multidrug-resistant organisms and antibiotic use in our inpatient population.

A Review of the Research Literature on Evidence-Based Healthcare Design

Roger S. Ulrich, PhD; Craig Zimring, PhD; Xuemei Zhu, BArch, PhD Candidate; Jennifer DuBose, MS; Hyun-Bo Seo, MArch; Young-Seon Choi, MArch; Xiaobo Quan, PhD; and Anjali Joseph, PhD

Abstract

Objective: This report surveys and evaluates the scientific research on evidence-based healthcare design and extracts its implications for designing better and safer hospitals.
Background: It builds on a literature review conducted by researchers in 2004.
Methods: Research teams conducted a new and more exhaustive search for rigorous empirical studies that link the design of hospital physical environments with healthcare outcomes. The review followed a two-step process, including an extensive search for existing literature and a screening of each identified study for the relevance and quality of evidence.
Results: This review found a growing body of rigorous studies to guide healthcare design, especially with respect to reducing the frequency of hospital-acquired infections. Results are organized according to three general types of outcomes: patient safety, other patient outcomes, and staff outcomes. The findings further support the importance of improving outcomes for a range of design characteristics or interventions, including single-bed rooms rather than multibed rooms, effective ventilation systems, a good acoustic environment, nature distractions and daylight, appropriate lighting, better ergonomic design, acuity-adaptable rooms, and improved floor layouts and work settings. Directions for future research are also identified.
Conclusions: The state of knowledge of evidence-based healthcare design has grown rapidly in recent years. The evidence indicates that well-designed physical settings play an important role in making hospitals safer and more healing for patients, and better places for staff to work.
Key Words: *Evidence-based design, hospital design, healthcare design, healthcare quality, outcomes, patient safety, staff safety, infection, hand washing, medical errors, falls, pain, sleep, stress, depression, confidentiality, social support, satisfaction, single rooms, noise, nature, daylight*

Introduction

Background

A visit to a U.S. hospital is dangerous and stressful for patients, families, and staff. Hospital-acquired infections and medical errors are among the leading causes of death in the United States, each killing more people than automobile accidents, breast cancer, or acquired immune deficiency syndrome (AIDS) (Institute of Medicine [IOM], 2001; Klevens, et al., 2007a). The resulting yearly cost for U.S. hospitals is estimated to be $5 billion for hospital-acquired infections (Centers

HERD VOLUME 1, NUMBER 3, PP 61-125 COPYRIGHT ©2008 VENDOME GROUP, LLC

for Disease Control and Prevention [CDC], 2000) and $17- to $29 billion for medical errors (Kohn, Corrigan, & Donaldson, 1999). According to the IOM (2001) in its landmark *Crossing the Quality Chasm* report: "The frustration levels of both patients and clinicians have probably never been higher. Yet the problems remain. Health care today harms too frequently and routinely fails to deliver its potential benefits" (p. 1). Problems with U.S. healthcare not only negatively influence patients; they affect staff. Registered nurses have a turnover rate averaging 20% (Joint Commission, 2002).

At the same time, a major boom in hospital construction is occurring in the United States and several other countries. The U.S. healthcare system is facing the confluence of the need to replace aging 1970s' hospitals, population shifts, the graying of the Baby Boom generation, and the introduction of new medical technologies. As a result, the United States will spend more than $180 billion for new hospitals in the next 5 years alone, and healthcare construction is projected to exceed $70 billion per year by 2011 (Jones, 2007). These new hospitals will remain in place for decades.

This once-in-a-lifetime construction program provides an opportunity to rethink hospital design and especially to consider how better design can improve patient and staff outcomes. Just as medicine has increasingly moved toward *evidence-based medicine* where clinical choices are informed by research, healthcare design is increasingly guided by rigorous research linking hospitals' physical environments to healthcare outcomes, and it is moving toward *evidence-based design* (EBD) (Hamilton, 2003). For example, the Center for Health Design Pebble Project includes approximately 50 healthcare providers and manufacturers committed to using EBD for their construction projects. The Military Health System has adopted EBD for a $6 billion capital construction program for its 70 hospitals, which serve more than 9.2 million people worldwide. Kaiser Permanente and its partners in the Global Health and Safety Initiative are using EBD as a strategy to increase *triple safety* for patients, staff, and the environment. The Global Health and Safety Initiative comprises partners that provide over 100,000 hospital beds.

This report is an updated and expanded version of a 2004 report, "The Role of the Physical Environment in the Hospital of the 21st Century" (Ulrich, Zimring, Quan, Joseph, & Choudhary, 2004). Research teams from Texas A&M University and the Georgia Institute of Technology conducted a new and more extensive search for empirical studies linking the design of the physical environments of hospitals with healthcare outcomes. The following questions are explored in this study: (1) What can rigorous research tell us about "good" and "bad" hospital design? (2) Can improved design make hospitals less risky and stressful and promote more healing for patients, their families, and staff? (3) Is there scientifically credible evidence that design affects clinical outcomes and staff effectiveness in delivering care?

Methodology

This review followed a two-step process. First, we conducted key word searches to identify potentially relevant studies published in English. Thirty-two key words were used, referring to patient and staff outcomes (such as *infection*, *medical error*, *pain*, *sleep*, *depression*, *stress*, and *privacy*), physical environmental factors (*hospital*, *hospital units*, *healthcare facility*, etc.), and other healthcare-related issues (such as *patient-* and *family-centered* care). We conducted an extensive series of cross-searches using combinations of key words through the EBSCO research database, which enabled the simultaneous search of multiple databases, such as Academic Search Premier, Alt Healthwatch, MEDLINE, PsycArticles, Psychology and Behavioral Sciences Collection, PsycINFO, and CINAHL. In addition, a supplemental search was conducted through the ISI Web of Knowledge and Google Scholar. The search included any study that alluded or referred to the physical environment of healthcare buildings in the title or the abstract. We also obtained additional relevant studies from the reference lists of identified articles.

In the second stage, we screened all identified references using two criteria: First, the study should be empirically based and examine the influence of environmental characteristics on patient, family, or staff outcomes. Second, the quality of each study was evaluated in terms of its research design and methods and whether the journal was peer-reviewed.

 A53210128

Summary of Key Findings

We found a growing number of rigorous studies that help establish the relationship between the physical design of hospitals and key outcomes. This report was organized according to three general types of outcomes. The first section focuses on *patient safety issues*, such as infections, medical errors, and falls. The second section examines studies related to *other patient outcomes*, such as pain, sleep, stress, depression, length of stay, spatial orientation, privacy, communication, social support, and overall patient satisfaction. The third section surveys the scientific research relevant to *staff outcomes*, such as injuries, stress, work effectiveness, and satisfaction. Although these outcomes were also discussed in the 2004 report, this new study has substantially expanded the scale of most sections. In particular, the section on hospital-acquired infections has been substantially revised and expanded, reflecting the rising severity and importance of infections, the rapid growth of infection research, and the appearance of several new studies directly relevant to hospital design. The last section of the paper, Conclusions and Design Recommendations, summarizes the findings according to design characteristics or interventions and their implications for various outcomes.

Overall, this review confirms the importance of improving the healthcare outcomes associated with a range of design characteristics or interventions, such as single-bed rooms rather than multibed rooms, effective ventilation systems, a good acoustic environment, appropriate lighting, better ergonomic design, and improved floor layouts and work settings. Compared to 2004, the body of evidence has grown rapidly and substantially in recent years. This is encouraging given that the importance of EBD has increased markedly as the need for better healthcare facilities has grown and become more urgent. It is now widely recognized that well-designed physical settings play an important role in making hospitals less risky and stressful, promoting more healing for patients, and providing better places for staff to work.

However, it is also important to address the limitations of the quality of existing evidence. In medical fields, a *randomized controlled trial* or *experiment* is considered the strongest research design for generating sound and credible empirical evidence. Our literature review, however, found relatively few randomized controlled trials linking specific design features or interventions directly to impacts on healthcare outcomes. This is not very surprising, because most changes of the physical environment in healthcare settings alter several environmental factors simultaneously. This creates confounding variables and makes it difficult to disentangle the independent effect of the environmental change of primary interest. As an example, renovating an intensive care unit (ICU) with two-bed patient rooms to create single-bed rooms would likely alter not only the number of patients per room, but also the ratio of hand-washing sinks per bed and possibly the room ventilation or air quality. However, there are certain design interventions that may alter only one environmental factor, and the intervention can be assigned randomly to some patients but not others. Examples include exposing patients to interventions such as nature distraction, art, and reduced noise. In the case of these types of interventions, particularly nature distraction, our literature search identified a number of prospective randomized clinical trials that provide strong evidence. Additionally, we identified many moderately strong quasi-experimental studies, and some well-conducted epidemiological investigations. The largest category of studies consisted of observational studies with or without control groups.

Although many studies are not well controlled, the strength of evidence is enhanced by the fact that in the case of certain environmental factors, *reliable patterns of findings* across several studies emerged with respect to outcome influences. Furthermore, these patterns were broadly consistent with predictions based on established knowledge and theory concerning environment and healthcare outcomes. For example, many studies have consistently found that high noise levels in hospitals worsen patient outcomes such as sleep quality, physiological stress, and satisfaction. It is important to note that validity is strengthened when findings tend to be reliable or consistent and are in accord with a priori hypotheses or predictions derived from previous knowledge. Thus, we believe the application of such findings in EBD should be encouraged despite

HERD VOLUME 1, NUMBER 3, PP 61-125 COPYRIGHT ©2008 VENDOME GROUP, LLC

the shortage of randomized experimental trials. On the other hand, future research should be carefully designed and controlled so that the independent role of specific environmental changes or interventions can be better understood.

Different Ways of Reading This Report

This report is written for readers from different disciplines and professions, including architects, healthcare professionals, administrators, and researchers in EBD or healthcare-related fields. It covers a wide range of topics and surveys hundreds of studies and therefore makes an exceptionally long article. It is organized in a systematic way to accommodate the needs of different readers and to facilitate reading at different levels of detail and scope, including: (1) reading the entire article; (2) reading through the article more quickly by looking at the Summary of Evidence and Recommendations that appears at the beginning of each section; (3) reviewing the subtitles and thoroughly reading one or more individual sections on specific outcomes of interest; and (4) reading the last section of the paper, Conclusions and Design Recommendations, to extract major findings and recommendations organized according to specific design issues.

In addition, readers may notice instances of redundancy, where the same study has been cited in different sections. This is necessary because some characteristics of hospital physical environments (such as nature distraction and noise) influence multiple outcomes. Therefore, certain studies are cited in multiple sections, each focusing on a different outcome. Second, as mentioned previously, some readers may choose to read individual sections related to their specific interests. Cross-references would make reading difficult for such readers. To avoid this, some studies have been cited in more than one place in the article.

Result I: Improving Patient Safety Through Environmental Measures

Reducing Hospital-Acquired Infections

Summary of Evidence and Recommendations

One critically important way that EBD improves safety is by reducing the risk of hospital-acquired infections (i.e., nosocomial infections), a leading cause of death in the United States. One general conclusion supported by the infection literature is that the design of the physical environment impacts nosocomial infection rates by affecting all three major transmission routes—air, contact, and water. This discussion addresses the three transmission routes separately and is followed by a discussion of several advantages of single-bed rooms, as compared to multibed rooms, in controlling infection.

There is a pattern across scores of studies indicating that infection rates are lower when there is very good air and water quality, and greater physical separation, isolation, or space per patient. Concerning hand washing, there is evidence that providing accessible, alcohol-based hand-rub dispensers at the bedside can increase hand-washing compliance and thereby reduce contamination spread by contact.

The large amount of research literature reviewed in this section strongly supports the following design measures for controlling and preventing infection:

- Use effective air quality control measures during construction and renovation to prevent the outbreak of airborne infections. Measures include, for example, using portable high-efficiency particulate air (HEPA) filters, installing barriers between patient-care areas and construction/renovation areas, generating negative air pressure for construction/renovation areas relative to patient-care areas, and sealing patient windows.
- Install alcohol-based hand-rub dispensers at the bedside and in other accessible locations to increase hand-washing compliance and reduce contact transmission of infection.
- Select easy-to-clean floor, wall, and furniture coverings, and employ proper cleaning and disinfection procedures.
- Design and maintain the water system at the proper temperature and adequate pressure; minimize stagnation and back flow; eliminate dead-end pipes; regularly clean point-of-use fixtures; and consider the location of decorative fountains and carefully maintain them to minimize the risk of waterborne infection.

A53210128

- Provide single-bed rooms with private toilets to enable separation or isolation of patients on admission, so that those with unrecognized infections can be tested and identified without being mixed in with uninfected individuals in multibed rooms; to reduce airborne infection transmission by increasing isolation capacity and facilitating the maintenance of good air quality through measures such as effective ventilation, filtration, and appropriate air flow direction and pressure (positive or negative); and to facilitate thorough cleaning after a patient leaves, including the use of decontamination methods such as hydrogen peroxide vapor (HPV), which may be much more effective than conventional cleaning.

Hospital-Acquired Infections: A Serious and Growing Problem

Hospital-acquired infection is one of the leading causes of death in the United States. In 2002 alone, hospital-acquired infections in U.S. hospitals numbered approximately 1.7 million, and the number of associated deaths reached 98,987 (Klevens et al., 2007a). This means that approximately 1 of every 22 hospitalized patients acquired an infection. According to the CDC (2000), the cost of treating hospital-acquired infections is estimated to be $5 billion per year. Many hospital-acquired infections are drug resistant and difficult to treat and eradicate. Patients are especially vulnerable to these infections when they are immunocompromised or otherwise weakened by age, medical or surgical treatments, or underlying disease (Weinstein, 1998). The international trend toward increasing intensity of care and patient acuity (American Hospital Association, 2005) portends a future of greater patient vulnerability to infection.

The importance of controlling hospital-acquired infection is increasingly recognized by health authorities and the general public as a crucial dimension of healthcare quality. The CDC and Healthcare Infection Control Practices Advisory Committee (HICPAC) have issued guidelines for infection control in healthcare facilities (Sehulster et al., 2004). A telephone survey of a national sample of U.S. households found that 93% of respondents indicated that if information on hospital infection rates were provided, it would influence their selection of hospitals (McGuckin, Waterman, & Shubin, 2006).

This research team identified a very large amount of scientific research pertinent to understanding the influences of the hospital physical environment on infection transmission and control. Generally speaking, infection transmission occurs via three routes: *contact*, *air*, and *water*. Contact is widely considered the principal or most frequent transmission route. In reality, these three routes may intertwine with each other in the spread of nosocomial infections. Advances in molecular detection methods and sampling techniques for viruses, bacteria, and fungi have enabled researchers to identify the exact strain and source of infections, and thereby develop a better understanding of transmission.

Reducing Infections Caused by Airborne Pathogens

Airborne transmission refers to infections that are contracted from airborne micro-organisms. Reservoirs for airborne pathogens range from dust (e.g., spores of *Clostridium Difficile* or *C. Diff.* and *Aspergillus*) to aerosol droplets (e.g., tuberculosis [TB], severe acute respiratory syndrome [SARS], influenza, chickenpox), to skin scales shed by patients infected with methicillin-resistant *Staphylococcus aureus* (MRSA) (Ulrich & Wilson, 2006). Airborne transmission has also been implicated in outbreaks of other infections such as *Acinetobacter spp*. and *Pseudomonas spp.* (Beggs, 2003; Beggs, Kerr, Snelling, & Sleigh, 2006). The relative importance of airborne transmission remains somewhat controversial (Bauer, Ofner, Just, Just, & Daschner, 1990). Brachmans's early study (1970) estimated that airborne transmission accounted for 10–20% of nosocomial infections. Beggs (2003) argued that the role of airborne transmission may have been underestimated, due to the difficulty of culturing many airborne organisms and the complexities of assessing the role such pathogens play in the contamination of environmental surfaces and subsequent contact transmission. Recently airborne infections have attracted more attention due to outbreaks of SARS in 2002–2003 and current concerns about an avian influenza (H5N1) pandemic. A few extensive research reviews have been conducted, notably Li et al.'s review (2007) on the relationship between ventilation systems and airborne transmission; Tang, Li, Eames,

HERD VOLUME 1, NUMBER 3, PP 61-125 COPYRIGHT ©2008 VENDOME GROUP, LLC

Chan, and Ridgway's report (2006) on airborne infection and ventilation control in healthcare settings; and Beggs' review (2003) on the importance of airborne transmission in healthcare-acquired infections.

This literature survey identified many studies that explicitly examine the relationships between airborne infections and environmental factors in healthcare buildings. There is a pattern of findings across these studies suggesting that hospital air quality plays a decisive role in affecting the concentration of pathogens in the air, and thereby has major effects on the frequency of airborne infectious diseases such as TB, aspergillosis, chickenpox, influenza, and SARS. The research also clearly indicates that multiple environmental approaches or interventions can be effective in controlling and preventing airborne infections. Though a sizable amount of sound research is available, data on certain aspects of air quality and infection are insufficient to permit the precise specification of, for example, minimum ventilation and filtration requirements for certain patient groups and treatment spaces (Li et al., 2007), or the maximum tolerable level of spores per cubic meter (Bouza et al., 2002) for the prevention of airborne transmission.

Sources and Environmental Routes of Airborne Infections

Airborne pathogens originate from different sources. Most pathogens in healthcare settings originate from patients, staff, and visitors within the buildings, from such sources as infected patients' respiratory tracts or skin squamae (scales). Other pathogens can enter buildings from *outside air* through dust that harbors pathogens such as *aspergillus*, *streptococci*, or *staphylococci* (Beggs, 2003). There are also less common sources of airborne infections; for example, bird droppings or aerosols from contaminated water in a warm-water therapy pool (Angenent, Kelley, St Amand, Pace, & Hernandez, 2005).

Several environmental factors and conditions have been identified as frequent sources of airborne infection outbreaks. The malfunction or contamination of ventilation systems and lack of cleaning and maintenance are commonly cited (Kumari et al., 1998; Lutz, Jin, Rinaldi, Wickes, & Huycke, 2003; McDonald et al., 1998; Schultz et al., 2003). In one MRSA outbreak, for example, the ventilation grilles in two patient bays were found to be harboring MRSA (Kumari et al., 1998). On occasions when this ventilation system was shut down, it sucked air from the ward environment into the system, contaminating the outlet grilles then it blew contaminated air back into the ward when the system was restarted. Additionally, several studies have identified hospital construction and renovation activities as the sources of airborne infection outbreaks due to dust or particulate generation (Humphreys et al., 1991; Iwen, Davis, Reed, Winfield, & Hinrichs, 1994; Loo et al., 1996; Opal et al., 1986; Oren, Haddad, Finkelstein, & Rowe, 2001).

Environmental Approaches for Reducing Airborne Infections

The research literature strongly supports implementing several environmental approaches for controlling and preventing airborne infections, including installing effective filters, specifying appropriate ventilation systems and air change rates, employing various control measures during construction or renovation, and using single-bed rooms instead of multibed rooms to increase isolation capacity and reduce transmission from infected patients. Also, limited research suggests that measures such as the use of ultraviolet irradiation can be effective in reducing airborne pathogens (Griffiths, Bennett, Speight, & Parks, 2005) and lowering the incidence of asthma in asthmatic children's homes (Bernstein et al., 2006).

High-efficiency particulate air (HEPA) filters. An effective way to control infections is to control their source. Filtration, the physical removal of particulates from air, is often the first step in ensuring good air quality. One experimental study of a commercial air purification system found that a chemical-coated filter demonstrated 61.46% efficiency in destroying pathogens and reached 99.99% efficiency when used in conjunction with ultraviolet lamps (Griffiths et al., 2005). In acute healthcare settings, a commonly used approach is the HEPA filter, which can be at least 99.97% efficient for removing particulates as small as 0.3 μm in diameter (as a reference, *Aspergillus* spores

A53210128

are 2.5 µm to 3.0 µm in diameter) (Sehulster et al., 2004). This is adequate for most healthcare settings in ambulatory care facilities and hospitals, including operating rooms (ORs) (Sehulster et al., 2004). Boswell and Fox's study (2006) revealed a significant reduction in environmental contamination by MRSA with the use of portable HEPA units in a clinical setting. In the CDC/HICPAC guidelines, the use of HEPA filtration is recommended for healthcare facilities, and it is either required or strongly recommended for all construction and renovation areas (Sehulster et al., 2004).

There is strong evidence that immunocompromised and other high-acuity patients have a lower incidence of infection when housed in HEPA-filtered isolation rooms. Bone-marrow transplant recipients in one study showed a 10-fold greater incidence of nosocomial *Aspergillus* infection when they were assigned beds outside a HEPA-filtered environment with *laminar airflow* (LAF), as compared to similar patients housed in a HEPA-filtered unit (Sherertz et al., 1987). A strong multisite study by Passweg and colleagues (1998) found that the use of HEPA and/or LAF reduced infections, decreased transplant-related mortality, and increased survival for leukemia patients after bone marrow transplant.

Ventilation systems and airflow control. After air is filtered, effective ventilation systems are needed to achieve optimal ventilation rates, airflow patterns, and humidity so that the spread of infections can be minimized. First, *ventilation rate* is an important measure to control indoor air quality. In healthcare facilities, it is usually expressed as room air changes per hour (ACH), where peak efficiency for particle removal in the air space often occurs between 12 ACH and 15 ACH. In a study of SARS infections, wards with the highest ventilation rate had a significantly lower infection rate among healthcare workers as compared with other wards (Jiang et al., 2003). A study of 17 Canadian hospitals found that the risk of healthcare workers acquiring TB was strongly linked with exposure to infected patients in rooms with low ACH rates, such as waiting areas (Menzies et al., 2000). Detailed ventilation standards are provided by the American Institute of Architects (AIA) and Facilities Guidelines Institute (FGI) in the *Guidelines for Design and Construction of Health Care Facilities* (AIA & FGI, 2006), and by the American Society of Heating, Refrigerating and Air-conditioning Engineers (ASHRAE) in *ASHRAE 62.1-2004—Ventilation for Acceptable Indoor Quality* (ASHRAE, 2004). Yet questions remain regarding the minimum ventilation requirements needed for effective prevention of infections (Li et al., 2007).

A second key aspect of ventilation is *airflow direction.* Negative pressure is preferred for rooms housing infectious patients to prevent the dispersion of pathogen-laden aerosols, dust, and skin scales from the locus of the infected patient to other spaces. Importantly, a review of 40 studies by Li et al. (2007) concluded that there is strong evidence to support and recommend the use of negatively pressurized isolation rooms. By contrast, if a care space houses an immunocompromised patient (e.g., surgical patients, patients with underlying chronic lung disease, or dialysis patients) or immunosuppressed patients (e.g., transplant patients or cancer patients), positive airflow pressure is desirable to safeguard them from aerial pathogens entering from adjacent spaces.

Finally, an exceptionally effective ventilation approach for maintaining indoor air quality is to use LAF, which is HEPA-filtered air blown into a room at a rate of 90 ± 10 feet/min in a unidirectional pattern with 100–400 ACH (Sehulster et al., 2004). When combined with HEPA filters, LAF can reduce air contamination to the lowest level; thus it is recommended for ORs and areas with ultraclean room requirements, such as those housing immunocompromised patients (Alberti et al., 2001; Arlet, Gluckman, Gerber, Perol, & Hirsch, 1989; Dharan & Pittet, 2002; Friberg, Ardnor, Lundholm, & Friberg, 2003; Hahn et al., 2002; Sherertz et al., 1987). A prospective cohort study found that the type of operating theater ventilation was an independent risk factor for the incidence of sternal surgical site infections (Yavuz et al., 2006). New theaters with LAF and automatically closing doors showed significantly better results in reducing infections than older theaters with conventional plenum ventilation.

Effective air quality control measures during construction and renovation. It is extremely important to employ effective control and prevention measures

HERD VOLUME 1, NUMBER 3, PP 61-125 COPYRIGHT ©2008 VENDOME GROUP, LLC

during construction and renovation, because such activities have been frequently implicated in outbreaks of airborne infection. Examples of such measures include using portable HEPA filters, installing barriers between patient-care areas and construction/renovation areas, generating negative air pressure for construction/renovation areas relative to patient-care areas, and sealing patient windows. Strong evidence indicates that using HEPA filters for air intakes near construction and renovation sites has positive effects on air quality and reduces the risk of infection for patients (Bouza et al., 2002; Cornet et al., 1999; Loo et al., 1996; Mahieu, De Dooy, Van Laer, Jansens, & Ieven, 2000; Opal et al., 1986; Oren et al., 2001). For example, a study conducted during extensive hospital construction and renovation documented an outbreak of invasive pulmonary aspergillosis (IPA) among acute leukemia patients housed in wards with natural ventilation, soaring to an infection rate of 50% (Oren et al., 2001). At this point some patients were moved to a hematology ward with HEPA filters. During the following 3 years, none of the patients hospitalized in the hematology ward developed IPA, although 29% of leukemia patients housed in the regular ward contracted aspergillosis. However, one strong study demonstrated that HEPA filters were not by themselves an adequate control measure during construction; they should be employed in conjunction with other measures such as sealing windows and installing barriers (Humphreys et al., 1991). It was noted earlier that the combination of LAF and HEPA filtration is capable of reducing air contamination to the lowest level. During construction or renovation activities, however, LAF is more expensive and especially difficult to achieve, because furnishings and other features can create turbulence. There is currently a lack of cost-benefit research to enable well-founded evaluations of the expense versus effectiveness of LAF for patient-care areas near construction and renovation sites.

Reducing Infections Spread by Contact

Although airborne transmission poses serious safety risks, contact contamination is generally recognized as the principal transmission route of nosocomial infections, including pathogens such as MRSA, *C. difficile*, and vancomycin-resistant enterococci (VRE), which survive well on environmental surfaces and other reservoirs (Bauer et al., 1990; IOM, 2004). The prevention of contact-spread infections is of paramount importance in healthcare settings.

Sources and Environmental Routes of Contact-Spread Infections

Environmental routes of contact-spread infections include direct person-to-person contact and indirect transmission via environmental surfaces. *Healthcare workers' hands* play a key role in both direct and indirect transmissions. A staff member may touch two patients in succession without washing his or her hands, or touch an environmental surface or feature after direct contact with an infected patient. Other staff and the patient may then acquire the pathogen by touching the same surface (Ulrich & Wilson, 2006). Research indicates that there is an inverse causal link between the hand-washing compliance rate of healthcare workers and contact transmission of infectious diseases (Larson, 1988, 1999). It is well established that hand hygiene is the most important single measure for preventing the spread of pathogens in healthcare settings (Boyce & Pittet, 2002).

In this context, the fact that hand-washing compliance rates are often low represents a very serious challenge to patient safety. Mallaret et al. (1998) reviewed 38 studies and reported that compliance rates were usually less than 40%. In more recent studies, compliance rates were still low, with most ranging between 20% and 35%; rates above 40% or 50% are the exception (Albert & Condie, 1981; Graham, 1990; Kuzu, Ozer, Aydemir, Yalcin, & Zencir, 2005; Larson, Albrecht, & O'Keefe, 2005; Randle, Clarke, & Storr, 2006; Saba et al., 2005; Sacar et al., 2006; Trick et al., 2007). Compliance rates usually are lower for indirect contact (through environmental surfaces) than for direct person-to-person contact (McArdle, Lee, Gibb, & Walsh, 2006). There is a pattern that compliance is worse in high-acuity units such as ICUs, because patient care in these units is often more demanding than in lower-acuity units (Karabay et al., 2005). Meanwhile, guidelines require staff to clean their hands more frequently when caring for sicker patients (Karabay et al., 2005). Hand hygiene tends to be especially poor in units that are busy due to understaffing and/or a high bed-occupancy

rate or patient census (Archibald, Manning, Bell, Banerjee, & Jarvis, 1997). High bed-occupancy rates have been identified as a factor contributing to higher rates of infections such as MRSA (Borg, 2003).

Furthermore, *environmental surfaces* in healthcare settings often become extensively contaminated by nearby patients or by healthcare workers' contaminated hands. Boyce, Potter-Bynoe, Chenevert, and King (1997) found that in rooms housing patients infected with MRSA, 27% of all environmental surfaces sampled were contaminated. Meanwhile, 42% of nurses who had no direct contact with MRSA patients but who had touched environmental surfaces contaminated their gloves with MRSA. Other research reports even higher levels of MRSA surface contamination (74%) in spaces previously occupied by colonized or infected patients (French et al., 2004). The same study found MRSA contamination in 100% of patient rooms sampled, regardless of whether or not the previous occupant had been infected. Furthermore, patient rooms can become contaminated with more than one type of MRSA, suggesting prolonged survival of MRSA strains from prior room occupants (French et al., 2004). It is not surprising that the risk of acquiring antibiotic-resistant infections such as MRSA and VRE is significantly increased if a patient is admitted to a room previously occupied by an infected individual (Huang, Datta, & Platt, 2006).

Because many nosocomial pathogens can survive on environmental surfaces for weeks or months (Bonilla, Zervos, & Kaufman, 1996; Kramer, Schwebke, & Kampf, 2006), such contaminated surfaces act as pathogen reservoirs and can become the source of infection outbreaks (Boyce et al., 1993; Lankford et al., 2006). Many of these environmental surfaces and features have direct relevance to architectural design, including floors (Anderson, Mackel, Stoler, & Mallison, 1982; Beyer & Belsito, 2000; Boyce et al., 1997; Skoutelis, Westenfelder, Beckerdite, & Phair, 1994), work surfaces or furniture such as chairs (Noskin, Bednarz, Suriano, Reiner, & Peterson, 2000), bed privacy curtains (Palmer, 1999), door handles (Roberts, Findlay, & Lang, 2001), sink faucets (Blanc et al., 2004; Bures, Fishbain, Uyehara, Parker, & Berg, 2000), bedside rails, over-bed tables, bed linens and patients' gowns (Boyce et al., 1997), clinical waste carts (Blenkharn, 2006), computer keyboards (Bures et al., 2000), bedside patient files (Panhotra, Saxena, & Al-Mulhim, 2005), and even toys in healthcare settings (Fleming & Randle, 2006; Merriman, Corwin, & Ikram, 2002). Other very frequently contaminated surfaces and objects include medical equipment such as infusion pumps (Aygun et al., 2002), blood pressure cuffs (Boyce et al., 1997), laryngoscope blades (Beamer & Cox, 1999), stethoscopes (Marinella, Pierson, & Chenoweth, 1997), and electronic ear-probe thermometers (Porwancher et al., 2001). The pervasiveness of such contamination underscores the importance of hand- and workplace hygiene in healthcare settings (Wilson & Ridgway, 2006; Ulrich & Wilson, 2006).

Environmental Approaches to Reduce Contact-Spread Infections

The research literature supports the effectiveness of certain environmental approaches for controlling and preventing contact-spread infections. Examples of such approaches include providing sufficient and accessible alcohol-based hand-rub dispensers, choosing easy-to-clean furniture and wall finishes, and providing single-rooms rather than multibed rooms.

Reducing contact transmissions by increasing hand-washing compliance. Education programs to increase hand-washing compliance alone have yielded, at best, mixed results (Bischoff, Reynolds, Sessler, Edmond, & Wenzel, 2000). Some investigations have found that education interventions generate no increase in hand washing. Even intensive education or training programs, such as classes and group feedback, may produce only transient increases in hand washing (Dorsey, Cydulka, & Emerman, 1996; Dubbert, Dolce, Richter, Miller, & Chapman, 1990). Recently, multifaceted interventions, in addition to education, have been more successful at increasing hand washing. These interventions include environmental measures such as providing localized availability of alcohol-rub dispensers and using posters as reminders to staff (Creedon, 2005; Gordin, Schultz, Huber, & Gill, 2005; Johnson et al., 2005; Lam, Lee, & Lau, 2004; Pittet et al., 2000; Randle et al., 2006; Trick et al., 2007).

HERD VOLUME 1, NUMBER 3, PP 61-125 COPYRIGHT ©2008 VENDOME GROUP, LLC

There is mounting evidence that the *type* of hand-washing facility influences hand-washing compliance and infection rates. Compared with traditional soap and water, alcohol-based hand-rub acts more rapidly and effectively, requires less time for staff to decontaminate their hands adequately, and has a lower risk of side-effects and recontamination (Boyce & Pittet, 2002). The CDC/HICPAC guidelines define alcohol-based hand-rub as the standard of care for hand hygiene practices in healthcare settings (Boyce & Pittet, 2002). Several studies have shown that the introduction of alcohol-based hand-rub boosted hand-washing compliance (Hugonnet, Perneger, & Pittet, 2002; Johnson et al., 2005; Trick et al., 2007). Importantly, several other studies supported the effectiveness of alcohol-based hand-rub, compared to soap and water, for improving the effectiveness of hand washing in terms of reducing microbial counts on hands (Bischoff et al., 2000; Cohen, Saiman, Cimiotti, & Larson, 2003; Girou, Loyeau, Legrand, Oppein, & Brun-Buisson, 2002; Graham, 1990; Karabay et al., 2005; Tvedt & Bukholm, 2005) and reducing infection rates (Gordin et al., 2005). MacKenzie and colleagues (2007) analyzed MRSA prevalence in more than 100 hospitals across Europe and found that the use of alcohol-based hand-rub was the single most important predictor of lower MRSA incidence after adjusting for other confounding factors. These findings have implications for designers, because alcohol-based hand-rub dispensers are small and inexpensive, and they do not require costly plumbing systems and sinks. These characteristics afford more flexibility than soap-and-water facilities, which in turn facilitates the distribution of dispensers to more locations, closer to patient-care activities and work spaces, thereby making them more accessible to busy clinicians and other staff.

The *number* and *accessibility* of hand-washing facilities also influence compliance and infection rates. In particular, the evidence suggests that installing alcohol-based hand-rub dispensers at the bedside usually improves adherence. Four studies examined the impact of multifaceted interventions that prominently included the provision of bedside alcohol-based hand-rub dispensers, and all demonstrated significant improvements in hand-washing compliance (Bischoff et al., 2000; Creedon, 2005; Pittet et al., 2000; Randle et al., 2006). Another study made a statistical adjustment for other known risk factors of poor hand-washing adherence; the positive effects of the intervention remained significant and were accompanied by decreased infection rates (Pettit et al., 2000). In an observation study, researchers compared the 3 years after the installation of alcohol-based hand-rubs in all rooms with the 3 prior years with fewer soap-and-water sinks; they observed a 21% decrease in MRSA infections and a 41% decrease in VRE infections. Although hand-washing compliance was not measured in this study, it is likely that it may have played a role in this improvement. In contrast to the effectiveness of locating hand-rub dispensers at the bedside, Muto, Sistrom, and Farr (2000) found that installing dispensers in hallway locations (near the doors to patient rooms) did not significantly increase the frequency of hand washing. Other investigations focusing on traditional sinks (soap-and-water) have obtained mixed results concerning the impact of increasing the number and accessibility of sinks, with a few studies reporting positive impacts (Kaplan & McGuckin, 1986); one finding a transient increase in compliance (Whitby & McLaws, 2004); and other studies reporting no significant changes (Lankford et al., 2000, 2003; Vernon, Trick, Welbel, Peterson, & Weinstein, 2003).

Automated technology has also been examined for its impact on hand-washing compliance for soap-and-water sinks and alcohol-based hand-rub dispensers. For traditional soap-and-water hand washing, automated sinks or faucets have shown mixed results (Larson et al., 1991; Larson, Bryan, Adler, & Blane, 1997). Simplicity of use seems to be important to the success of automation. In this regard, limited research suggests that automated touch-free alcohol-based rub dispensers are easy to use and are used more frequently than manual dispensers (Larson, Albrecht, & O'Keefe, 2005). Swoboda, Earsing, Strauss, Lane, and Lipsett (2004) examined the effect on compliance of an automatic system that monitored entries and exits from patient rooms, recorded usage of sinks and alcohol-based hand-rub dispensers, and incorporated voice-prompt devices that reminded healthcare workers and visitors to wash their hands. The system improved hand-cleaning com-

pliance from 19% to 27% and was associated with a reduction in the nosocomial infection rate.

There are some limitations, however, in current hand-washing research knowledge. Because many studies have employed multifaceted interventions, it is not clear how much of the effectiveness of increased hand washing, reduced microbial counts, or reduced infection rates can be attributed to the installation of more numerous and/or accessible alcohol-based hand-rub dispensers. Future research should include prospective controlled experiments, for example, that systematically vary the number and location of alcohol hand-rub dispensers. There is also a conspicuous need for studies that define accessible locations for hand-washing facilities in an evidence-based manner—that is, on the basis of empirical analysis of staff movement paths, visual fields, interactions with patients and families, and work processes. In this regard, the neglect of human factors and research methods are major weaknesses of hand-washing research and of the infection control literature in general. Research teams should include a human factors specialist and sometimes an environmental psychologist. The urgent need to increase hand-washing frequency underscores the high priority that should be accorded to this research direction.

Reducing contact transmission by controlling surface contamination. As previously mentioned, contaminated environmental surfaces often serve as an intermediate step in the contact spread of infections. Several design-related factors should be considered to minimize the risk of infection stemming from contaminated surfaces.

Selection of *appropriate floor and furniture coverings* is an important step, where ease of cleaning should be a key consideration. Some studies have examined flooring materials (Anderson et al., 1982; Skoutelis et al., 1994) and furniture coverings (Lankford et al., 2006; Noskin et al., 2000) as they relate to environmental contamination in healthcare settings. The use of *carpet* can be a controversial issue. On one hand, many people believe that carpet is more difficult to clean than hard floor coverings (Harris, 2000). A few studies have identified carpeting as susceptible to contamination by fungi and bacteria (Anderson et al., 1982; Beyer & Belsito, 2000; Boyce et al., 1997; Skoutelis et al., 1994). However, a recent rigorous study suggests that certain serious pathogens such as VRE survive less well or for shorter periods on carpet than on other floor coverings, including rubber tile, linoleum, vinyl sheet goods, and vinyl composition tile (Lankford et al., 2006). In addition to discovering that carpet harbors less VRE, this research found that carpeting transferred less VRE to hands via contact than rubber and vinyl flooring and performed as well in cleaning as any other floor covering tested (Lankford et al., 2006). There is limited research comparing the air above carpeted areas and hard flooring with respect to concentrations of micro-organisms, and the findings are conflicting. Anderson et al. (1982) found higher concentrations above carpeted areas, whereas Harris (2000) reported higher particulate concentrations above hard flooring.

In summary, the advantages and disadvantages of carpeting versus other floor coverings with respect to infection control are neither clear-cut nor fully resolved. However, in judging different floor coverings, it should be kept in mind that carpeting, compared to hard floorings, offers important advantages unrelated to infection control, including noise reduction (Philbin & Gray, 2002), greater ease of walking and perceived safety for the elderly (Wilmott, 1986), a possible reduction in falls (Counsell et al., 2000), longer family visits in patient rooms, and more positive evaluations and emotional responses from patients and families (Harris, 2000).

It is worth mentioning that CDC/HICPAC guidelines do not recommend against the use of carpeting in patient-care areas. However, the guidelines suggest that carpeting should be avoided in areas where spills are likely to occur or where patients are at greater risk of airborne infections (Sehulster et al., 2004). Similarly, the EBD standards for neonatal intensive care units (NICUs) of the National Perinatal Association state that suitable flooring materials "include resilient sheet flooring (medical grade rubber or linoleum) and carpeting with an impermeable backing, heat- or chemically welded seams and antimicrobial and antistatic properties. Carpeting has been shown to be an accept-

HERD VOLUME 1, NUMBER 3, PP 61-125 COPYRIGHT ©2008 VENDOME GROUP, LLC

able floor covering in the hospital and the NICU and has obvious aesthetic and noise reduction (NR) appeal, but it is not suitable in all areas (e.g., around sinks or in isolation or soiled utility/holding areas)" (White, 2006, p. S12).

The selection of *furniture-covering materials* may also influence the incidence of contamination and risk of infection. Noskin et al. (2000) identified fabric-covered furniture as a source of VRE infection in hospitals and suggested the use of easily cleanable, nonporous material. Another study compared the performance of a variety of furniture upholstery types with respect to VRE and *Pseudomonas aeruginosa* (PSAE) contamination (Lankford et al., 2006). Performance was similar across different furniture coverings in terms of reductions in VRE and PSAE after cleaning and the transfer of VRE and PSAE to hands through contact. However, for the ability to harbor pathogens, although upholstery types showed no differences with respect to PSAE, there was a difference related to VRE. Vinyl upholstery performed the best for VRE—that is, the VRE pathogen survived less well or for shorter periods on vinyl (Lankford et al., 2006). In addition, as with evaluating carpeting and other floor coverings, it is worth considering that fabric-covered furniture might foster a more home-like, less institutional feeling. The CDC/HICPAC guidelines for upholstery are broadly similar to those for carpeting in that they do not recommend against using it in patient-care areas, but they suggest minimizing its use in areas housing immunocompromised patients (Sehulster et al., 2004).

A limited amount of research has compared different *wall finishes* and *metals* with respect to their infection control properties. One study evaluated the effectiveness of copper, brass, and stainless steel surfaces in reducing the viability of air-dried deposits of MRSA (Noyce, Michels, & Keevil, 2006). The results suggested that copper had a better antimicrobial effect than stainless steel. The use of antimicrobial metals such as copper may not reduce the need for careful cleaning, however, because dirt or dust on their surfaces may diminish or eliminate their antimicrobial effects. Lankford and colleagues (2006) compared the performance of different wall finishes (latex paint with eggshell finish, microperforated vinyl, vinyl with nonwoven backing, and Xorel® wall covering), and reported that all harbored VRE and were capable of transferring the pathogen through hand contact. No reduction in VRE was found 7 days after inoculation for two of the wall products—Type II microvented vinyl with paper backing and Xorel® wall covering—indicating that harboring was a greater problem than for other wall products tested. Latex paint with eggshell finish performed worse in cleaning and disinfection than other wall finishes, indicating that cleaning produced inadequate reduction of VRE and PSAE (Lankford et al., 2006).

Proper cleaning and disinfection is another very important step in preventing the spread of infections by contact. The limited and conflicting nature of research on environmental surface materials poses a perplexing challenge to designers attempting to select materials to help control infection. It appears that for each general category of surfaces—flooring, upholstery, and wall finishes—no single material has yet been identified that consistently outperforms others across diverse performance criteria (e.g., harboring, capacity to transfer) and for different pathogens. This underscores the importance of selecting materials that are easily cleaned and of proper cleaning and disinfection procedures (Aygun et al., 2002; Barker, Vipond, & Bloomfield, 2004; Dettenkofer, Wenzler, et al., 2004; French et al., 2004; Griffiths, Fernandez, & Halcomb, 2002; Hota, 2004; Martinez, Ruthazer, Hansjosten, Barefoot, & Snydman, 2003; Neely et al., 2005; Wilson & Ridgway, 2006). As noted, some research suggests that latex paint with eggshell finish does not perform adequately in cleaning/disinfection for VRE and PSAE (Lankford et al., 2006). Detailed cleaning recommendations for environmental surfaces are available in the CDC/HICPAC Guidelines (Sehulster et al., 2004).

Notwithstanding the importance of cleaning, there is alarming evidence indicating that conventional cleaning techniques often do not adequately eliminate contamination by serious pathogens such as MRSA and *C. difficile*. This problem has led infection control researchers to investigate the effectiveness of alternative decontamination methods or technologies, notably hydrogen peroxide vapor (HPV). French and colleagues

(2004) conducted a prospective study of multibed patient rooms contaminated with MRSA in the United Kingdom, assigning six rooms to be cleaned using conventional methods and six similar rooms using HPV. Before cleaning, 70% of 359 sample swabs from the study rooms yielded MRSA. An important and disturbing finding was that following conventional cleaning, 66% of swabs taken from rooms decontaminated by traditional methods yielded MRSA, indicating that conventional cleaning failed to remove most MRSA contamination. By contrast, following HPV cleaning only 1.2% of swabs yielded MRSA, indicating that HPV was a far more effective method for decontaminating patient rooms (French et al., 2004). Another British study by Jeanes, Rao, Osman, and Merrick (2005) found that even after an exceptionally intensive three-day period of deep cleaning using traditional methods (detergent, steam cleaning, chlorine disinfectant), 16% of surfaces sampled in a Nightingale ward were still cultured with MRSA. Following HPV decontamination of the Nightingale ward, however, no MRSA at all was cultured from surfaces. These studies support the effectiveness of HPV cleaning and have implications for hospital architecture, because a key consideration in employing HPV is that no patients or staff can be in a room during the process of vapor decontamination. Accordingly, the use of HPV in multibed rooms or open bays necessitates temporarily removing all patients from the space, shutting and sealing the space for several hours, and disrupting patient care and flow. By comparison, evacuating persons from single-bed rooms following patient discharge poses little hindrance to using HPV.

Reducing Waterborne Infection Transmission

Compared with airborne and contact transmission of infection, fewer studies were identified on waterborne transmission in relation to hospital design factors. The literature nonetheless makes it clear that waterborne infections can be a serious threat to patient safety. Many bacterial and some protozoal micro-organisms can proliferate or remain viable in moist environments or aqueous solutions in healthcare settings (Sehulster et al., 2004). Anaissie, Penzak, and Dignani (2002) reviewed studies between 1966 and 2001 on waterborne nosocomial infections caused by micro-organisms other than *Legionella*. The review identified 43 reported outbreaks and an estimated 1,400 deaths each year in the United States alone resulting from waterborne nosocomial pneumonia caused by *Pseudomonas aeruginosa*. A study of 115 randomly selected dialysis facilities in the United States detected nontuberculous mycobacteria in 83% of centers (Carson et al., 1988). Contaminated water systems in healthcare settings (such as inadequately treated wastewater) may lead to the pollution of municipal water systems, enter surface or ground water, and affect residents (Iversen et al., 2004).

Sources and Environmental Routes of Waterborne Transmission

The CDC/HICPAC guidelines (Sehulster et al., 2004) identify the following categories of environmental routes or sources of waterborne transmission: (1) direct contact, such as hydrotherapy (Angenent et al., 2005); (2) ingestion of water, such as drinking water (Conger et al., 2004; Squier, Yu, & Stout, 2000); (3) inhalation of aerosols dispersed from contaminated water sources, such as improperly cleaned or maintained cooling towers, showers (Mineshita, Nakamori, Seida, & Hiwatashi, 2005), respiratory therapy equipment, and room air humidifiers; and (4) aspiration of contaminated water.

Environmental Approaches to Reduce Waterborne Infection Transmission

Based on our literature review, the following environmental approaches that aid in controlling and preventing waterborne infections were identified.

Water supply system. The water supply system should be designed and maintained with proper temperature and adequate pressure; stagnation and back flow should be minimized; and dead-end pipes should be avoided (AIA and FGI, 2006; Sehulster et al., 2004). To prevent the growth of Legionella and other bacteria, the CDC/HICPAC guidelines recommend that healthcare facilities maintain cold water at a temperature below 68°F (20°C), store hot water above 140°F (60°C), and circulate hot water with a minimum return temperature of 124°F (51°C) (Sehulster et al., 2004). When the recommended standards cannot be achieved because of inadequate facilities that cannot be renovated,

HERD VOLUME 1, NUMBER 3, PP 61-125 COPYRIGHT ©2008 VENDOME GROUP, LLC

other measures such as chlorine treatment, copper-silver ionization, or ultraviolet lights are recommended to ensure water quality and prevent infection (Sehulster et al., 2004). For example, in a university hospital where endemic nosocomial legionellosis was present and all previous disinfection measures had failed, the implementation of a copper-silver ionization system substantially decreased environmental colonization by Legionella, and the incidence of nosocomial legionellosis decreased dramatically (Modol et al., 2007). The review by Anaissie and colleagues (2002) recognized the potential severity of waterborne infections and recommended that high-risk patients should not be exposed to tap water, but should use sterile water instead.

Point-of-use fixtures. Water fixtures such as sinks, faucets, aerators, showers, and toilets have been identified as potential reservoirs for pathogenic microorganisms (Blanc et al., 2004; Conger et al., 2004; Mineshita et al., 2005; Squier et al., 2000). Such fixtures produce aerosols that can disperse microbes, and they have wet surfaces on which molds and other microorganisms can proliferate. However, empirical evidence linking these fixtures to nosocomial infections is still limited; no consensus has been reached regarding the disinfection or removal of these devices for general use (Sehulster et al., 2004). Regular cleaning, disinfection, and good maintenance should be provided, especially in areas housing immunocompromised patients.

Decorative fountains in healthcare settings. Decorative fountains increasingly are being used by designers for healthcare facilities, because they can serve as landmarks and wayfinding elements as well as positive distractions that reduce stress (Joseph, 2006). The infection control departments of some hospitals may oppose the installation of fountains out of concern for the possible generation of infectious aerosols. However, Rogers' review (2006) found no empirical study linking a waterborne infectious disease or nosocomial outbreak to the indoor placement of a water fountain or water feature in hospitals. The only related case was an outbreak of Legionnaires' disease among a group of older adults in a hotel. The source was traced to a fountain in the lobby, which was not regularly maintained and which was heated by underwater lighting (Hlady et al., 1993). Despite the absence of empirical documentation linking properly maintained fountains to hospital-acquired infections, the AIA & FGI Guidelines (2006) recommend that fountains not be installed in enclosed spaces in hospitals.

Reducing Multiroute Transmission by Means of Single-Bed Rooms and Increased Isolation

Thus far the three routes of infection transmission have been examined and discussed separately. In reality, these three routes often intertwine, and environmental approaches may influence more than one transmission route. This research team has found credible evidence for the multiroute impact of single-bed rooms and increased isolation in infection control. Therefore, we have opted to present this information in a separate section instead of within the previous sections addressing individual transmission routes.

Several literature review articles have supported the association between single-bed rooms and reduced infection rates, including Dettenkofer, Seegers, et al.'s (2004) review on the relationship between architectural design and nosocomial infections and Chaudhury, Mahmood, and Valente's review (2005) on the advantages and disadvantages of single- versus multibed accommodations. Also, Calkins and Cassella (2007) surveyed research on nosocomial infections in nursing homes and similarly concluded that private bedrooms reduce the risk of infection as compared to shared bedrooms. The present review conducted a broader, updated survey and analysis, and evaluated not only environment-infection *associations*, but also the underlying *mechanisms* that could plausibly account for these associations.

Effect of single-bed rooms in reducing airborne infection. Because infected patients carry airborne pathogens into patient rooms and nursing units, it is important to ensure sufficient isolation capacity for such patients to prevent the spread of pathogens. Providing single-bed rooms increases isolation capacity; facilitates filtration, ventilation, and airflow control (e.g., negative room pressurization); and by these well-established measures or mechanisms, it plays a key role in preventing a patient with an aerial-spread infection from infecting others and protects immunocompro-

A53210128

mised patients in nearby rooms from airborne pathogens. As might be expected, studies of cross-infection for contagious airborne diseases (such as influenza, TB, measles, and chickenpox) have revealed that placing patients in single rooms (Ben-Abraham et al., 2002), single-bed cubicles with partitions (Gardner, Court, Brocklebank, Downham, & Weightman, 1973), isolation rooms (Mulin et al., 1997), or rooms with fewer beds and more space between patients (McKendrick & Emond, 1976) is safer than housing them in multibed spaces with more patients. Vonberg and Gastmeier (2005) reviewed literature on the isolation of cystic fibrosis patients, for whom respiratory tract infections contributed markedly to morbidity and mortality. They found in 31 out of 39 studies that cross-infection of *Pseudomonas aeruginosa* had been halted by isolating patients. Research on burn patients and other vulnerable or immunosuppressed patient groups provides strong evidence that single rooms in combination with air filtration substantially reduce the incidence of infection and mortality (McManus, Mason, McManus, & Pruitt, 1994; Passweg et al., 1998; Shirani et al., 1986). In a study of nursing homes, Drinka, Krause, Nest, Goodman, and Gravenstein (2003) found that roommates of persons infected with influenza had a 3.07 higher relative risk of acquiring the illness than did individuals assigned to single-bed rooms.

Although MRSA is spread mainly by contact, it has been known for decades that patients with *Staphylococcus aureus* infections shed skin scales contaminated with the pathogen, which become suspended throughout the air in rooms and which can spread the infection to other patients sharing that space. Lidwell et al. (1970) documented a significantly reduced rate of nasal acquisition of *Staphylococcus aureus* for patients in single-bed rooms than for those in multibed rooms. Shiomori and colleagues (2002) found that in rooms with a MRSA patient, the air concentration of MRSA-contaminated skin scales reached 116 per cubic foot, representing an added risk of airborne transmission to uninfected patients.

The SARS outbreaks in Asia and Canada highlighted dramatically the failings of multibed rooms for controlling or preventing infections among both patients and healthcare workers. SARS is transmitted by droplets that can be airborne over a limited area. The point should be emphasized that SARS in Canada was predominantly a *hospital-acquired*—not a community-acquired—infection, because approximately 75% of SARS cases resulted from exposure in hospital settings (Farquharson & Baguley, 2003). In Canadian and Asian hospitals, the pervasiveness of multibed spaces in emergency departments (EDs) and ICUs worsened SARS cross-infection. Furthermore, the scarcity of isolation rooms with negative pressure was a serious obstacle to implementing effective treatment and control measures. Toronto hospitals were forced, on a crisis basis, to construct hard wall partitions with doors to replace curtain partitions between beds in multibed spaces, and to implement airflow and pressure adaptations in EDs and ICUs to create many additional negative-pressure isolation rooms with HEPA filtration (Farquharson & Baguley, 2003).

Effect of single-bed rooms in reducing contact transmission. The use of single-bed rooms instead of multibed rooms also helps to control infections spread by contact. Single-bed rooms can *facilitate cleaning and decontamination*. As discussed earlier, many surfaces and features near infected patients quickly become contaminated, creating numerous reservoirs that can transfer pathogens to patients and staff. Given the vital importance of cleaning for the removal of contamination, one advantage of single-bed rooms compared to multibed rooms is that they are easier to clean and decontaminate thoroughly after a patient is discharged. In certain countries, when a patient has been discharged from a multibed room, cleaning staff are not permitted to clean electrical equipment or anything attached to other patients remaining in the space, thus increasing the risk of cross-infection (Ulrich & Wilson, 2006). Scrupulous cleaning of double rooms, or the four-bed and six-bed spaces prevalent in many countries, often entails the disruptive and costly temporary removal of all patients from these rooms. In addition, as mentioned in an earlier section, even when conventional cleaning methods are used according to prescribed protocols or the manufacturers' instructions, extensive contamination by pathogens such as MRSA still remains on surfaces (French et al., 2004; Jeanes et al., 2005). If more

HERD VOLUME 1, NUMBER 3, PP 61-125 COPYRIGHT ©2008 VENDOME GROUP, LLC

effective cleaning techniques such as HPV are used, multibed rooms present additional challenges because all patients in the room must be transferred to other spaces during the vaporization treatment.

Single-patient rooms may also help to *improve hand-washing* compliance and thereby contribute to infection control. Some studies offer evidence that when all single-bed rooms are furnished with a conveniently located sink in each, the nosocomial infection rates in ICUs and burn units diminish, as compared to when the same staff and comparable patients are in multibed open units with few sinks (Goldmann, Durbin, & Freeman, 1981; McManus et al., 1994; McManus, McManus, Mason, Aitcheson, & Pruitt, 1985; Mulin et al., 1997). Although these studies did not measure hand-washing frequency, the investigators posited that increased hand washing was an important factor in reducing infections in the units with single-patient rooms and more sinks.

In several studies documenting the positive association between single-bed rooms and reduced infection rates, the reduction in contact transmission (such as via reduced contamination of surfaces) was not directly measured, but it might have played an important role, based on previous knowledge. For example, MRSA is spread mainly by contact. Single-bed rooms appeared to reduce or prevent MRSA infections compared to multibed rooms in various healthcare settings, including 212 ICUs across Germany (Gastmeier, Schwab, Geffers, & Ruden, 2004), 173 hospitals across Europe (MacKenzie et al., 2007), a U.K. hospital with 1,100 beds (Wigglesworth & Wilcox, 2006), and a NICU in the United States (Jernigan, Titus, Groschel, GetchellWhite, & Farr, 1996). Also, having a roommate has been identified as a risk factor for nosocomial diarrhea and gastroenteritis (Chang & Nelson, 2000; Pegues & Woernle, 1993). Ben-Abraham and colleagues (2002) found that nosocomial infection frequency was much lower in a single-bed pediatric intensive care unit (PICU) than in a unit with multibed rooms and comparable patients, and they tentatively concluded that single-bed rooms helped to limit the person-to-person spread of pathogens among patients. Although the pattern of results across studies on balance strongly suggests that single rooms reduce infection, Preston, Larson, and Stamm's (1981) finding is anomalous in that it found single-bed ICU isolation rooms were associated with only a slight, insignificant reduction in infection rates compared to multibed rooms.

Several deadly outbreaks of *C. difficile* in North American and European hospitals and thorough published investigations have underscored powerfully the threat to patient safety posed by multibed rooms. A highly virulent infection characterized by diarrhea and colitis, in several countries *C. difficile* causes more deaths than MRSA. The infection is spread mainly by contact, and *C. difficile* spores can be viable for months on environmental surfaces (Kramer, Schwebke, & Kampf, 2006). Two outbreaks in the United Kingdom at two National Health Service hospitals have caused approximately 40 deaths (Healthcare Commission, 2006) and 90 deaths (Healthcare Commission, 2007), respectively. The investigations in these hospitals identified a predominance of multibed rooms with shared toilets, and a scarcity of single rooms with private toilets as key factors that prevented the timely isolation of patients and contributed to the spread of *C. difficile* and the duration and high mortality of these outbreaks (Healthcare Commission, 2006, 2007). Another study has also reported that single-bed isolation helped prevent the spread of *C. difficile* (Malamou-Ladas, O'Farrell, Nash, & Tabaqchali, 1983).

Single rooms, admission, and proactive separation of patients. Providing a high proportion of single rooms in hospitals conveys a major safety advantage, because it enables *separation of patients upon admission* and makes it possible to prevent cross-infection from unrecognized carriers of pathogens (Ulrich & Wilson, 2006). Even if patients are screened for MRSA, *C. difficile*, or other pathogens immediately upon admission, processing test results often requires two or three days, during which time environmental surfaces in the rooms of infected patients quickly become extensively contaminated, creating pathogen reservoirs that will be touched by staff and possibly by patients (e.g., French et al., 2004). Accordingly, assigning an unidentified carrier initially to a multibed room height-

ens the risk of cross-infection. By the time test results revealing that the patient is colonized or infected are available, it may be too late to isolate the individual, because transmission to one or more roommates may already have occurred. A prospective study by Cepeda et al. (2005) screened patients for MRSA when they were admitted and placed in multibed rooms in the ICUs of two London hospitals. Patients who proved to be MRSA-positive (after a 3-day delay for testing) were assigned either to be moved into isolation or to remain in their multibed rooms. Findings indicated that moving patients to single-bed rooms after testing positive for MRSA did not reduce cross-infection to other patients (Cepeda et al., 2005), supporting the interpretation that the contamination of surfaces and/or the spread of the infection to roommates occurred in the period prior to isolation.

Single-bed rooms may also help manage the *growing problem of community-acquired infection*. MRSA and other serious multidrug resistant infections are no longer confined to healthcare settings, but are increasingly widespread and endemic in communities internationally. According to a study by the U.S. CDC, 13.7% of MRSA infections in 2005 originated in the community (Klevens et al., 2007b). Another 58.4% of MRSA infections in the United States were *community-onset*, or manifested themselves outside the hospital, but had a healthcare link, such as a patient history of surgery, hospitalization, or residence in a long-term care facility. Hospital-onset MRSA infections accounted for only 26.6% of the cases. These findings imply that mounting numbers of people admitted to the hospital as inpatients, or who visit EDs or ambulatory clinics for care, will be carriers of serious community-acquired or community-onset infections. The difficult and escalating infection control challenge for hospitals that is posed by community-acquired and community-onset infections is reflected, for example, in the fact that MRSA has become the most common cause of skin and soft-tissue infections among patients presenting to EDs in U.S. cities (Moran et al., 2006). Furthermore, the growing trend toward the spread of antibiotic-resistant pathogens in communities will inevitably continue as sicker, more vulnerable patients are cared for at home or in long-term care facilities, and as they receive frequent and prolonged courses of antibiotics (Ulrich & Wilson, 2006). Against this background, in the future hospitals may need to screen and assign all inpatients to single rooms upon admission to prevent infections from spreading to other patients. Apart from MRSA, the spread of infections such as *C. difficile* in communities implies that single rooms with toilets and good air quality will increasingly be needed in EDs and outpatient surgery clinics as well as in inpatient units.

Reducing Medical Errors

Summary of Evidence and Recommendations

Like hospital-acquired infections, medical errors pose serious threats to patient safety. This research team identified several rigorous studies linking environmental factors with medical errors. The limited literature shows that medical errors are not caused only by the mistakes of a few individuals, but by a combination of both people and the environment, and that environmental approaches can play an important role in reducing errors.

Environmental factors discussed in relation to medical errors include *noise*, *light*, and *acuity-adaptable*, *single-patient rooms*. There is limited evidence that prescription error rates increase sharply when there is an interruption or distraction from an unpredicted noise (e.g., a telephone call) (Flynn et al., 1999; Kistner, Keith, Sergeant, & Hokanson, 1994). Poor lighting levels can also affect the performance of healthcare workers and lead to medical errors. One study has shown significantly lower rates of medication-dispensing errors when the lighting level for work surfaces is sufficiently high (Buchanan, Barker, Gibson, Jiang, & Pearson, 1991). Further, as demonstrated by empirical studies (Hendrich, Fay, & Sorrells, 2002, 2004), the use of acuity-adaptable rooms can substantially reduce possible sources of medical error (such as transfers, delays, communication discontinuities among staff, loss of information, and changes in computers or systems), and thereby lower error rates. Additional research is needed to further confirm the findings of limited previous studies, and to identify ways to design better working environments that may reduce or prevent medical errors.

HERD VOLUME 1, NUMBER 3, PP 61-125 COPYRIGHT ©2008 VENDOME GROUP, LLC

Severity and General Causes of Medical Errors

The IOM (1999) estimates that 44,000 to 98,000 people die each year of preventable medical errors, based on annual percentages derived from two major studies and the annual hospital admissions rate of 1997. Even the lower estimate is more than the number of annual deaths caused by motor vehicle accidents (43,458), breast cancer (42,297), or AIDS (16,516). The report also draws attention to the total cost of medical errors in addition to the lives lost (including the expense of additional care necessitated by the errors, lost income and household productivity, and disability), which is estimated to range between $17 billion and $29 billion per year in hospitals nationwide (Kohn, et. al., 1999).

Medical errors can include a range of adverse events, including physical errors made during surgical procedures, incorrect diagnoses, and medication errors. Errors are generally triggered by a combination of active failures and latent conditions. *Active failures* are caused by the unsafe performance of caregivers or by the system through lapses, mistakes, and procedural violations. *Latent conditions* are established by designers, builders, and top level management and they make errors more likely. Examples of latent conditions caused by management include work overload, staff shortage, and inexperience with working conditions. Latent conditions related to design include noise, lack of space, and other design failures.

Impact of Noise on Medical Errors

Unpredictable loud noise can distract people and interrupt their performance. A large number of studies have documented the negative impact of noise on workers' performance in nonhealthcare settings, and unpredictable noises disrupt task performance more than predictable ones. Additionally, noise has a greater negative impact when tasks are more complicated (Leather, Beale, & Sullivan, 2003). The combination of unpredictable noise and complicated tasks can increase errors in calculation, tracking, and monitoring tasks, and lead to slower learning and poor memorization (Sundstrom & Sundstrom, 1986).

However, these findings have not been fully explored yet in healthcare settings. A number of studies investigated the contribution of auditory factors, such as high levels of ambient noise (80 dB–85 dB), different types of music (classical or rock), and auditory distractions in the occurrence of surgical and diagnostic errors (Goodell, Cao, & Schwaitzberg, 2006; Moorthy, Munz, Undre, & Darzi, 2004; Sanderson et al., 2005; Zun & Downey, 2005) and found no significant evidence of their effects. However, most of these studies have been conducted in experimental settings by carrying out simulated tasks and/or with simulated noises. Additional research is needed to test the impact of different auditory factors under real-life conditions.

There is some evidence regarding the impact of interruptions or distractions on medication dispensing errors by hospital pharmacists (Flynn et al., 1999; Kistner et al., 1994). They found that error rates for prescriptions increased sharply when there was an interruption or distraction, including unexpected noises (e.g., a telephone call).

Impact of Lighting Level on Medical Errors

Many studies in nonhealthcare settings have demonstrated that performance and errors can be affected by lighting level as well as noise. Such poor performance in healthcare settings may lead to medical errors. Sundstrom and Sundstrom (1986) found that visual inspection task performance declined when light is not bright enough. A large-scale study in pharmacy examined the effects of different illumination levels on pharmacists' prescription-dispensing errors, and it strongly suggested that the frequency of such errors was reduced when work-surface light levels were relatively high (Buchanan et al., 1991). It evaluated the error rate under three different illumination levels, including 450 lux, 1,100 lux, and 1,500 lux. Results showed that medication-dispensing error rates were significantly lower (2.6%) at an illumination level of 1,500 lux, compared to an error rate of 3.8% at 450 lux.

Reducing Patient Transfers by Means of Acuity-Adaptable Rooms

The transfer of patients between rooms or units is a source of medical error (Cook, Render, & Woods, 2000; Ulrich & Zhu, 2007). Reasons for these errors

A53210128

include delays, communication discontinuities among staff, loss of information, and changes in computers or systems. A possible solution is to create an acuity-adaptable care process and to provide patient rooms that substantially reduce transfers. When the Methodist Hospital in Indianapolis, Indiana, changed its coronary ICUs from two-bed rooms to acuity-adaptable single-bed rooms, transfers were reduced by 90% and medication errors were lowered by 67% (Hendrich, Fay, & Sorrells, 2002, 2004). Reducing transfers also saves staff time, shortens patient stays, and reduces cost (IOM, 2004). Single-patient rooms, even nonacuity-adaptable ones, have been associated with better staff communication, less patient transfer, fewer medical errors, and lower infection rates as compared to multibed patient rooms (Chaudhury, Mahmood, & Valente, 2006). Additional studies and demonstration projects are needed to ascertain the safety advantages of acuity-adaptable, single rooms for other types of units and patient categories.

Reducing Patient Falls

Summary of Evidence and Recommendations

There is a large literature that examines the causes and risk factors involved in patient falls in hospitals. This is an area of great importance, because patients who fall incur physical injuries and adverse psychological effects and have greater lengths of stay in the hospital (Brandis, 1999). Among elderly persons (more than 65 years old), most falls occur in hospitals and nursing homes, where the rate of falls reaches 1.5 per bed annually, which is almost three times the rate for community-dwelling elderly persons (American Geriatrics Society, 2001). It is estimated that the total cost of fall injuries for older people was $20.2 billion per year in the United States in 1994, and that it would reach $32.4 billion (in 1994 U.S. dollars) in 2020 (Chang, Morton, Rubenstein, & Mojica, 2004).

Although the role of the environment in causing or preventing patient falls is widely accepted, there is no conclusive evidence linking environmental interventions with reduced falls. Studies have sought to identify the design issues that might have contributed to falls (such as the placement of doorways, handrails, and toilets), but no studies have compared different design options to determine the independent impact of a single design factor on the incidence of falls. One study has provided some promising findings, suggesting that decentralized nurse stations can reduce falls; but more research in more rigorous studies is needed to confirm these findings and to identify all the variables involved. Several studies have clearly shown that despite a popular misconception, bedrails do not reduce the rate of falls and can, in fact, increase the severity of falls.

Causes and Locations of Patient Falls

Previous studies have examined the locations of fall incidents retrospectively or discussed environmental-modification programs, such as improving lighting, securing carpeting, and so on. However, a meta-analysis and systematic review of randomized controlled trials of fall-prevention interventions found that there was no clear evidence for the independent effectiveness of environmental-modification programs (Chang et al., 2004). Nonetheless, several studies have indicated that most patient falls occur in the bedroom, followed by the bathroom, and that comprehensive fall-prevention programs can have a positive effect. Brandis (1999) reported transfers to and from bed as the cause of 42.2% of inpatient falls. In another study, a group of researchers analyzed 1-year fall data (267 falls), and reported that 38% of the falls occurred during transfers to and from bed and 16.1% during toileting (Tan et al., 2005). Brandis (1999) reported design shortcomings in the bathroom and bedroom areas, including slippery floors, inappropriate door openings, poor placement of rails and accessories, and inappropriate heights of toilet and furniture. After the fall-prevention program (which included identification of high-risk patients, management strategies, environmental and equipment modification, and standardization) was implemented, there was an overall decrease in falls of 17.3%. Thus, fall-prevention strategies that include environmental modification have worked in the past. But it is not clear how much the effectiveness of such strategies can be attributed to environmental factors alone.

Unit Configuration

An innovative and promising environmental strategy for reducing falls has its origins in evidence that suggests that many falls occur when patients attempt to

HERD VOLUME 1, NUMBER 3, PP 61-125 COPYRIGHT ©2008 VENDOME GROUP, LLC

get out of bed unassisted or unobserved (Uden, 1985; Vassallo, Azeem, Pirwani, Sharma, & Allen, 2000). To facilitate the observation of patients and the provision of timely assistance, Methodist Hospital in Indianapolis, Indiana, renovated a coronary critical care unit from centralized nurse stations with two-bed rooms to decentralized nurse stations with large single-bed rooms. These changes resulted in families being present more often and therefore being available to help patients or call for aid when needed, in addition to other positive impacts (Hendrich et al., 2002, 2004). A comparison of data from 2 years prior and 3 years after the renovation showed that falls were cut by two-thirds—from six falls per thousand patients to two per thousand. Given that falls are a critical safety problem, additional research is needed to understand more completely the effectiveness of this approach and its implications for designing safe patient-care units that reduce patient falls.

Bedrails

Although there is a common conception that bedrails prevent falls and reduce injuries, there is considerable evidence demonstrating that bedrails are *ineffective* for reducing falls and may actually increase the severity of injuries caused by falls from bed (Capezuti, Maislin, Strumpf, & Evans, 2002; Hanger, Ball, & Wood, 1999; Leeuwen, Bennett, West, Wiles, & Grasso, 2001; Talerico & Capezuti, 2001; Tan et al., 2005). Examining the one-year incident reports from a 730-bed university teaching hospital, a group of researchers found that 55% of the restrained falls resulted in injury; 11.8% of bed-area falls and 27.8% of all bedside injuries were associated with bedrails (Tan et al., 2005). They also found that the restrained falls resulted in more severe injuries. In his commentary on the outcomes of bedrail use, O'Keefe (2004) cited the high rates of deaths within the bedrail-related incident reports of the U.S. Food and Drug Administration (228 deaths from 1985 to 1999), the Medical Devices Bureau of Canada (25 deaths from 1980 to 2000), and the Medical Devices Agency in the United Kingdom (15 deaths from 1995 to 2000), to further underline that bedrail use can lead to deaths.

Other studies on inpatient falls have focused on the factors associated with patients' physical, mental, medical, or cognitive conditions. Most of these studies examined the development and/or application of protocols for identifying risk factors for patient falls and corresponding interventions for their prevention, including organizational-, educational-, and practice-related interventions (Chang et al., 2004; Hendrich, 2003; Lyons, 2005; McCarter-Bayer, Bayer, & Hall, 2005; Stenvall et al., 2006; Suzuki et al., 2005; Walker, 2004).

Result II: Improving Other Patient Outcomes Through Environmental Measures

Reducing Pain

Summary of Evidence and Recommendations

Pain is a pervasive and serious problem in hospitals. However, it is encouraging that mounting scientific evidence, including that from prospective randomized controlled studies, has shown that exposing patients to nature can produce substantial and clinically important alleviation of pain (Malenbaum, Keefe, Williams, Ulrich, & Somers, 2008; Ulrich, Zimring, Quan, & Joseph, 2006; Ulrich, 2008). Limited research also suggests that patients experience less pain when exposed to higher levels of daylight in contrast to lower levels of daylight in their hospital rooms. The state of knowledge on the environment-pain relationship has grown to the point where a leading international pain research journal recently published an article that emphasizes the importance of designing healthcare facilities to harness *nature*, *light*, and other environmental factors to enhance pain control (Malenbaum et al., 2008).

Regarding design measures to reduce pain, the research implies that patient rooms should be designed with large windows so that bedridden persons suffering from pain can look out onto sunny nature spaces. Also, attention should be given to affording nature window views in procedure spaces, treatment rooms, and waiting areas where pain is a problem (Ulrich, 2008). Research also supports displaying visual art (paintings, prints, and photographs) with representational nature subject matter in healthcare settings where pain is experienced. Well-controlled randomized studies support providing technology (such as television screens and eyeglass displays) to simulate nature in spaces where patients undergo painful procedures and it is not fea-

sible to provide distraction with actual nature. Nature simulations with both visual and auditory distraction may be more diverting and engrossing and hence more effective for relieving severe pain. Furthermore, pain theories and research findings imply that patients should not be placed in rooms or treatment spaces that lack nature distraction and contain environmental stressors such as noise, because pain may thereby be exacerbated (Malenbaum et al., 2008). Finally, the evidence implies that careful attention should be given to building orientation and site planning in healthcare projects, and that plans where some buildings block pain-relieving nature views and daylight from others should be avoided.

Effects of Nature Distraction on Pain

Viewing nature may decrease pain by eliciting positive emotions, reducing stress, and distracting patients from focusing on their pain (Malenbaum et al., 2008; Ulrich et al., 2006; Ulrich, 2008). According to distraction theory, pain requires considerable conscious attention. However, if patients become diverted by or engrossed in a pleasant distraction such as a nature view, they have less attention to direct to their pain, and the experienced pain therefore will diminish. The theory predicts that the more engrossing an environmental distraction, the greater the pain reduction (McCaul & Malott, 1984). This implies that nature distractions may be more diverting and hence effective in reducing pain if they involve sound as well as visual stimulation, and induce a heightened sense of immersion (Ulrich, 2008).

A study of matched patients recovering from abdominal surgery found that those assigned to rooms with a bedside view of nature (trees) had better postoperative recovery than matched patients assigned to identical rooms with windows overlooking the wall of a brick building (Ulrich, 1984). Patients with the nature view suffered substantially less pain, as indicated by their need for far fewer doses of strong pain medication than their counterparts with the wall view. In addition, the patients exposed to nature had shorter post-surgery stays, better emotional well-being, and fewer minor complications such as persistent nausea or headache (Ulrich, 1984). Another study prospectively and randomly assigned bedridden heart-surgery patients to view color pictures mounted in their line of vision (Ulrich, Lundén, & Eltinge, 1993). Patients assigned a picture of a spatially open, well-lighted view of trees and water needed fewer doses of strong pain drugs than patients exposed to abstract images or a control condition of no picture (Ulrich et al., 1993). A well-controlled prospective study by Tse, Ng, Chung, and Wong (2002) found that healthy volunteers in a hospital setting had a higher pain threshold and greater tolerance when they looked at a videotape of nature scenery.

As noted, theory predicts that nature exposures may be more engrossing and hence pain relieving when they involve sound as well as visual distraction. Lee and colleagues (2004) conducted a randomized prospective clinical trial on the effects of nature distraction on patients undergoing colonoscopy, and they found that visual distraction alone reduced pain but did not lower the intake of sedative medications. However, a combination of nature scenery with classical music reduced both pain and self-administered sedation during colonoscopy (Lee et al., 2004). Research on burn patients suffering from intense pain found that distracting individuals during burn dressings with a nature videotape accompanied by music lessened both pain and anxiety and stress (Miller, Hickman, & Lemasters, 1992). A randomized clinical trial of patients undergoing painful bronchoscopy found that individuals assigned to look at a ceiling-mounted nature scene and listen to nature sounds (moving water, birds) reported less pain than a control group who looked at a blank ceiling during bronchoscopy (Diette, Lechtzin, Haponik, Devrotes, & Rubin, 2003). Kozarek and colleagues (1997) investigated the effects of seeing and listening to a nature travelogue on patients undergoing painful gastric procedures. Patient reports and nurse observations converged in suggesting that the combination of visual and auditory distraction improved comfort and tolerance for the procedures, as compared to a control condition without distraction (Kozarek et al., 1997). Other research suggests that a virtual reality audiovisual nature distraction (a walk through a forest with bird sounds) reduced discomfort and symptomatic distress in female chemotherapy patients (Schneider, Prince-Paul, Allen, Silverman, & Talaba, 2004).

HERD VOLUME 1, NUMBER 3, PP 61-125 COPYRIGHT ©2008 VENDOME GROUP, LLC

Effects of Daylight Exposure on Pain

The presumed pain reduction mechanism for daylight is different than for nature. Sunlight exposure increases levels of serotonin, a neurotransmitter known to inhibit pain pathways. Walch and colleagues (2005) conducted a well-controlled prospective study of the effects of daylight on pain in patients undergoing spinal surgeries, who were admitted postoperatively to rooms either on the bright or shaded side of a surgical ward. Patients in the bright rooms were exposed to 46% greater sunlight intensity than those assigned to the more shaded rooms. Findings indicated that patients in rooms with more sunlight reported less pain and stress, and took 22% less analgesic medications, resulting in a 21% reduction in medication costs. It should be mentioned that the shaded patient rooms—and associated heightened pain—resulted when a new building was constructed and blocked sunlight from reaching this side of the facility.

Improving Patients' Sleep

Summary of Evidence and Recommendations

Hospitalized patients have an increased need for sleep because of their illnesses. However, in reality, they often suffer from diminished circadian rhythms and poor sleep while hospitalized (Southwell & Wistow, 1995), which may lead to increased stress (Novaes, Aronovich, Ferraz, & Knobel, 1997; Topf & Thompson, 2001), impaired immune function, ventilatory compromise, disrupted thermoregulation, and delirium (Wallace, Robins, Alvord, & Walker, 1999). These effects may hinder the healing process and contribute to increased morbidity and mortality (Krachman, Dalonzo, & Criner, 1995; Parthasarathy & Tobin, 2004).

The research team identified more than 70 articles about sleep in healthcare settings, including descriptive, correlational, and intervention studies. The literature confirmed that sleep disruption and deprivation were very common problems in healthcare settings, especially for high-acuity patients who are more susceptible to unfavorable environmental conditions. Environmental factors such as noise and light may result in electroencephalographic arousals and awakenings, and thereby fragment sleep and prevent patients from progressing into deeper and more restorative sleep stages (BaHammam, 2006). Increased acoustic performance with reduced reverberation time and noise level increased sleep quality (Aaron et al., 1996; Topf, Bookman, & Arand, 1996).

Certain environmental approaches have shown promising results in improving patient sleep. First, *single-bed rooms* can reduce noise disturbance from roommates, visitors, and healthcare staff (Southwell & Wistow, 1995; Yinnon, Ilan, Tadmor, Altarescu, & Hershko, 1992), and thereby improve patient sleep (Gabor et al., 2003). Second, experimental studies support the installation of *high-performance sound-absorbing materials* to reduce reverberation time, sound propagation, and noise intensity levels, as well as to improve sleep (Berg, 2001; Hagerman et al., 2005; Philbin & Gray, 2002). Other noise reduction strategies such as adopting *a noiseless paging system* could also be considered. Furthermore, findings suggest that patient rooms should be carefully oriented and designed to receive *natural daylight* and maintain the normal light-dark cycle of 24-hour periods to help patients retain normal circadian rhythms and improve sleep (BaHammam, 2006; Wakamura & Tokura, 2001).

Quantity and Quality of Sleep in Healthcare Settings

Measurement of sleep. Sleep should be measured in terms of both *quantity* (such as total sleep time) and *quality* (such as the type and depth of sleep, the distribution over 24 hours, and other sleep architecture parameters) (Parthasarathy & Tobin, 2004). Even if total sleep time appears adequate, sleep quality may nonetheless be poor because of fragmentation and poor sleep architecture. Previous sleep studies have employed either subjective measures such as patients' self-reports (Sheely, 1996; Topf & Thompson, 2001; Tranmer, Minard, Fox, & Rebelo, 2003) or objective measures including direct observation (Kroon & West, 2000), polysomnography (PSG) (Freedman, Gazendam, Levan, Pack, & Schwab, 2001; Gabor et al., 2003; Singh, Mahowald, & Mahowald, 2004; Wallace et al., 1999), and bispectral index (Nieuwenhuijs, Coleman, Douglas, Drummond, & Dahan, 2002) or Actigraph (Kroon & West, 2000). Most studies have monitored sleep only at night, while some have focused on the 24-hour period and revealed that about half of the total sleep in acute care settings occurred during

the daytime (BaHammam, 2006). We found it difficult to compare findings across studies because of the different measures used.

Sleep deprivation in different healthcare settings. Patient sleep has been studied more often in *high-acuity units* than other settings (BaHammam, 2006; Parthasarathy & Tobin, 2004; Redeker, 2000). Overall, high-acuity patients show sleep fragmentation, increases in stage 1 and stage 2 sleep, and decreases in more restorative stages—slow-wave and rapid eye movement sleep—as well as reductions in sleep efficiency (BaHammam, 2006; Parthasarathy & Tobin, 2004). In a survey study of 84 neurosurgery ICU patients, 79% of patients reported sleep disturbances (Ugras & Oztekin, 2007). In another survey of randomly selected ICU patients, sleep difficulty was identified as the second most important physical stressor, following pain (Novaes et al., 1997). Parthasarathy and Tobin (2004) reported that the number of sleep arousals and awakenings ranged from 20–68 per hour and varied across different acute care settings. Findings concerning total sleep time differ considerably across studies, ranging from normal or near normal sleep time at 7–10.4 hours a day (Freedman et al., 2001; Gottschlich et al., 1994), to decreased time at 3.6–6.2 hours per day (Aurell & Elmqvist, 1985; Gabor et al., 2003; Hilton, 1976). In a study of mechanically ventilated ICU patients using continuous PSG measurements, the mean total sleep time per 24-hour period was 8.8 ± 5.0 hours, the sleep-awake cycles were fragmented, and a mean of 57 ± 18% of total sleep time occurred during the day (Freedman et al., 2001).

General wards have been studied less frequently than high-acuity settings, and most studies have employed less reliable subjective measures, such as self-report surveys (Dogan, Ertekin, & Dogan, 2005; Kuivalainen, Ryhänen, Isola, & Meriläinen, 1998; Shafiq et al., 2006). Results strongly suggest that sleep deprivation is also a widespread problem among general ward patients. In a Finnish study, 65 percent of the medical and surgical patients reported sleeping badly in the hospital (Kuivalainen et al., 1998). Another study of medical and surgical patients in Canada found moderate to high disturbance scores for awakenings and soundness of sleep (Tranmer et al., 2003).

Sleep deprivation among different patient populations. Although most sleep studies have focused on adult populations, some have examined special populations, such as older people (Béphage, 2005; Ersser et al., 1999; Vinzio, Ruellan, Perrin, Schlienger, & Goichot, 2003; Wakamura & Tokura, 2001), children and infants (Al-Samsam & Cullen, 2005; Corser, 1996; Cureton-Lane & Fontaine, 1997; Zahr & de Traversay, 1995), and specific groups, such as cardiac surgery patients (Simpson, Lee, & Cameron, 1996). In a study of PICU patients, children slept for a mean total of only 4.7 hours during the 10-hour night, with an average of 9.8 awakenings, and the mean length of a sleep episode was only 27.6 minutes (Cureton-Lane & Fontaine, 1997). In another study of 11 mechanically ventilated PICU patients, restorative sleep accounted for only 3% of total sleep time due to severe sleep fragmentation, as reflected in the high number of awakenings (Al-Samsam & Cullen, 2005).

Environmental Factors Affecting Sleep

A number of factors contribute to poor sleep in healthcare settings, including environmental factors like noise, light, and staff-patient interactions; physiological factors, such as the underlying disease and impact of medication; and the psychological characteristics of patients (BaHammam, 2006; Dogan et al., 2005; Reid, 2001). Environmental factors have been studied in several settings across different types of patients for their impact on sleep (Corser, 1996; Cureton-Lane & Fontaine, 1997; Freedman, Kotzer, & Schwab, 1999; Kuivalainen et al., 1998). In the Finnish study mentioned earlier, 80% of patients who reported poor sleep regarded environmental factors as the cause (Kuivalainen et al., 1998).

Impacts of noise. Environmental noise is one of the most important yet modifiable environmental factors affecting patients' sleep (Gabor et al., 2003; Meyer et al., 1994; Parthasarathy & Tobin, 2004; Schnelle, Ouslander, Simmons, Alessi, & Gravel, 1993; Topf & Davis, 1993; Topf & Thompson, 2001; Yinnon et al., 1992). In a survey of neurosurgery ICU patients, among those who reported sleep disturbance, 58% considered environmental noise a frequent disturbing factor (Ugras & Oztekin, 2007). Another study in an

HERD VOLUME 1, NUMBER 3, PP 61-125 COPYRIGHT ©2008 VENDOME GROUP, LLC

intermediate respiratory care unit showed a strong correlation between the number of high sound peaks (≥ 80 dBA) and arousals from sleep (Aaron et al., 1996). One study of ICUs suggested that about 20% of arousals and awakenings were related to noise, and 10% were related to patient care activities (Parthasarathy & Tobin, 2004). Topf and colleagues (1996) conducted a study with healthy volunteers in an experimental setting that replicated noise in ICUs and compared their sleep quality with that of control subjects who were not exposed to the ICU noise (Topf et al., 1996). Results showed that participants assigned to the ICU noise condition took longer to fall asleep, slept less, and experienced more awakenings and poorer sleep quality.

Impact of lighting conditions. In addition to noise, lighting is an important environmental factor affecting sleep/awake patterns (Béphage, 2005; Higgins, Winkelman, Lipson, Guo, & Rodgers, 2007). One study found that night lighting on wards was dimmed for a sleep duration that is no longer than that required by the average healthy person (Southwell & Wistow, 1995). This is a disturbing finding considering that patients need more sleep when they are ill and are more susceptible to sleep disturbances. Other research suggests that the inappropriate location, orientation, and design of patient rooms might reduce daylight exposure, diminish patients' circadian rhythms, and worsen their sleep at night (BaHammam, 2006; Wakamura & Tokura, 2001).

Environmental Approaches to Improve Sleep

Various interventions have been employed to improve patient sleep. Pharmacological assistance alone cannot achieve the desired quantity and quality of sleep in ICUs (Brown & Scott, 1998), not to mention its detrimental side effects. Environmental interventions have been developed to reduce environmental noise and disruptive staff-patient interactions at night, or to maintain the normal light-dark cycle of a day, and they have shown favorable results. Furthermore, some environmental interventions appeared to be more successful than organizational interventions like staff education or quiet hours (Gast & Baker, 1989; Moore et al., 1998; Walder, Francioli, Meyer, Lancon, & Romand, 2000).

Improving the acoustic environment. Certain environmental interventions have been found effective for reducing noise in hospital settings, including installing high-performance sound-absorbing ceiling tiles, eliminating or reducing noise sources (e.g., adopting a noiseless paging system), and providing single-bed rather than multibed rooms.

Installing high-performance sound-absorbing materials for environmental surfaces such as ceilings and walls can reduce reverberation time, sound propagation, and noise intensity levels (Berg, 2001; Hagerman et al., 2005; Philbin & Gray, 2002). Hagerman et al. (2005) examined the effects of sound-absorbing versus sound-reflecting ceiling materials in a coronary ICU by periodically changing the ceiling tiles. When the sound-absorbing tiles were in place, patient rooms showed a 5–6 dB drop in sound levels and a reduction in reverberation time from 0.8 to 0.4 second, indicating better acoustic conditions. Patients also reported fewer awakenings caused by noise. Further, Berg's research (2001) showed that even if the noise level (dB) remains almost the same, the reduction in reverberation time achieved by sound-absorbing ceiling tiles can improve sleep quality. Meanwhile, even relatively low decibel levels (27–58 dB), when coupled with longer reverberation times (sound-reflecting ceiling), significantly increased arousals in healthy volunteers sleeping in patient rooms. These findings have disturbing implications, because most hospitals have nighttime sound peaks exceeding those of the patient rooms in the study.

Providing single-bed rooms as opposed to multibed rooms can also lower noise levels and improve sleep quality. For multibed rooms in medium- and high-acuity units, most noises stem from the presence of other patients, whether caused by visitors, staff caring for other patients, or patient sounds such as coughing, crying out, and rattling bedrails (Southwell & Wistow, 1995; Yinnon et al., 1992). One study of multibed bays in a children's hospital concluded that noise levels were so high that consideration should be given to abolishing open-bay rooms (Couper et al., 1994). These findings also have important implications for patient sleep, because noises stemming from the presence of other patients can be the major cause of sleep loss in mul-

tibed rooms, (Southwell & Wistow, 1995; Yinnon et al., 1992). In the Finnish study mentioned previously, the presence of other patients was reported as one of the most disturbing factors (Kuivalainen et al., 1998). Gabor and colleagues (2003) compared the effect of open areas and single rooms on noise levels and the sleep of six healthy volunteers in an ICU. The average noise level was higher (51 dB) in the open ICU than in the single room (43 dB), as were the respective peak levels (65 dB versus 54 dB). Furthermore, total sleep time in the single-bed room (9.5 hours) was greater than that in the open ICU (8.2 hours), although the number of arousals was similar in both settings.

Avoiding light pollution. One study examined the impact of simulated bright daylight in a north-facing room with limited natural light, affixing to the bed a lamp that was turned on at 10:00 a.m. and off at 5:00 p.m. (Wakamura & Tokura, 2001). Findings suggested that hospitalized elderly patients experienced better deep sleep at night when they were exposed to the artificial diurnal daylight compared to when they had darker daytime conditions. However, not all light-related interventions are successful. Another intervention study implemented guidelines to control nighttime light levels, and this resulted in significantly lower mean light disturbance intensity and shorter periods with high light levels (Walder et al., 2000). However, these changes were accompanied by greater variation in light levels, which could disturb patients' sleep patterns. More research is needed to better understand how both daytime and nighttime light environments can be optimized to improve sleep. Design details such as flexible light controls with various lighting intensities might be considered.

Directions for Future Research

Despite emerging evidence, gaps in our knowledge still remain. To better understand the independent effect of environmental interventions, future research should control effectively for other variables that influence sleep, such as acuity of illness, sedation level, pain, and disruptive patient-care procedures. Longitudinal designs with larger numbers of patients should be developed and employ standard sleep measures over 24-hour periods rather than at night only.

Reducing Patient Stress

Summary of Evidence and Recommendations

Stress experienced by patients is an important negative outcome, which directly and adversely affects many other healthcare outcomes. If hospital physical environments contain stressful features or characteristics such as noise, patient stress and other outcomes will often be worsened. By contrast, hospital design that minimizes environmental stressors and fosters exposure to stress-reducing or restorative features should advance improved outcomes (Ulrich 1991; Ulrich et al., 2006).

Our literature review identified certain environmental features that can *reduce stress* and improve outcomes. Several well-controlled experimental studies have generated strong evidence that real or simulated views of *nature* can produce substantial restoration from psychological and physiological stress within a few minutes. Other studies using self-report methods and behavioral observation suggest that *gardens* in hospitals can reduce stress among patients and families by providing nature distraction and fostering social support. Based on these findings, it is recommended that hospital siting and design should provide restorative window views of nature and gardens from patient rooms and other interior areas where stress is a problem. Additionally, limited research on hospital *art* suggests that the great majority of patients prefers and responds positively to representational nature art, but that abstract or ambiguous art can elicit stressful reactions in many patients.

Considerable research has shown that noise is a pervasive stressor that elevates psychological and physiological stress in patients, and worsens other outcomes. Research also indicates that hospital noise levels around the world have been rising steadily since the 1960s. Therefore, a high priority should be placed on creating much quieter environments when constructing or renovating hospitals. As mentioned in another section (Improving Patients' Sleep), research has identified effective environmental approaches for quieting healthcare settings, the most important of which appears to be providing single-bed rooms. Other noise-reducing measures supported by research include insulating or eliminating noise sources (e.g., replacing overhead pag-

HERD VOLUME 1, NUMBER 3, PP 61-125 COPYRIGHT ©2008 VENDOME GROUP, LLC

ing with a noiseless system) and installing high performance sound-absorbing materials on ceiling and wall surfaces.

Stress as a Major Problem in Healthcare Facilities

Much research has confirmed that hospitalized patients experience stress, and that a large proportion suffers from acute stress. Many stressors are unavoidable accompaniments of illness and medical treatments, but others result from shortcomings in the culture of healthcare organizations. Additional stress is produced by poorly designed physical environments. In addition to afflicting patients, stress is a major burden for their families (Ulrich, 1991; Ulrich et al., 2006).

The stress experienced by a patient is an important negative outcome in itself, and it directly and adversely affects many other outcomes. These unhealthy effects are related to detrimental psychological, physiological, neuroendocrine, and behavioral changes associated with stress responses (Gatchel, Baum & Krantz, 1989; Ulrich, 1991). The neuroendocrine component, for example, elevates levels of a natural steroid, cortisol, and releases stress hormones that tax the heart and other major organs. Importantly, much research has shown that stress responses suppress immune system functioning through their effects on neuroendocrine activity and the central nervous system (Kiecolt-Glaser, et al., 1987). Stress-related immune impairment decreases resistance to infection and worsens recovery outcomes such as wound healing (Cohen, Tyrrell, & Smith, 1991; Kiecolt-Glaser et al., 1995).

Reduce Stress by Controlling Noise

Noise levels and sources in hospitals. The World Health Organization (WHO) provides guideline values for continuous background noise in hospital patient rooms, which are 35 dBA during the day and 30 dBA at night, with nighttime peaks in wards not to exceed 40 dBA (Berglund, Lindvall, & Schwela, 1999). However, much research has shown that actual background and peak noise levels fall in far higher ranges, and a review of 35 studies concluded that hospital noise levels around the world have been rising consistently since the 1960s (Busch-Vishniac et al., 2005). Background noise levels typically are 45 dB to 68 dB, with peaks frequently exceeding 85 dB to 90 dB (Aaron et al., 1996; Allaouchiche, Duflo, Debon, Bergeret, & Chassard, 2002; Balough, Kittinger, Benzer, & Hackl, 1993; Blomkvist, Eriksen, Theorell, Ulrich, & Rasmanis, 2005; Cureton-Lane & Fontaine, 1997; Falk & Woods, 1973; Guimaraes et al., 1996; Hilton, 1976; Homberg & Coon, 1999; Kent, Tan, Clarke, & Bardell, 2002; McLaughlin, McLaughlin, Elliott, & Campalani, 1996; Robertson, Cooper-Peel, & Vos, 1998). In evaluating these noise levels, it should be noted that the decibel scale for quantifying loudness or sound pressure intensity is logarithmic; each 10 dBA increase therefore represents a sound pressure level that is 10 *times* higher.

Medical equipment and staff voices often produce noise at 70–75 dB levels at the patient's head, which approach the noise level in a busy restaurant (Blomkvist et al., 2005). Noises from alarms and certain equipment (e.g., a portable X-ray machine) exceed 90 dB, which is comparable to walking next to a busy highway when a motorcycle or large truck passes. A study in a NICU measured peak levels once per minute and found that 31% of peaks exceed 90 dB (Robertson et al., 1998). One study even recorded 113 dB during shift changes at a large hospital (Cmiel, Karr, Gasser, Oliphant, & Neveau, 2004). OR noises from drills, saws, and other equipment are in the range of 100–110 dB, presenting a significant risk for noise-induced hearing loss (Hodge & Thompson, 1990; Love, 2003; Nott & West, 2003).

Our review of the research identified at least three major reasons why hospitals are excessively noisy and therefore stressful (Ulrich, 2003). First, as mentioned previously, the sources of noise are unnecessarily numerous and loud. Well-documented examples include staff voices, paging systems, alarms, bedrails moved up or down, telephones, ice machines, pneumatic tubes, and trolleys. Second, many environmental surfaces (e.g., floors, ceilings, walls) are hard and sound-reflecting, not sound-absorbing; this creates poor acoustic conditions (long reverberation times) that enable noise to echo, linger, and propagate over large areas and into patient rooms (Blomkvist et al., 2005; Ulrich, 2003). Finally, hospitals are noisy because many patients are

housed in multibed rooms in which much noise originates from other patients (Baker, 1984; Southwell & Wistow, 1995; Yinnon et al., 1992).

Effects of noise on patient stress and other outcomes. Another section in this report, "Improving Patients' Sleep," surveys research showing that noise is a major cause of awakenings and poor sleep. In addition to worsening sleep quality, noise elevates psychological and physiological stress in patients, as indicated by negative feelings such as anxiety and annoyance (Bentley, Murphy & Dudley, 1977; Haslam, 1970; Hilton, 1976; Synder-Halpern, 1985) and detrimental physiological changes such as elevated heart rate and blood pressure (Baker, 1992; Morrison, Haas, Shaffner, Garrett, & Fackler, 2003). A prospective study by Hagerman et al. (2005) examined the effects of sound-reflecting versus sound-absorbing tiles on coronary intensive care patients. When the sound-absorbing ceiling tiles were in place, patients evidenced lower physiological stress (lower sympathetic arousal), slept better, reported better care from nurses, and had a lower incidence of rehospitalization in the weeks following discharge. Other studies have focused on infants in NICUs, finding that higher noise levels elevate blood pressure, heart, and respiration rates, and decrease oxygen saturation, thereby increasing the need for oxygen support therapy (Slevin, Farrington, Duffy, Daly, & Murphy, 2000; Zahr & de Traversay, 1995).

Environmental approaches to reduce noise and stress. The foregoing discussion makes it clear that hospitals are far too noisy, and that noise in combination with acoustically poor environmental surfaces and multibed patient rooms worsens stress and other outcomes. As discussed in detail in an earlier section (Improving Patients' Sleep), there are effective environmental approaches available to quiet healthcare settings, which can be more successful than organizational interventions such as staff education or establishing quiet hours (Gast & Baker, 1989; Moore et al., 1998; Walder et al., 2000).

The most important design measure to reduce noise for inpatients appears to be single-bed rooms. In this regard, the research literature indicates that noise levels are lower in single- than multibed rooms (Gabor et al., 2003; Southwell & Wistow 1995; Yinnon et al., 1992). The major advantage of single-bed rooms is reflected in Press Ganey's national satisfaction survey, which obtained data from 2.1 million patients in 1,462 facilities during 2003. Results showed that satisfaction with noise levels was on average 11.2% higher for patients in single-bed rooms than for those in multibed rooms; this pattern held across all patient categories and for different ages, genders, and facility sizes and types (Press Ganey, 2003). This is an extremely large difference, considering that it can be difficult for hospitals to increase satisfaction scores by even two or three percentage points.

Apart from providing single rooms, another approach for quieting facilities and reducing stress is to *eliminate noise sources*, for example, by replacing overhead paging with a noiseless system and insulating pneumatic tubes and ice machines. Also, there is convincing evidence that *installing high performance sound-absorbing materials* on surfaces such as ceilings, floors, and walls can be effective in reducing noise levels, reverberation or echoing, and sound propagation (Berg, 2001; Blomkvist et al., 2005; Philbin & Gray, 2002).

Provide Nature Distraction to Reduce Stress

Biophilia theory. Wilson's biophilia hypothesis (1984) holds that humans have a partially genetic tendency to respond positively to nature. Ulrich et al. (1993) and Ulrich (2008) have developed theoretical arguments as to why a capability for rapid recovery from stress following challenging episodes was vital for the survival of early humans, and why evolution favored the selection of individuals with this partially genetic proneness for a restorative response to nature. This restoration theory implies that modern humans, as a genetic carryover of evolution, have a capacity to derive stress-reducing responses from certain nature settings and content (e.g., vegetation or water), but have no such disposition toward most built or artifact-dominated environments and materials (e.g., concrete, glass, and metal) (Ulrich, 1993, 1999, 2008). "These theoretical arguments have a practical design implication, which is that designing healthcare buildings with nature features may harness therapeutic influences that are carryovers from evolu-

HERD VOLUME 1, NUMBER 3, PP 61-125 COPYRIGHT ©2008 VENDOME GROUP, LLC

tion, resulting in more restorative and healing patient care settings" (Ulrich, 2008, forthcoming).

Research on restorative effects of nature. Upwards of a score of scientific studies of people in nonhealthcare situations as well as patients in hospitals have generated strong evidence that real or simulated views of nature can produce substantial restoration from stress. The strength of these findings is enhanced by the fact that some studies have used randomized controlled research designs and obtained physiological as well as self-report measurements of stress. Investigators have reported consistently that stress-reducing or restorative benefits of viewing nature are manifested as a constellation of positive emotional, psychological, and physiological changes. Positive feelings such as pleasantness and calm increase, while anxiety, anger, or other negative emotions diminish (Hartig, Book, Garvill, Olsson & Gärling, 1995; Ulrich, 1979; Ulrich, 1991; Van den Berg, Koole, & Van der Wulp, 2003). Also, many nature scenes sustain positive interest and thus function as pleasant distractions that may block worrisome, stressful thoughts (Ulrich, 1981.) Regarding the physiological effects of nature exposure, restoration is apparent when changes in bodily systems indicate decreased stress mobilization (for instance, reduced sympathetic nervous system activity). Physiological restoration is manifested within 3 minutes at most, or as fast as a few seconds in certain systems (Fredrickson & Levenson, 1998; Hartig, Evans, Jamner, Davis & Gärling, 2003; Joye, 2007; Laumann, Gärling, & Stormark, 2003; Parsons & Hartig, 2000; Parsons, Tassinary, Ulrich, Hebl, & Grossman-Alexander, 1998; Ulrich, 1981; Ulrich, Simons & Miles, 2003). In contrast to viewing nature-dominated settings, there is convincing evidence that looking at built environments that lack nature (e.g., parking lots, roof tops, and rooms) is significantly less effective in fostering restoration and may worsen stress (e.g., Ulrich, 1979, 1991; Van den Berg et al., 2003).

Nature and patient stress. In an interview study of the elderly in long-term care facilities, residents reported a preference for windows with prominent views of nature, but expressed dislike for window views of built content that lacked nature (Kearney & Winterbottom, 2005). Survey research on hospital patients also suggests that they prefer and attribute importance to having a bedside window view of nature (Verderber, 1986).

Furthermore, studies on patients indicate that viewing nature images for only a few minutes can promote significant restoration from stress or anxiety. One well-controlled clinical trial measured restoration from anxiety in patients waiting to undergo dental surgery in a room with or without an aquarium on different days (Katcher, Segal, & Beck, 1984). Findings suggested that anxiety was lower on days when the aquarium was present, and clinicians' ratings for patient compliance during surgery were higher. Heerwagen (1990) studied patients in a dental clinic and found that psychological and physiological markers of stress—including elevated blood pressure and heart rate—were diminished on days when a large nature mural was hung on a wall of the waiting room, in contrast with days when the wall was blank. One strong randomized prospective study of blood donors in a waiting room found that blood pressure and pulse were lower on days when a wall-mounted television displayed a nature videotape, compared to days when continuous daytime television programs or a videotape of urban areas and buildings were aired (Ulrich et al., 2003). A quasi-experimental study of patients with dementia, including Alzheimer's disease, suggested that adding large, color nature images and a nature sound track (birds, brook) to a shower room diminished stress and reduced incidents of aggressive, agitated behavior (Whall et al., 1997).

As mentioned in another section (Reducing Patients' Pain), strong studies have found that exposing patients to nature lessens stress, anxiety, and pain. A prospective clinical trial by Ulrich and colleagues (1993) found that heart-surgery patients in ICUs who were randomly assigned a picture with a landscape scene with trees and water reported less anxiety and stress and needed fewer doses of strong pain drugs than a control group that had been assigned no pictures. In the same study, another group of patients assigned an abstract picture had worse outcomes than the control group. Ulrich (1984) reported that patients recovering from abdominal surgery suffered fewer minor postsurgical complications linked to stress (e.g., headache), had better emotional well-being, required fewer doses of pain drugs, and had

shorter hospital stays if they had a bedside window view of nature (trees) rather than a brick wall. Research on burn patients suggested that exposure to a nature videotape during burn dressing changes reduced anxiety, stress, and pain intensity (Miller et al., 1992).

Gardens for reducing stress. A few studies suggest that gardens can be effective restorative settings for stressed patients, families, and staff (Marcus & Barnes, 1999; Sherman, Varni, Ulrich, & Malcarne, 2005; Ulrich, 1999; Whitehouse et al., 2001). Well-designed gardens not only can provide restorative nature views, but they also reduce stress and improve outcomes through other mechanisms, such as fostering access to social support, restorative escape, and control with respect to stressful clinical environments (Ulrich, 1999, 2008). Marcus and Barnes (1995) used behavioral observation and interview methods in postoccupancy studies of four hospital gardens and concluded that recovery from stress was the most important benefit realized by nearly all garden users. Other postoccupancy research likewise has found that patients and families who use hospital gardens report reduced stress and improved emotional well-being (Whitehouse et al., 2001). A quasi-experimental investigation of three gardens in a pediatric cancer center showed that participants (patients, families, staff) reported lower stress levels when in the gardens than inside the hospital (Sherman et al., 2005).

Limited evidence suggests that gardens tend to alleviate stress effectively for adult users when they contain green or verdant foliage, flowers, water, grassy spaces with trees or large shrubs, a modicum of spatial openness, and compatible pleasant nature sounds, such as birds and water (Marcus & Barnes, 1995, 1999; Ulrich, 1999, 2008). Broadly similar findings have emerged from research on gardens and outdoor spaces in assisted living facilities for the elderly. Rodiek (2005) surveyed elderly residents and observed their behavior in 14 assisted living facilities and reported that residents preferred outdoor spaces with greenery, flowers, birds, and water features.

Art in healthcare environments. Rigorous studies on hospital art are sparse, and most have measured patient art preferences rather than effects on outcomes such as pain. The limited findings nonetheless show similarities to results from nature studies. Results suggest a consistent pattern wherein the great majority of patients prefer and respond positively to representational nature art, but many react negatively to abstract art (Carpman & Grant, 1993; Ulrich, 1991; Ulrich & Gilpin, 2003). Nanda, Hathorn, and Neumann (2007) displayed a diverse collection of 17 paintings to patients in their hospital rooms, and asked them to rate each painting for the following questions: (1) How does the picture make you feel, and (2) Would you like to hang this picture in your hospital room? Findings indicated that patients were significantly more positive about nature paintings (landscapes with verdant foliage, flowers, and water) than they were about best-selling pictures or even works by masters such as Chagall and Van Gogh (Nanda et al., 2007). The most positively rated painting depicted a gentle waterfall with vegetation. In the same research, representational nature paintings containing human figures and harmless animals such as deer were preferred over counterparts that were somewhat abstract. Eisen (2006) studied the art preferences of schoolchildren and hospitalized pediatric patients across four age groups: 5–7, 8–10, 11–13, and 14–17 years of age. Findings suggested that, irrespective of age or gender, the great majority of hospitalized pediatric patients and schoolchildren were similar in preferring nature art (such as a forest setting with lake and deer) over abstract or cartoon-like images.

Although nature pictures elicit positive reactions, there is limited evidence that emotionally inappropriate art subject matter or styles can increase stress and worsen other outcomes (Ulrich, 1991, 1999; Ulrich & Gilpin, 2003). It may be unreasonable to expect all art to be suitable for high-stress healthcare spaces, because art varies enormously in subject matter and style, and much art is emotionally challenging or provocative. The pitfalls of displaying emotionally challenging art are revealed by a study of psychiatric patients housed in a unit extensively furnished with a diverse collection of wall-mounted paintings and prints (Ulrich, 1991). Interviews with patients suggested strongly negative reactions to artworks that were ambiguous, surreal, or could be interpreted in multiple ways. The same patients, however, reported having positive feelings and

HERD VOLUME 1, NUMBER 3, PP 61-125 COPYRIGHT ©2008 VENDOME GROUP, LLC

associations with respect to nature artwork. Additional evidence on the stressful impact of abstract art comes from a study of a sculpture installation created for cancer patients in a large university hospital (Ulrich, 1999). Prominent in the installation were several tall metal sculptures dominated by straight-edged and abstract forms, many having pointed or piercing features. A questionnaire study found that 22% of the patients reported having an overall negative emotional response to the sculpture garden (Hefferman, Morstatt, Saltzman & Strunc, 1995). Many found the sculpture ambiguous ("doesn't make any sense"), and some patients interpreted the sculptures as frightening and asked for a room change so they would not overlook the artworks (Ulrich, 1999).

Reducing Depression

Summary of Evidence and Recommendations

Depression is a serious, widespread, and costly problem in healthcare facilities. A large body of rigorous evidence indicates that exposure to bright artificial light and daylight is effective in reducing depression and improving mood, even for people hospitalized with severe depression. Artificial light is commonly used in structured or formal protocols for treating depression. A few retrospective studies suggest that hospitalized adult patients with depression can have more favorable recovery outcomes, including shorter stays, if they are assigned to sunnier rooms rather than rooms that receive less daylight or are always in shade. (See also Reducing Patients' Pain.) The credibility of the limited findings linking greater daylight or sun exposure to improved depression-related outcomes is enhanced by the fact that the many strong studies using bright artificial light have obtained broadly parallel results.

The evidence that patients' depression is diminished by daylight exposure implies the importance of the orientation and site planning of healthcare buildings (Ulrich et al., 2006). Site plans where some buildings block daylight or sun from others should be avoided. Hospitals—and in particular mental health facilities—should be designed and sited to ensure that depressed patients have abundant natural light. Providing larger windows in patient rooms and other spaces might also help alleviate depression by permitting more exposure to daylight. The use of bright artificial light warrants consideration in settings where depression is a problem and sufficient daylight is not available.

Effects of Light on Depression

The mechanisms by which *light treatment* alleviates depression are not fully understood. Light falling on the retina influences the activity of the pineal gland and by this pathway suppresses or delays secretion of melatonin, thereby reducing depression, increasing daytime alertness, and fostering better sleep quality (Martiny, 2004). A meta-analysis of 20 randomized controlled studies published in the *American Journal of Psychiatry* reached the powerful conclusion that light treatment for nonseasonal and seasonal depression is "efficacious, with effect sizes equivalent to those in most antidepressant pharmacotherapy trials" (Golden et al., 2005, p. 656). Additionally, light exposure offers the important advantage of being faster acting than antidepressant drugs. In this regard, several studies suggest that light can produce significant reduction of depression after less than 2 weeks of treatment, while antidepressant drugs require at least 4–6 weeks before effective onset. Some studies suggest that exposure to morning light may be more effective than afternoon or evening light (e.g., Lewy et al., 1998). However, exposure occurring in the middle of the day or afternoon also significantly reduces depression (Martiny, 2004).

Other research focused on *daylight* rather than artificial light. A retrospective study in a Canadian facility found that adult patients hospitalized for severe depression had shorter stays by an average of 2.6 days if they were assigned to sunny rooms rather than rooms that were always in shade (Beauchemin & Hays, 1996). Similarly, a study in an Italian hospital found that patients hospitalized for bipolar depression stayed an average of 3.7 fewer days if they were assigned east-facing rooms exposed to bright morning light, compared to patients in west-facing rooms with less sunlight (Benedetti, Colombo, Barbini, Campori, & Smeraldi, 2001). Depression is a serious problem not only for mental health patients, but also for several other categories of patients, such as those with cardiovascular disease and cancer. An investigation of myocardial infarction patients in an ICU in a Canadian

hospital suggested that female patients had shorter stays if their rooms had sunny versus shaded or dim window exposures (Beauchemin & Hays, 1998). In the same study, mortality in both sexes was lower in sunny rooms than in north-facing shaded rooms.

Reducing Length of Stay

Summary of Evidence and Recommendations

There is limited literature that directly links the physical environments of hospitals with patients' length of stay. However, the few studies conducted on light and nature views among specific types of patients have been strong, and they have consistently identified a positive impact from both. Additional studies are needed to confirm these findings and to test them among a broader range of patient types.

Sunlight

As mentioned in the section on Reducing Depression, exposure to sunlight has been reported to affect the length of patients' hospital stays. One research group studied the impact of the amount of natural light on the length of hospitalization of patients with unipolar and bipolar disorder. The researchers found that bipolar patients randomly assigned to the brighter, east-facing rooms (exposed to direct sunlight in the morning) had a 3.67-day shorter mean hospital stay than patients in west-facing rooms (Benedetti et al., 2001). Beauchemin and Hays (1996) analyzed the two-year data of psychiatric unit patients with depression and found that patients in the sunny rooms stayed an average of 2.6 fewer days than those in the sunless rooms. In another study, the researchers examined the length of stay and mortality rate of 628 myocardial infarction patients who had been randomly assigned to sunny and dull rooms. Patients in sunny rooms had shorter lengths of stay than patients in dull rooms, with a more significant difference for women patients (2.3 days in sunny rooms versus 3.3 days in dull rooms) (Beauchemin & Hays, 1998). The rate of mortality in sunny rooms was also lower than in the dull rooms (21/293 sunny versus 39/335 dull). A retrospective study of *climate* and patient data documented a correlation between climate variables and the average length of stay of psychiatric inpatients in Veterans Health Administration hospitals nationwide (Federman, Drebing, Boisvert, & Penk, 2000). Medical centers located in warmer and drier climates had shorter lengths of stay, and those in colder climates had the longest lengths of stay in winter and fall.

Views of Nature

As discussed previously, various studies have demonstrated the beneficial impact of exposure to nature views (real nature or simulated nature, such as pictures, videos, or virtual reality) in improving patient outcomes such as stress, pain, and length of stay (e.g., Diette et al., 2003; Tse et al., 2002; Ulrich, 1984, 1991). One strong study reported the relationship between exposure to nature views and length of stay, where patients recovering from abdominal surgery had a shorter stay if they had a bedside window view of nature rather than looking out onto a brick wall (Ulrich, 1984). More research is needed to examine the impact of visual exposure to nature on the overall healing process and length of stay.

Comprehensive Programs

In reality, changes in procedural or programmatic activities to improve healthcare often were accompanied by design modifications. In such cases, it is difficult to disentangle the independent effect of design interventions. For example, Good Samaritan Hospital in Cincinnati, Ohio, conducted a study in its NICU for 1 year before and 1 year after an intervention, which consisted of a major renovation and the implementation of a comprehensive developmental care program that included training and other activities (Altimier, Eichel, Warner, Tedeschi, & Brown, 2005). The design modifications focused on improving lighting and acoustics, increasing square footage per infant bed, and addressing family and staff needs (e.g., increased privacy). The sample included 852 infants—419 preintervention and 433 postintervention—grouped into three categories based on gestation (24–27 weeks, 28–30 weeks, and 31–34 weeks). The preintervention infants had lengths of stay of 79, 58, and 34 days, respectively, as compared to 58, 45, and 23 days for infants postintervention. Other health-related benefits from the environmental and programmatic changes also were observed.

Furthermore, in the section of this article called Reducing Hospital-Acquired Infections, a large body of literature indicated that the design of the physical envi-

HERD VOLUME 1, NUMBER 3, PP 61-125 COPYRIGHT ©2008 VENDOME GROUP, LLC

ronment strongly influences infection rates by affecting the airborne, contact, and waterborne transmission of infections. In this respect, EBD measures, by reducing nosocomial infection rates, play a key role in shortening hospital stays.

Reducing Spatial Disorientation

Summary of Evidence and Recommendations

Wayfinding problems in hospitals are costly and stressful and have a particular impact on outpatients and visitors, who are often unfamiliar with the hospital and are otherwise stressed and disoriented. In a study conducted at a major regional 604-bed tertiary-care hospital, the annual cost of the wayfinding system was calculated to be more than $220,000 per year in the main hospital, or $448 per bed per year in 1990. Much of this was the hidden cost of direction-giving by people other than information staff, which occupied more than 4,500 staff hours, the equivalent of more than two full-time positions (Zimring, 1990). Several other studies have also documented the high cost of wayfinding problems in hospitals (Carpman, Grant, & Simmons, 1990; Christensen, 1979; Foxall & Hackett, 1994).

A large body of literature has explored how people find their way through hospitals and other complex buildings. For example, Peponis, Zimring, and Choi (1990) found that people tend to have predictable paths when they explore and find their way in hospitals. However, space syntax analysis shows that these are often not the most direct paths or the routes that are designated as the "main paths," but rather the routes that are the most accessible to all of the other paths in the hospital. Not surprisingly, more complex overall layouts are more difficult to find one's way in (Arthur & Passini, 1992; Drinkard, 1984; O'Neill, 1992; O'Neill, 1991a and 1991b; Ortega-Andeane & Urbina-Soria, 1988). Several studies have found that characteristics such as turns other than right turns are harder to maintain (Carpman & Grant, 1993).

Whereas there is growing evidence about how people find their way, there is relatively little research that directly assesses the comparative performance of different wayfinding systems or the impact of wayfinding on other healthcare outcomes. Limited evidence shows that wayfinding problems cannot be tackled piecemeal. A wayfinding system, as the name implies, is not just about better signage or colored lines on floors. Rather, hospitals should provide integrated systems that include coordinated elements, such as visible and easy-to-understand signs and numbers; clear and consistent verbal directions; consistent and clear paper, mail-out, and electronic information; and a legible physical setting (Carpman & Grant, 1993). A well-integrated wayfinding system includes four main components that work at different levels: (1) administrative and procedural levels, (2) external building cues, (3) local information, and (4) global structure.

Administrative and Procedural Information

Certain organizational strategies can provide key information to patients and help them prepare for their hospital visit. Examples include mail-out maps, electronic information available on the Web or at kiosks, and verbal directions. These issues are not dealt with in this review because they are not directly related to the design of hospital physical environments.

External Building Cues

Signs and cues that lead to the hospital, especially to the parking lot, must be considered carefully because they are the patient's first point of contact with the hospital. For example, Carpman, Grant, and Simmons (1985) conducted a video simulation study to assess the relative role of signs and seeing a destination. The hospital wanted to direct most traffic to a parking structure rather than to a drop-off lane. When the researchers showed prospective visitors a simulated video with a design alternative that allowed arriving drivers to see the main pavilion with the drop-off lane, 37% of the respondents said that they would turn into the drop circle when they could see the entry to the garage, ignoring the signs. Consequently, the hospital chose to redesign the entry.

Local Information

Once patients find their way to the building from the parking lot, they are faced with the prospect of identifying their destination. Informational handouts, information desks, you-are-here maps, directories, and signage along the way are critical wayfinding aids (Carpman,

Grant, & Simmons, 1983; Levine, Marchon, & Hanley, 1984; Nelson-Shulman, 1983-84; Wright, Hull, & Lickorish, 1993). In an experimental study, researchers found that patients who had the benefit of an information system (including welcome sign, hospital information booklet, patient letter, and orientation aids) upon reaching the admitting area were more self-reliant and made fewer demands on staff. In contrast, uninformed patients rated the hospital less favorably and had elevated heart rates (Nelson-Shulman, 1983-84). Information provided in you-are-here maps can be useful. However, you-are-here maps should be well oriented so that the top signifies the direction of movement for ease of use. When the maps were aligned in directions other than the forward position, people not only took much longer to find their destination, but their efforts were significantly less accurate (Levine et al., 1984). Another study found that people who used signs found their destination faster than those who used only maps (Butler, Acquino, Hissong, & Scott, 1993). However, people who were given a combination of handheld maps and wall signs reached their destination more often than those who used only wall signs (Wright et al., 1993).

It is critical to design signage systems with logical room numbering and comprehensible nomenclature for departments (Carpman & Grant, 1993; Carpman, Grant, & Simmons, 1984). For example, inpatients, outpatients, and visitors to a hospital preferred simple terms such as *walkway* or *general hospital* over more complex or less familiar terms such as *overhead link*, *medical pavilion*, or *health-sciences complex*.

Contrary to the belief that fewer signs in hospital hallways means less clutter and hence less confusion, an experimental study found that patients who had access to more signs along the way were faster, less hesitant, asked for directions fewer times, and reported lower levels of stress (Carpman et al., 1984). Based on this study, the authors suggest that directional signs be placed at or before every major intersection, at major destinations, and where a single environmental cue or a series of such cues (e.g., changes in flooring material) convey the message that the individual is moving from one area into another. If there are no key decision points along a route, signs should be placed approximately every 150 to 250 feet.

Global Structure

In addition to local properties of the spaces that people move through, there are specific characteristics of the overall structure of the system of rooms and corridors that affect the paths people take (Haq & Zimring, 2003; Peponis et al., 1990). Based on observations of participants' search patterns and objective measures of spatial characteristics, researchers found that participants tended to move along more "integrated" routes—routes that are, on average, more accessible from a greater number of spaces because there are fewer turns from all other routes in the hospital. This research suggests that it may be important to identify such integrated routes in the plan when situating important facilities and key points such as the entrance (Peponis et al., 1990). In support of these findings, Baskaya, Wilson, and Ozcan (2004) found that people got lost less frequently in a hospital where the entrance is next to the main hallway than in a hospital where the entrance is not next to the main hallway. One limitation of the study, however, is that the hospitals compared in this case study were quite different; the hospital with better wayfinding systems also had an asymmetrical layout and outside views that the comparison hospital did not have, which might also have contributed to the improved wayfinding.

Some studies at the global scale have looked at properties of building layout that facilitate or impede movement. For example, when 56 study participants were given the wayfinding task of locating five targets in four synthetic office floor plans that were modeled on an actual floor plan, virtual environments with perpendicular intersecting hallways had better wayfinding performance than those with angled intersections (Werner & Schindler, 2004). Another study supports this finding by a design experiment that compared perpendicular and angled intersections. The study had the same 12 participants for both types of intersections in synthetic floor plans (Ruddle & Peruch, 2004).

The research supports the value of a systems approach to wayfinding, and it is not sufficient to consider one

HERD VOLUME 1, NUMBER 3, PP 61-125 COPYRIGHT ©2008 VENDOME GROUP, LLC

or two components separately. Well-designed signs are likely to be quite ineffective in a building that is highly complicated and does not provide simple cues that enable natural movement. For example, some hospitals with existing complex buildings tend to simply superimpose a signage system to try to make things work. This strategy is ineffective in most cases. On the other hand, while there are more than 18 studies that look at wayfinding in hospitals and other buildings (Baskaya et al., 2004; Brown, Wright, & Brown, 1997; Butler et al., 1993; Carpman & Grant, 1993; Carpman et al., 1983, 1984; Grover, 1971; Haq & Zimring, 2003; Levine et al., 1984; Nelson-Shulman, 1983-84; Ortega-Andeane & Urbina-Soria, 1988; Passini, Rainville, Marchand, & Joanette, 1995; Peponis et al., 1990; Schneider & Taylor, 1999; Weisman, 1981; Wright et al., 1993; Zimring, 1990), it is quite difficult to isolate the independent role of a single design factor on wayfinding performance or visitors' stress.

It is essential that these different pieces of information come together while designing new hospitals, when there is an opportunity to develop an effective wayfinding system at multiple levels. Additional studies are needed to ascertain the magnitude of stress that wayfinding problems may create for outpatients and family members.

Improving Patient Privacy and Confidentiality

Summary of Evidence and Recommendations

The protection of patient confidentiality and privacy has been written into U.S. law through the Health Insurance Portability and Accountability Act (HIPAA). Research has shown that inadequate privacy may lower patient satisfaction and can worsen healthcare outcomes if patients withhold personal information or refuse to be examined because of privacy concerns (Barlas, Sama, Ward, & Lesser, 2001). *Speech privacy* is one important issue addressed by HIPAA, including how well a private conversation can be overheard by an unintended listener. The *AIA/AHA Draft Interim Sound and Vibration Design Guidelines for Hospital and Healthcare Facilities* were developed in 2006, and they will be revised and enforced in professional practice (ANSI S12/WG44 [Healthcare Acoustics and Speech Privacy] and the Joint ASA/INCE/NCAC Subcommittee on Healthcare Acoustics & Speech Privacy; Skyes, 2006).

Despite the growing importance of speech privacy in healthcare settings, existing research in this area is sparse. We identified nine pertinent empirical studies that provide some evidence-based guidance regarding what designers can do to protect the privacy of patient speech. Extensive national survey data support the provision of single-bed rooms to increase patient privacy and confidentiality (Press Ganey, 2003). When single rooms are not available, as in many EDs, installing hard-wall partitions to provide speech privacy is preferable to curtains (Barlas et al., 2001; Karro, Dent, & Farish, 2005; Mlinek & Pierce, 1997). To prevent sound leakage and privacy breaches through the ceiling, hard-wall partitions should extend to the support ceiling or deck instead of stopping at the ceiling plane. Installing high-performance sound-absorbing ceiling tiles can shorten reverberation times, improve speech intelligibility, diminish propagation of voices and sounds, and lessen sound pressure intensity (Hagerman et al., 2005; Philbin & Gray, 2002). Furthermore, providing private discussion rooms near waiting, admission, and reception areas may help prevent breaches of speech privacy (Joseph & Ulrich, 2007).

Locations and Rates of Speech Privacy Incidents

Speech privacy in EDs. The ED is the most studied setting within healthcare facilities with respect to speech privacy. EDs are subject to frequent privacy breaches due to high volumes of patients and staff, the severity of patients' diseases or injuries, numerous conversations involving confidential patient information, and the widespread practice of placing patients in multibed rooms with curtain partitions. Mlinek and Pierce's (1997) observational study in EDs found that 100% of healthcare staff committed breaches of speech privacy. Karro and colleagues (2005) reported a rate of 45% for visual and auditory privacy breaches in EDs. Additionally, studies have examined specific locations within EDs for rates of privacy incidents. For triage/waiting areas, Mlinek and Pierce (1997) observed a rate of 53% for speech privacy breaches, and Karro et al. (2005) found a self-reported rate of 55% for both speech and visual privacy incidents. For

A53210128

all ED cubicle areas, Karro et al. (2005) reported a rate of 62% for speech and visual privacy breaches, and Olsen & Sabin (2003) found that 36% of patients overheard conversations. Rooms located closest to physician and nurse work areas typically had the highest rates of confidentiality breaches (Karro et al., 2005).

Speech privacy in patient rooms. No rigorous study was identified that directly observed the occurrence of speech privacy violations within patient rooms in general wards or ICUs. However, extensive survey data have shown that single-bed rooms, compared to multibed rooms, provide better protection for patient speech privacy (Press Ganey, 2003).

Environmental Approaches to Protect Speech Privacy

Speech privacy research in healthcare settings is at an early stage of development. The limited evidence suggests that some design measures can enhance speech privacy, including the use of hard-wall space partitions, single-bed rooms, high-performance sound-absorbing materials, and private discussion rooms or spaces.

Space partitions in EDs. The comparison between hard-wall and curtain partitions, especially in EDs, is the most studied architectural issue in this area (Barlas et al., 2001; Karro et al., 2005; Mlinek & Pierce, 1997; Olsen & Sabin, 2003). As might be expected, hard-wall partitions provide substantially better protection for speech privacy than curtains. Karro et al.'s survey study of EDs reported the rate for both visual and auditory privacy breaches to be 45% in areas with curtain partitions, but only 13% in hard-walled rooms. Mlinek & Pierce's (1997) direct observation research found the rate of speech privacy incidents (i.e., conversations being overheard from the next room) to be 100% for bed spaces with curtain partitions or even single-pane glass partitions, but 0% for rooms with solid walls and doors. It is noteworthy that these two studies arrived at different results, probably because of different measurement methods. In addition, an earlier study (Barlas et al., 2001) that used the same survey instrument as Karro et al. (2005) also found a much lower rate of privacy incidents in hard-walled cubicles than curtained cubicles. Different findings emerged from Olsen and Sabin's (2003) self-report surveys, where adult patients and parents of pediatric patients reported no significant differences in the overall rates of patients or parents overhearing conversations between curtained rooms and walled rooms with open doors or curtained entrances. However, the locations of overheard conversations were quite different; in hard-walled rooms, participants overheard fewer conversations from adjacent rooms or bed spaces than curtained spaces (15% versus 55%), but more conversations from hallways or nursing stations. A possible explanation is the tunneling effect of the particular hallway design and the use of open doors or curtained entrances instead of solid, closed doors.

Single-bed patient rooms. For patient rooms, it is reasonable to expect that single rooms help to protect speech privacy because fewer unintended listeners (e.g., patients and healthcare staff) are present compared with multibed rooms. Press Ganey's national data (2003) showed that patients in single-bed rooms were consistently much more satisfied with their privacy (4.5% higher) than patients in double rooms, across all major patient categories and types of units, and across different age and gender groups. Although speech privacy was not directly measured in this survey, it likely played a role in the overall sense of privacy. Other research has found that nurses perceive single-bed rooms to be more appropriate for patient examinations and collection of patient histories (Chaudhury et al., 2006). Enhanced confidentiality and privacy were among the important reasons for such evaluations.

High-performance sound-absorbing materials for environmental surfaces. As previously mentioned (in Reducing Patients' Sleep and Reducing Patient Stress), materials for surfaces such as ceilings, floors, and walls substantially affect acoustic conditions. Existing studies have demonstrated the positive effects of installing high-performance ceiling tiles and other sound-absorbing surface materials in reducing reverberation time, sound propagation, and noise pressure levels (Hagerman et al., 2005; Philbin & Gray, 2002). Such design measures also would likely enhance the speech privacy

HERD VOLUME 1, NUMBER 3, PP 61-125 COPYRIGHT ©2008 VENDOME GROUP, LLC

of environments, because the improved acoustic conditions, such as reduced sound propagation, would lessen voice travel to adjoining spaces.

Other environmental approaches to protect speech privacy. Certain other environmental approaches may also be helpful. As pointed out by Joseph and Ulrich (2007), *providing private discussion rooms* should help reduce privacy breaches in spaces such as waiting areas and admission and reception areas, where confidential information often is discussed. Such rooms are also necessary for patient floors with multibed rooms to protect speech privacy during communication between physicians and patients or their families. Additionally, the use of a *wireless communication system* may be considered so that healthcare staff, patients, and their families need not raise their voices to be heard across large spaces or down hallways. In addition, to protect speech privacy some ceiling system manufacturers recommended the use of *sound masking*, which is "the precise application of electronic background sound that blends into the environment to cover up or mask unwanted noise" (Armstrong Ceiling System, 2003). However, there appears to be a lack of solid research supporting its appropriateness and safety in healthcare settings, because sound masking in some situations might lower clinicians' ability to detect and respond to many different types of sounds, ranging from alarms to the spoken communication of staff (Joseph & Ulrich, 2007).

Directions for future research. Although the limited amount of research discussed here provides some important evidence, there is a need for future studies that use more sensitive and advanced acoustic measures, such as the privacy index (PI). PI takes into account the acoustic performance of all finishes in a space, including ceilings, floors, and furniture (Armstrong Ceiling System, 2003), and it was employed by the new *Interim Sound and Vibration Design Guidelines for Hospital and Healthcare Facilities* (ANSI S12/WG44 [Healthcare Acoustics and Speech Privacy] and the Joint ASA/INCE/NCAC Subcommittee on Healthcare Acoustics & Speech Privacy). It is important that both researchers and designers keep informed regarding these updated standards.

Improving Communication with Patients and Family Members

Summary of Evidence and Recommendations

The communication among patients, family, and staff is important because it can provide social support to patients and family members, facilitate family members' involvement in patient care, and also increase patient satisfaction with care (Laitinen & Isola, 1996; Press Ganey, 2007). Several studies have demonstrated that providing *single-patient rooms* and *private discussion areas* can facilitate communication (Astedt-Kurki, Paavilainen, Tammentie, & Paunonen-Ilmonen, 2001; Kaldenburg, 1999). Limited evidence supports the use of *dim lighting* instead of bright lighting in counseling rooms to achieve better communication and counseling results (Miwa & Hanyu, 2006). More research is needed to explore further environment-communication relationships in more diverse healthcare settings and how design measures can enhance communication.

Importance of Communication

Evidence has shown that staff-family communication can provide social support to patients, their family members, and staff, and facilitate family members' involvement in patient care. A survey comprising 369 relatives and significant others of elderly patients indicated that family-staff communication is a good source of social support for families: it helps meet family needs and reduces patient and family anxiety (Laitinen & Isola, 1996). The same study also found that better family-staff communication increased the level of family members' involvement in providing care. In fact, the lack of communication between family members and staff was the primary reason cited for family members' failure to be involved in the care of patients.

Good communication is also of the utmost importance in terms of patient satisfaction with care across different patient categories (Press Ganey, 2007). According to the data obtained from 2,359,935 patients nationally in 2006, the five top-priority issues that patients identified as affecting satisfaction are associated with communication and empathy, including (1) response to concerns/complaints made during the hospital stay; (2) staff sensitivity to the inconvenience that health problems and hospitalization can cause; (3) staff effort to include you

 A53210128

in decision making about your treatment; (4) degree to which hospital staff addressed your emotional needs; and (5) how well the nurses kept you informed. These five priorities also represent specific needs of family members, such as information, assurance, proximity, support, and comfort, which were identified by several other studies (Engli & Kirsivali-Farmer, 1993; Mathis, 1984; Molter, 1979; Verhaeghe, Defloor, Van Zuuren, Duijnstee, & Grypdonck, 2005).

Environmental Factors Affecting Communication

Several studies have found that the degree of interaction and communication in healthcare settings depends on nurses' and family members' personal characteristics, as well as how the staff-family relationship has been built (Astedt-Kurki et al., 2001; Hupcey, 1998; Soderstrom, Saveman, & Benzein, 2006; Soderstrom, Benzein, & Saveman, 2003).

Providing single-patient rooms and private areas has the benefit of facilitating communication, along with other important advantages such as preventing infections, better privacy, and less noise and crowding for families. A study by Astedt-Kurki et al. (2001) identified several factors facilitating or complicating the interaction between an adult patient's family members and nursing staff. Using a questionnaire, data were collected from 155 nursing staff working on the wards and outpatient departments at a university hospital in Sweden. Interestingly enough, one of the factors complicating interaction was the absence of a peaceful place for discussion, along with the staff's haste, shift-work, and family members' shyness of approaching the staff. Semiprivate patient rooms are perceived as busy places where roommates and their families can overhear discussions. This study implies that spaces that are private and peaceful may contribute to improved communication. Kaldenburg (1999) has found that staff members in multibed rooms are reluctant to discuss patient issues or give information when they are within hearing distance of a roommate, out of respect for patient privacy. National survey data also show that patients consistently report significantly higher satisfaction with communication from nurses and physicians when they are in single rooms compared to when they have one or more roommates (Press Ganey, 2003).

It is unfortunate that there is not much research on how the built environment enhances or hinders communication, other than for single- versus multibed rooms. There is one study that examined the effect of a specific environmental factor—dim lighting—on enhancing communication (Miwa & Hanyu, 2006). Using 80 undergraduate students as subjects, this experimental study compared four different interior conditions of counseling rooms by using different decorations (with or without home-like decorations) and types of lighting (bright or dim). The researchers found that participants in the dim lighting conditions spoke longer about themselves and their identity during the interview than did participants in the bright lighting conditions, which meant more self-disclosure, more pleasant and relaxed feelings, and more favorable impressions of the interviewer. However, they found the decorations had no significant effect. Thus, this study suggested that dim lighting in counseling rooms could enhance communication.

Fostering Social Support

Summary of Evidence and Recommendations

Social support has been described as emotional, informational, and tangible support (Kahn & Antonucci, 1980), and is normally received from people in a social network and the family (McMurray, 1998). However, contacts with one's social support network are limited while the patient is hospitalized (Koivula, Tarkka, Tarkka, Laippala, & Paunonen-Ilmonen, 2002). This is unfortunate because the need for social support increases when an individual experiences changes such as an unexpected situation or stressful event (Tarkka, Paavilainen, Lehti, & Astedt-Kurki, 2003), including a hospitalization. There is strong evidence showing the benefits of social support for patients and their families (Kaunonen, Tarkka, Paunonen, & Laippala, 1999; Koivula, Paunonen-Ilmonen, Tarkka, Tarkka, & Laippala, 2002; Koivula, Tarkka et al., 2002; McMurray, 1998; Tarkka et al., 2003).

However, there is only a moderate level of evidence linking design features to the level or quality of social support. Some studies have shown that *single-patient rooms* increase the presence of family members and social support, as compared with multibed rooms (Chaudhury,

HERD VOLUME 1, NUMBER 3, PP 61-125 COPYRIGHT ©2008 VENDOME GROUP, LLC

Mahmood, & Valente, 2003; Sallstrom, Sandman, & Norberg, 1987). There is also evidence that recommends the provision of *lounges, day rooms, and waiting rooms with comfortable, movable furniture arranged in small, flexible groupings*, in order to facilitate social interactions (Holahan, 1972; Melin & Gotestam, 1981; Peterson, Knapp, & Rosen, 1977; Sommer & Ross, 1958). The use of *carpeting* instead of vinyl for floors in patient rooms appeared to increase the length of family's stay (Harris, 2000). But such measures should be applied with a comprehensive consideration, including the possible impact on infection control and cleaning, which is an area that awaits more research. (See Reducing Hospital-Acquired Infections.)

Social Support for Patients

Several studies have found that social support from nurses, families, and significant others reduces patient stress, improves patients' physiological outcomes, and has a positive influence on both patients and family members (Kaunonen et al., 1999; Koivula, Tarkka et al., 2002; McMurray, 1998; Tarkka et al., 2003). Researchers in Finland examined the impact of in-hospital social support on coronary artery bypass grafting patients' preoperative fear and anxiety, using the survey data collected from 193 inpatients (Koivula, Paunonen-Ilmonen, Tarkka, Tarkka, & Laippala, 2002). They found that when the amount of social support was high, patients experienced lower levels of fear and anxiety.

Several studies also found that increased patient-family interactions, as part of social support from families, improve patients' physiological outcomes and facilitate patient progress (Bay, Kupferschmidt, Opperwall, & Speer, 1988; Chatham, 1978; Happ et al., 2007). An experimental study by Chatham (1978) looked at the impact of social support through patient-family interaction on a patient's postoperative behaviors. An 11-item "Behavioral Checklist" was used to measure manifestations of postcardiotomy psychosis, such as the disorientation, alertness, inappropriateness, confusion, sleep, and anxiety of open-heart surgery patients. Results showed that patients with specific social interactions with families (such as eye contact, frequent touch, and verbal orientation to time, person, and place) exhibited fewer manifestations of postcardiotomy psychosis. The studies by Hendrickson (1987) and Bruya (1981) showed a decrease in intracranial pressure during family presence and patient-family interactions among patients at risk for increased intracranial pressure. A qualitative study by Happ et al. (2007) also found that family presence and their social support through touching, talking, and surveillance helped patients to deal with their treatments better and facilitated their clinical progress. The study showed that ICU and step-down patients with family members present withdrew significantly more quickly from long-term mechanical ventilation.

Support for Family Members

There is an extensive body of literature emphasizing the need for the social support of patients' families. The evidence indicates that social support reduces families' stress, anxiety, and depression, and increases their satisfaction with the hospital stay. A family member's long-term illness affects the well-being and health of the entire family. Family members also need support to cope with a long-term illness or the death of their loved one (Tarkka et al., 2003). For example, a questionnaire study of 318 Finnish widows and widowers found that social support helped in coping with grief (Kaunonen et al., 1999). The results showed that the study subjects receive social support most often from their own families and friends and that they perceived support to be helpful. Respondents who had social support were able to grieve by expressing their feelings and forgetting the demands of normal life, whereas those without support had to hold themselves up and continue the duties of normal life, which could produce excessive psychological demands without adequate sources for coping. Based on data collected through subject interviews and questionnaires, a study of 417 patient-spouse pairs found that spouse anxiety and depression were correlated with patient psychosocial distress (Moser & Dracup, 2004). They found that patients' psychosocial adjustment to illness was worse when spouses were more anxious or depressed than the patients.

Role of the Physical Environment in Encouraging Social Support

Despite the well-established importance of social support, there is only a moderate amount of research con-

cerning how hospital design can facilitate or hinder access to social support. There is strong evidence that levels of social interaction, and presumably beneficial social support as well, can be increased by providing *lounges, day rooms, and waiting rooms with comfortable, movable furniture arranged in small, flexible groupings*. A few well-designed studies in psychiatric wards and nursing homes have found that the appropriate arrangement of movable seating in dining areas enhances social interaction and also improves eating behaviors, as indicated by the increased food consumption of geriatric patients (Melin & Gotestam, 1981; Peterson et al., 1977). Much research on dayrooms and waiting areas has shown that the widespread practice of arranging seating side-by-side along room walls inhibits social interaction (Holahan, 1972; Sommer & Ross, 1958). A novel study by Harris (2000) found that family and friends stayed substantially longer during visits to rehabilitation patients when patient rooms were carpeted rather than covered with vinyl flooring.

Much evidence indicates that *single-bed rooms* are markedly better than multibed rooms for supporting or accommodating the presence of family and friends. A clear advantage of single-bed rooms in fostering social support stems from the fact that they provide more space and furniture than double rooms to accommodate family presence (Chaudhury et al., 2003). Some research suggests that open-plan multibed rooms deter family presence and therefore reduce social support (Sallstrom et al., 1987). One reason is that multibed rooms greatly reduce privacy for patient-family interactions compared to single rooms, and they are much more likely to have restricted visiting hours. A survey of staff in four hospitals, each of which had a mix of single and double rooms, found that nurses assigned higher ratings to single rooms for accommodating family members (Chaudhury et al., 2003).

Increasing Patient Satisfaction

Summary of Evidence and Recommendations

Environmental satisfaction is a significant predictor of overall satisfaction in healthcare settings (Harris, McBride, Ross, & Curtis, 2002). There is strong evidence that a satisfying environment should be designed with patients' and families' needs in mind. It should provide a comfortable and aesthetically pleasing environment (through the use of color, artwork, etc.), and provide nice window views (preferably with nature), adequate lighting or sunlight, and a helpful information guide. The provision of single-patient rooms can afford favorable environmental features, such as quiet, privacy, an accessible bathroom, and a sense of control, and thereby can improve patients' satisfaction with the healthcare experience.

Evidence From Intervention Studies and Surveys

Telephone interviews with 380 discharged inpatients have helped determine that environmental satisfaction was a significant predictor of overall satisfaction with healthcare, ranking only below perceived quality of nursing and clinical care (Harris et al., 2002). The same study also identified specific environmental factors that were perceived to be pleasing and satisfactory to patients, including: (1) color of the wall, artwork, comfortable bed, television working properly, and easy access to anything in the patient room; (2) a window with a nice view, an accessible bathroom in the room, and a room located away from noisier areas of unit; (3) adequate lighting, quiet surroundings, and a comfortable temperature; (4) a private room, environmental means for privacy (e.g., a closed door); and (5) cleanliness of the room.

Data obtained nationally by Press Ganey (2007) support the importance of and need for better room environments to improve patient satisfaction with the hospital experience. Data show that patients complained about temperatures ("too cold") and high noise levels ("so noisy") in their rooms. Another study by Hagerman et al. (2005) also found a relationship between the noise level in patient rooms and patient satisfaction by comparing patients' responses during the bad acoustic period (with sound-reflecting ceiling tiles) to those in the good acoustic period (with sound-absorbing ceiling tiles). They found that patients treated during the good acoustic period considered staff attitude to be much better, implying that good room acoustics has an effect on patient satisfaction with staff.

There is strong evidence that design changes that make the environment more comfortable, aesthetically pleas-

HERD VOLUME 1, NUMBER 3, PP 61-125 COPYRIGHT ©2008 VENDOME GROUP, LLC

ing, and informative relieve patient stress and increase satisfaction with the quality of care. Renovating a traditional waiting area in a neurology clinic (e.g., making small changes to the general layout, color scheme, furniture, floor covering, curtains, and providing informational material and information displays) resulted in more positive environmental appraisals, an improved mood, an altered physiological state, and greater reported satisfaction among waiting patients (Leather, Beale, Santos, Watts, & Lee, 2003). Patients in well-decorated and well-appointed, hotel-like rooms rated their attending physicians, housekeeping, food-service staff, food, and the hospital higher than patients in standard rooms (with typical hospital beds, inexpensive family sitting chairs, and no artwork) in the same hospital. Also, they had stronger intentions to use the hospital again and would recommend the hospital to others (Swan, Richardson, & Hutton, 2003).

It is also important to consider how the physical environment can help family members meet their needs to increase their satisfaction with hospital stays. There is a considerable body of literature identifying the needs of family members, especially in the intensive care setting (Engli & Kirsivali-Farmer, 1993; Mathis, 1984; Molter, 1979; Verhaeghe et al., 2005). Molter (1979) investigated and developed the most commonly used instrument for measuring family needs in the ICU—the Critical Care Family Needs Inventory (CCFNI). Among 45 family need statements in CCFNI, there are eight family needs that can be addressed by means of the physical environment: (1) have a waiting room near the patient; (2) see the patient frequently; (3) have a bathroom near the waiting room; (4) have comfortable furniture in the waiting room; (5) have friends nearby for support; (6) have a telephone near the waiting room (7) have a place to be alone while in the hospital; and (8) provide the ability to be alone at any time. Another study also indicated that having a place to rest, having a waiting area, and offering overnight accommodations were essential for families' satisfaction in the neonatal intensive care setting (Conner & Nelson, 1999).

The previous studies agree in predicting that single-patient rooms could significantly improve patients' and family members' satisfaction with the healthcare experience, because they can accommodate many preferred environmental features such as quiet, privacy, an accessible bathroom, and a sense of control. Several studies have focused on the impact of specific types of single-patient rooms on patient satisfaction and other clinical and financial measures (Brown & Gallant, 2006; Hendrich et al., 2004). Hendrich et al. (2004) conducted a pre/post comparison of the two years before the move to acuity-adaptable, single-patient rooms and three years after the move; they found improvements in predictive indicators of patient satisfaction. Patients were less nervous or withdrawn and treated with more respect, and nurses were regarded as more caring.There was also an improvement in quality and operational cost.

Result III: Improving Staff Outcomes Through Environmental Measures

Decreasing Staff Injuries

Summary of Evidence and Recommendations

Hospital workers experience a high rate of occupational injury, especially musculoskeletal injuries attributable to patient handling. Some injuries take healthcare workers away from their normal job duties. It is estimated that up to 38% of all nurses in the United States suffer from back injuries (American Nurses Association, 2002). Based on 2005 data, the rate of occupational injuries and illnesses for hospitals is almost double the rate for all of private industry (8.1 cases per 100 full-time workers versus 4.6 cases per 100 in industry) (Bureau of Labor Statistics, 2007). Further, as a result of these injuries, hospital workers were away from work or on restricted job duties for 3.3 days per year per 100 full-time workers.

Many studies have been undertaken to evaluate the physical stress and strain caused by patient handling. *Ceiling lifts* have been identified the most consistently as reducing the incidence of injury and the cost of injury claims. The research findings have not been as clear regarding the use of ceiling lifts for *repositioning patients*, which, because of the awkward angles required to perform this task, results in greater numbers of injuries; these injuries are not reduced as dramatically by the use of lifts. As with all physical environment interventions, to be most effective it is critical that the introduction of

lifts be accompanied by a comprehensive patient lifting program. In fact, most of the studies reviewed involved a combination of lifts and cultural change; therefore it is difficult to isolate the effect of the lifts alone.

Lifts

Musculoskeletal injuries are often caused or aggravated by patient handling. However, it is encouraging that many studies have documented reductions in staff back injuries following the installation of assistive devices and improved procedures or room design (Chhokar et al., 2005; Engst, Chhokar, Miller, Tate, & Yassi, 2005; Evanoff, Wolf, Aton, Canos, & Collins, 2003; Garg & Owen, 1992; Hignett & Evans, 2006; Keir & MacDonell, 2003; Li, Wolf, & Evanoff, 2004; Miller, Engst, Tate, & Yassi, 2006; Yassi et al., 2001). For example, using ceiling-mounted or mobile lifts may help to reduce back injuries. Several studies have found that ceiling lifts were more effective at reducing injuries and require less time and space to use, compared with mobile lifts (Hignett & Evans, 2006; Keir & MacDonell, 2003). A study comparing two long-term care facilities in Canada identified a dramatic difference in the cost of nursing injury claims for the facility that installed ceiling lifts versus the facility that had only mechanical floor lifts. For the year following the installation of the ceiling lifts, this facility experienced a 70% decrease in claims costs and 18 fewer days lost compared to the prior year. In contrast, the facility without the ceiling lifts experienced a 241% increase in claims costs and had 499 additional days lost during the same year compared with the previous year (Miller et al., 2006). Similarly, Engst et al.'s (2005) prospective study found that the unit with ceiling lifts reduced compensation costs for injuries from lifting and transferring patients by 68%, while the control unit without ceiling lifts saw a rise in cost of 68%.

Not surprisingly, lifts are more useful in facilities that require nurses to perform more patient handling activities, such as long-term care facilities. In a comparison of the effect of lifts in acute care settings versus long-term care facilities, the use of lifts was more frequent in long-term care facilities, which consequently showed greater reductions in lost staff time due to injury (Evanoff et al., 2003). Even when the upfront cost of the lifts is considered, the savings have been demonstrated to be worthwhile. Two separate studies of ceiling lifts revealed a payback of the initial cost in 2.5 years or less (Chhokar et al., 2005; Joseph & Fritz, 2006).

Repositioning

Although overall injury rates are generally found to decline with the introduction of lifts, there have been less consistent findings about the value of lifts when used for repositioning patients rather than lifting them. Two articles reported findings from a study conducted at an extended care unit of a British Columbia hospital that installed 65 ceiling lifts to support 125 beds and three tubs in 1998. The first article examined data from the 20-month period following the installation of the lifts (Ronald et al., 2002). Although there was no overall decrease in musculoskeletal injuries, there was a reduction in the rate of workforce injuries caused by lifting and transferring patients from 14.5 injuries per 100,000 hours worked preintervention to 8.1 injuries per 100,000 hours worked postintervention. A subsequent article looked at data over a three-year period and found a reduction in the overall number of claims and a decrease in the number of injuries from repositioning (Chhokar et al., 2005). Overall claims from patient handling went from 65 during the three years preintervention to 47 postintervention. The difference in repositioning injuries is explained by the fact that there were no repositioning slings available during the first year. Chhokar and colleagues further suggested that the actual reduction in injuries might be greater because back injuries can result from cumulative rather than acute stress, and therefore, some of the injuries reported in the first year after the intervention might be the result of lifting tasks from prior years. In contrast, another study in a 75-bed extended care unit of a community hospital tracked impacts for 21 months after the intervention and found no decrease in injuries from repositioning (Engst et al., 2005). In fact, more than half the staff in the intervention ward preferred to reposition patients manually with the help of other staff rather than use a lift.

More research is needed to understand whether or not ceiling lifts can reduce staff injuries from repositioning patients. An evaluation of insurance records

HERD VOLUME 1, NUMBER 3, PP 61-125 COPYRIGHT ©2008 VENDOME GROUP, LLC

(2000–2001) from seven hospitals found that 17.9% of reported injuries from hospital workers were the result of repositioning patients, which was the highest single cause of injury (Fragala & Bailey, 2003).

Comprehensive Patient Handling Programs

The majority of previous studies have focused on comprehensive patient lifting programs without isolating the independent effect of mechanical lifts. All of these studies support the importance of changing both the culture and the physical environment. A case study from a 525-bed nursing home shows impressive results from the implementation of a comprehensive strategy, which included protocol changes, training, and regular maintenance of equipment in addition to making mechanical lifting devices available (Brophy, Achimore, & Moore-Dawson, 2001). Results showed a reduction in the average annual costs attributed to low-back injuries from $201,000 to $91,000. In another nursing home study, Garg and Owen (1992) examined an ergonomic intervention strategy, which selected patient transferring devices that produced less physical stress for nursing personnel. This intervention also included training nurse assistants to use these devices and modifying toilets and shower rooms. This ergonomic intervention resulted in a reduction in back injuries of almost 50%, from 83 per 200,000 work hours to 47 per 200,000 work hours, and a reduction in physical stress and risk of low-back pain to nursing personnel.

Specialized Devices

One study found that strain on the backs of nursing staff could be reduced simply by providing slings to assist in moving patients from one seat to another, which also decreased capital outlay (Elford & Straker, 2000). However, the researchers measured only the spinal strain on nurses with and without slings; they did not estimate the impact in terms of reduced injuries or cost. Another laboratory study evaluated different pieces of equipment used to assist with bathing and how they affected the postural load on caregivers. Results showed that the adjustable shower chair, the adjustable bath, and the adjustable shower trolley caused the least stress on postural load, and the fixed shower chair and trolley caused the most postural stress (Knibbe & Knibbe, 1996).

Contradictory Evidence

It should be noted that not all of the previous studies found a conclusive link between the provision of mechanical lifting aids and the reduction of back injuries. One study in the United Kingdom did not reach significant findings, perhaps owing to the research design: the control hospital ended up implementing a patient handling program halfway through its research and the program implemented at its intervention hospital was not very robust. It was unclear what kind of hoists were used and how many of them were provided; the focus appears to be on training and other assistive device, such as sliding sheets (Smedley et al., 2003).

A Canadian study did not show differences in the rate and cost of injuries in wards with and without mechanical lift devices, but it did find that staff with access to assistive devices reported improved comfort, an increased sense of safety, and decreased fatigue (Yassi et al., 2001). In contrast, a 2005 study found that staff in the ward *without* ceiling lifts felt less stressed about their jobs and less worried about making mistakes than did the intervention group that had ceiling lifts, despite the fact that 96% of the staff members in the intervention group reported that the ceiling lifts made their jobs easier. One possible explanation for this is that using ceiling lifts to transfer patients took more time than manual lifts and transfers, and this additional time might lead to the perception of a more hectic work environment (Engst et al., 2005).

On the other hand, despite the mostly consistent positive impacts of mechanical lifts, many studies found that staff often declined to use the lifts for a variety of reasons (e.g., it takes more time and requires more space; lifts are not conveniently located, etc.) and the presence of lifts does not ensure their adoption (Chhokar et al., 2005; Evanoff et al., 2003; Joseph & Fritz, 2006; Li et al., 2004). Therefore, special attention should be paid to changing the workplace culture, such as providing training and enforcing a no-lift policy. Overall, the literature showed that comprehensive safe-patient-handling programs are important for reducing staff injuries; having mechanical lifts that are readily available and easy to use is a key component of successful programs.

Decreasing Staff Stress

Summary of Evidence and Recommendations

Healthcare providers, especially nurses, experience a high level of work stress (Jayaratne & Chess, 1984; Pines & Maslach, 1978; Siefert, Jayaratne, & Chess, 1991; Tummers, Janssen, Landeweerd, & Houkes, 2001). Several studies indicate that high workplace stress contributes to employee burnout and an intention to leave the job (Barrett & Yates, 2002; Pines & Maslach, 1978; Topf & Dillon, 1988). Registered nurses have an annual turnover rate averaging 20% (Joint Commission, 2002). Stress is a particular problem as nurses approach the possibility of retirement: 55% of nurses surveyed, predominantly managers, reported they intended to retire between 2011 and 2020 (Hader, Saver, & Steltzer, 2006). Auerbach, Buerhaus, and Staiger (2007) recently estimated that the U.S. shortage of registered nurses will increase to 340,000 by the year 2020. Although this is substantially less than the forecast made in 2000 predicting a shortfall of 800,000 registered nurses, the authors note that the nursing shortage is expected to increase to three times the size of the current shortage (Auerbach et al., 2007).

Despite convincing evidence on the negative impact of stress on healthcare workers, especially ICU nurses, relatively few studies have examined how the physical environment contributes to staff stress. Environmental factors associated with stress include noise, light, and single- versus multibed patient rooms. Noise is the most frequently studied environmental factor related to stress in hospitals, and it can be reduced by environmental approaches such as using high-performance, sound-absorbing materials. A few studies have documented the importance of light in modulating circadian rhythms and thereby improving the adjustment to night-shift work among staff. The administration of bright light in staff work areas can be useful to alleviate stress among night-shift nurses, but the specific design implications should be further examined. Finally, survey research in NICUs found that single-bed patient rooms were perceived to be less stressful for both family and staff than open-bay multibed rooms (Harris, Shepley, White, Kolberg, & Harrell, 2006).

Severity of Staff Stress

Several studies have examined the effects of stress on healthcare workers, especially nurses working in intensive care settings (Corr, 2000; Fischer, Calame, Dettling, Zeier, & Fanconi, 2000a, 2000b; Le Blanc, de Jonge, de Rijk, & Schaufeli, 2001; Sexton, Thomas, & Helmreich, 2000; Smith et al., 2001). Oehler and Davidson (1992) found acute care nurses had higher levels of job stress and *burnout* than nurses in nonacute settings. Fischer et al. (2000a, 2000b) studied stress in ICU staff by measuring levels of the stress hormone cortisol. They found that stress-related cortisol surges occurred frequently in a sample of 112 nurses and 27 physicians in NICUs and PICUs.

Stress affects *performance*, especially for novices. For example, Smith et al. (2001) examined the relationship between psychological stress and performance by studying 45 novice registered nurses in ICUs. They found that nurses in a high state of anxiety performed less well in endotracheal suctioning than their more relaxed peers. This implies that nurses with high anxiety may be at risk for medical errors and poor performance, in addition to higher burnout and attrition.

Environmental Factors Affecting Stress

Although there is considerable evidence on the negative effects of stress on healthcare workers, relatively few studies have examined how the physical environment contributes to staff stress. Several descriptive studies on staff stress have assessed the possible effects of the characteristics of intensive care environments, such as blinking lights, alarms, and equipment noise (Corr, 2000; Donchin & Seagull, 2002; Dyson, 1999). A review paper by Corr (2000) identified the healthcare physical environment as one of the causes of occupational stress, along with the job itself and the organization. Several studies of nonhealthcare workplaces such as commercial offices have found that environmental factors associated with stress include noise, crowding, poor ambient conditions (light, air quality, and temperature), and lack of control over the environment, especially the inability to regulate social conditions and achieve privacy when desired (Baum, Singer, & Baum, 1981; Evans & Cohen, 1987). However, comparatively little research has evaluated the impact of

HERD VOLUME 1, NUMBER 3, PP 61-125 COPYRIGHT ©2008 VENDOME GROUP, LLC

these various environmental factors on staff stress in healthcare settings.

Reduce staff stress by controlling noise. *Noise* is the most frequently studied environmental factor related to stress in hospitals. However, much research has examined the effects of noise on patients, and few studies have focused on its impact on healthcare staff. Survey research has found that staff perceived higher sound levels as stressful and interfering with their work (Bayo, Garcia, & Garcia, 1995; Norbeck, 1985). More importantly, Topf and Dillon (1988) found that noise-induced stress correlates with reported emotional exhaustion or burnout among critical care nurses. A quasi-experimental study by Blomkvist et al. (2005) in Sweden demonstrated the positive impact of a single environmental factor—sound-absorbing ceiling tiles (versus sound-reflecting ones)—on the perceived reduction of stress by the same group of coronary intensive care nurses over a period of months. Nurses perceived significantly lower work demands and reported less pressure and strain when the sound-absorbing tiles were in place. A survey by Harris et al. (2006) in NICUs has found that staff perceived a unit with single-patient rooms to be less stressful for both family and staff than an open-bay unit, owing to better privacy and control over the environment with respect to noise, light, temperature, and traffic.

Reduce staff stress with light. Several studies have documented the importance of light in reducing depression (see Reducing Depression), modulating circadian rhythms, and improving sleep quality (see Improving Patients' Sleep). By controlling the body's circadian system, appropriate exposure to intermittent bright light also aids the adjustment to night-shift work among staff, as demonstrated by several studies (Baehr, Fogg, & Eastman, 1999; Boivin & James, 2002; Crowley, Lee, Tseng, Fogg, & Eastman, 2003; Horowitz, Cade, Wolfe, & Czeisler, 2001; Iwata, Ichii, & Egashira, 1997; Leppamaki, Partonen, Piiroinen, Haukka, & Lonnqvist, 2003). One study with 87 female night-shift nurses examined whether repeated, brief exposure (4x 20 minutes) to bright light (over 5,000 lux) during night shifts improved subjective well-being during and after night work (Leppamaki et al., 2003). Results showed that light significantly alleviated the subjective distress associated with night-shift work, in both summer and winter. Bright light (over 2,500 lux) is used for the treatment of seasonal affective disorder in winter (Partonen & Lonnqvist, 1998). A recent study by Partonen and Lonnqvist (1998) found that bright light exposure appears to have a positive effect on mood even in healthy people.

Another study found that staff with more than three hours of *daylight* exposure during their shift had higher job satisfaction and less stress than staff with less daylight exposure. However, the findings are complicated by the factor of types of nursing activities: Nurses from ICUs, EDs, or ORs were mostly exposed to daylight for less than 3 hours, while nurses from inpatient units mostly had an exposure of more than 3 hours (Alimoglu & Donmez, 2005). More research is needed to understand the impact of natural light on staff stress.

Increasing Staff Effectiveness

Summary of Evidence and Recommendations

Jobs by nurses, physicians, and other healthcare workers often require a complex choreography of direct patient care, critical communications, charting, accessing technology and information, and other tasks. Many hospital settings have not been redesigned, although jobs have been changed, and as a result, hospital environments often increase staff stress and reduce effective care delivery. The challenge of maintaining staff effectiveness will be increasingly important as the nurse shortage mounts and the aging population increases the demand on the healthcare system. While much research in the hospital setting has been aimed at patients, there is a growing and convincing body of evidence suggesting that improved hospital design can make the jobs of staff easier. The physical environment interventions that have been shown to affect staff effectiveness include unit configuration, noise, and other distractions. Lighting levels may also have an impact on staff effectiveness, but relevant studies are still limited.

Unit Configuration

Workplace design that reflects a closer alignment of work patterns and the physical setting, such as the re-

A53210128

design of a pharmacy layout, has been shown to improve workflow, reduce waiting times, and increase patient satisfaction with service (Pierce, Rogers, Sharp, & Musulin, 1990).

According to one study of nursing staff, walking accounted for 28.9% of work time and was ranked second among various activities, following patient-care activities that accounted for 56.9% of work time (Burgio, Engel, Hawkins, McCorick, & Scheve, 1990). At least four studies have shown that the *type of unit layout* (e.g., radial, single corridor, double corridor) influences the amount of walking among nursing staff (Shepley, 2002; Shepley & Davies, 2003; Sturdavant, 1960; Trites, Galbraith, Sturdavant, & Leckwart, 1970), and two studies showed that time saved from walking was translated into patient-care activities and interaction with family members (Trites et al., 1970). Sturdavant (1960) found that fewer trips were made to patient rooms in radial units, because nurses were able to better supervise patients visually from the nursing station, although the average time spent with patients was the same in radial units as in single-corridor designs. Shepley and Davies (2003) found that nursing staff in the radial unit walked significantly less than staff in the rectangular unit (4.7 steps versus 7.9 steps per minute). However, they also noted that radial designs might provide less flexibility in managing patient loads. In addition, the majority of the staff surveyed preferred to work in the radial units.

Some studies showed that *decentralized nurse stations* reduced staff's walking time and increased patient-care time, especially when supplies were also decentralized and placed near the nurse stations (Hendrich, 2003; IOM, 2004). The location of supplies is particularly important. Centralized location of supplies could double staff walking and substantially reduce care time irrespective of whether nurses stations were decentralized (Hendrich, 2003). Other studies that compared delivery times in centralized and *decentralized pharmacy systems* found that medication delivery times were reduced by more than 50% when using decentralized distribution systems (Hibbard, Bosso, Sward, & Baum, 1981; Lomonte, Besser, & Thomas, 1983; Reynolds, Johnson, & Longe, 1978).

By shifting over to an *acuity-adaptable model* for cardiac-care patients, Clarian Health's Methodist campus reduced the number of patient transfers by 90%, and thereby reduced the amount of nursing time expended on this "nonvalue" activity (Hendrich et al., 2004). Methodist Hospital also introduced decentralized nursing stations and supply centers. Researchers observed a reduction in staff time spent walking to get supplies and a resulting increase in nursing time, although this change was not quantified in the article. Another interesting finding was that they were able to accommodate a greater number of patient days with fewer beds, with 56 acuity-adaptable beds postintervention versus a total of 63 beds preintervention (Hendrich et al., 2004).

The *co-location of similar services* can result in better coordination of caregivers. Gilleard and Tarcisius (2003) found this to be the case in a pediatric unit in Hong Kong that was redesigned to put all physical therapy needs (e.g., speech therapy, physiotherapy, occupational therapy) in one large room. Surveys showed that both staff and patients preferred the consolidated arrangement over the previous distributed model.

Noise and Distractions

Noise levels can be high in hospital environments and noise is recognized as a distraction and stressor for staff, resulting in reduced productivity. Hospital staff often complains that noise levels make their work more difficult, particularly when it comes to monitoring patients' vital signs (Sanderson et al., 2005; Zun & Downey, 2005).

ED personnel experience especially high levels of ambient noise. Previous studies have confirmed that it can be difficult for staff members to assess patients' breathing and heartbeat in noisy and moving environments such as ambulances and helicopters (Zun & Downey, 2005). Despite these complaints, a recent study tested the ability of hospital staff to measure patients' heart and lung sounds under high ambient noise conditions (90dB), and found that the majority of the staff (>90%) had no problem accurately detecting these sounds using standard equipment (Zun & Downey, 2005). The study involved 104 participants, ranging from attending physicians to technicians, and

HERD VOLUME 1, NUMBER 3, PP 61-125 COPYRIGHT ©2008 VENDOME GROUP, LLC

subjects were exposed to noise levels that were over 20 dB higher than the peak volume in a study of four EDs in Phoenix, Arizona. However, noise often has chronic rather that acute effects on performance and stress. Some studies such as those by Blomkvist and colleagues (2005) have identified long-term negative effects of noise on staff.

Loud ambient noise is the source of significant complaints in the OR (Sanderson et al., 2005). Studies have found noise levels in operating theatres to be 80–85 dB for a background level with intermittent spikes of 110–115 dB (Moorthy et al., 2004). However, not all studies indicate that a noise level of 80–85 dB is problematic. A controlled study of 12 surgeons performing laparoscopic procedures on a test module under various noise conditions (80–85 dB, both with music and under quiet conditions) found no impact of noise on the quality of performance or time taken to perform the procedure (Moorthy et al., 2004). But this study did not evaluate the impact of high peaks of intermittent noise. More research is needed to evaluate the impact of noise on communication among staff, particularly in ORs and EDs.

In addition, the typical noise produced by talking, equipment, and procedures may be compounded by noise from music, which may be played in the OR for a variety of reasons. In one U.K. survey, 72% of anesthesiologist respondents reported that music was regularly played in the OR, although 51% found music distracting and 26% found that music reduced their vigilance (Hawksworth, Asbury, & Millar, 1997). To test whether and how music plays a role in the performance of anesthesiologists, Sanderson and colleagues (2005) asked 24 participants with no medical or physiological training to monitor and report vital signs from a simulated patient using visual and auditory displays. Participants were tested under three auditory conditions: no music playing, classical music playing, and rock music playing. While participants believed that completing the task while listening to classical music was more enjoyable, a majority of participants (16 of 24) believed that the task itself was easier when completed in silence. However, the presence of music appeared to help participants to gauge correctly the direction of trends in vital signs, which were provided by the auditory display. Sanderson and colleagues speculated that this effect was because the music provided a metrical standard against which the participants could compare auditory data. It still remains to be answered whether any of these findings can be generalized to anesthetists, surgeons, or healthcare workers in general. At least one study casts doubt on the ability to generalize such findings from nonsurgeons to surgeons, and it suggests that surgeons may acquire a certain ability to block out extraneous noise while in the OR (Moorthy et al., 2004).

Surgeons are less adept when they are required to process healthcare tasks and respond to auditory distractions at the same time. In Goodell et al.'s (2006) study, 13 participants, consisting of surgical residents and medical students, were asked to perform a laparoscopic task under an uninterrupted control condition and an interrupted experimental condition, where participants were required to solve a number of arithmetic problems while performing the procedure. While the quality of the participants' work did not suffer because of cognitive distractions, the time spent on the task rose significantly during the interrupted condition. In some cases, the presence of interruptions increased the time for a given procedure by one third. Though it is not an explicit finding, this suggests the possibility that designs that minimize intrusions, particularly while surgeons are operating, may speed up a given procedure.

In short, while high noise levels are often reported as a problem by hospital staff, it appears that, with few exceptions, staff members are able to avoid the adverse effects of noise on their performance quality, although the time needed for procedures tends to increase. It is important to note that most of these studies were conducted using recorded hospital noise with constant volume; it is unclear whether staff can cope with sounds with startling volume changes (which occur frequently in hospital settings) as effectively. Overall, it is clear that the long-term effects of high levels of ambient noise on staff are troubling; although the noise may not directly hamper staff performance, the cumulative effects of stress may lead to adverse outcomes.

Impact of Other Environmental Factors on Staff Effectiveness

Other aspects of the environment, such as *lighting levels* and *auditory or visual distractions*, can also affect staff effectiveness when performing critical tasks such as dispensing medical prescriptions. There have been studies in manufacturing showing a positive effect of higher lighting levels on the speed of production (Juslen, Wouters, & Tenner, 2007). However, none that was specifically related to healthcare environments or tasks was identified. A small pilot study was conducted in a nursing home to evaluate the usefulness of providing light-emitting diode lighting triggered by motion sensors for nighttime lighting. The 17 staff members in the study reported that they found these lights convenient and useful for conducting nighttime rounds without disturbing residents' sleep (Taylor, 2005). There are several studies that have evaluated the effect of bright light (2,500 lux) and set sleep schedules on staff working the night shift (Horowitz et al., 2001). These studies report that the most significant positive effect is seen only when these factors are used in combination. Once again, such findings confirm that environmental interventions are most effective when paired with cultural or behavioral programs.

Increasing Staff Satisfaction

Summary of Evidence and Recommendations

Excellent care will hardly happen with dissatisfied hospital staff. Job satisfaction is known to be influenced by many nonphysical working conditions, such as autonomy (O'Rourke, Allgood, VanDerslice, & Hardy, 2000), compensation (Best & Thurston, 2006), and performance (Douglas, Meleis, Eribes, & Kim, 1996). Lack of support from the physical environment can make already stressful working conditions worse. Investments in the environment to increase staff satisfaction could potentially reduce the cost of staff turnover, which can cost more than $62,100 per nurse replaced (Jones, 2004). However, not many studies have examined the effects of environmental factors on job satisfaction. Natural light is one of the exceptions.

Natural Light

Mrockzek, Mikitarian, Vieira, & Rotrius (2005) conducted an Internet survey of staff working in a newly constructed facility and found that natural light in the new facility had the most positive environmental impact on work life, followed by live music in the atrium. Another study found that staff with more than 3 hours of daylight exposure during their shift had higher job satisfaction than staff with less daylight exposure. However, the findings are complicated by the types of nursing activities performed by each group (Alimoglu & Donmez, 2005). In addition, new healthcare facilities might not increase job satisfaction if they are not carefully designed. In a study comparing an old and a new ward in a mental healthcare facility, Tyson, Lambert, and Beattie (2002) concluded that the new ward resulted in no increase in job satisfaction, probably owing to the isolation of nurses caused by the larger space and separated observation wings, and understaffing in the new acute ward.

Conclusions and Design Recommendations

This study reviewed the literature linking hospital physical environments with healthcare outcomes, and identified a number of design strategies and interventions that can influence outcomes. The main body of this paper was organized by type of healthcare outcome. However, designers and healthcare workers often face the question of whether to employ specific design strategies or interventions. Therefore, the following sections discuss specific design measures and the improved outcomes that can be expected from them. Table 1 provides an overview of the relationships between design factors and healthcare outcomes. It should be noted that some of the relationships indicated in this table have not been directly tested by empirical studies, but they have been supported in an indirect way by strong available evidence.

Single-Bed Rooms

The design intervention that positively affects the largest number of outcomes in a hospital setting is the provision of single-bed patient rooms. The value of single-bed rooms has been acknowledged by the AIA after extensive research and has been included in the *2006 Guidelines for Design and Construction of Health Care Facilities* (AIA & FGI, 2006). Strong evidence indicates that single-bed rooms improve the following outcomes:

HERD VOLUME 1, NUMBER 3, PP 61-125 COPYRIGHT ©2008 VENDOME GROUP, LLC

Hospital-Acquired Infections. The use of single-patient rooms reduces airborne, contact, and waterborne transmission of hospital-acquired infections by increasing isolation capacity, facilitating the thorough cleaning of rooms and the maintenance of air quality, and also possibly increasing hand-washing compliance by healthcare workers.

Patient Sleep. Patients in single-bed rooms benefit from increased privacy and the reduction in noise from roommates, visitors, and healthcare staff. These factors improve sleep and facilitate the healing process.

Patient Privacy. Single-bed rooms help protect auditory and visual privacy compared with multibed rooms. The absence of a roommate in hospital rooms helps prevent privacy breaches during discussions between patients and care providers. Patients in single-bed rooms are more willing to provide personal information to care providers, which facilitates diagnosis and treatment.

Table 1. Summary of the Relationships Between Design Factors and Healthcare Outcomes

Healthcare Outcomes \ Design Strategies or Environmental Interventions	Single-bed rooms	Access to daylight	Appropriate lighting	Views of nature	Family zone in patient rooms	Carpeting	Noise-reducing finishes	Ceiling lifts	Nursing floor layout	Decentralized supplies	Acuity-adaptable rooms
Reduced hospital-acquired infections	**										
Reduced medical errors	*		*				*				*
Reduced patient falls	*		*		*	*			*		*
Reduced pain		*	*	**			*				
Improved patient sleep	**	*	*				*				
Reduced patient stress	*	*	*	**	*		**				
Reduced depression		**	**	*	*						
Reduced length of stay		*	*	*							*
Improved patient privacy and confidentiality	**				*		*				
Improved communication with patients & family members	**				*		*				
Improved social support	*				*	*					
Increased patient satisfaction	**	*	*	*	*	*	*				
Decreased staff injuries								**			*
Decreased staff stress	*	*	*	*			*				
Increased staff effectiveness	*		*				*		*	*	*
Increased staff satisfaction	*	*	*	*			*				

* Indicates that a relationship between the specific design factor and healthcare outcome was indicated, directly or indirectly, by empirical studies reviewed in this report.

** Indicates that there is especially strong evidence (converging findings from multiple rigorous studies) indicating that a design intervention improves a healthcare outcome.

Communication with Patients and Families. Because of enhanced auditory privacy, single-bed rooms can improve communication among patients, families, and care providers. Patients in single-bed rooms report greater satisfaction with communication from nurses and physicians compared with patients in multibed rooms.

Social Support. Compared with multibed rooms, single-bed rooms provide enhanced privacy, encourage family visits and social interaction, and are more likely to provide space to accommodate visiting relatives and friends.

Staff Stress. Staff also appreciates the benefits of single-bed rooms and reports finding them less stressful than multibed or open-bay settings.

Patient Satisfaction. Considering all the above-mentioned benefits, it is no surprise that patients are more satisfied with their hospital stays when they are placed in single-bed rooms.

Access to Daylight and Appropriate Lighting

The quality and quantity of daylight exposure and artificial lighting is associated with several patient and staff outcomes in healthcare settings. Access to daylight is important for both staff and patients. For patients, it has been found to reduce pain and the incidence of depression, and for certain types of patients, it also may reduce length of stay. For staff, access to daylight contributes to higher satisfaction. Therefore, site planning and the orientation of healthcare facilities should be carefully considered to ensure sufficient daylight and avoid situations where some buildings block light for others. Larger windows in patient rooms not only provide natural light, but they also have the potential benefit of offering views of nature and should be considered in the design process.

The amount and timing of light in healthcare settings should be tailored to the activities that take place in them. In general, sufficient lighting is beneficial to both patients and staff. Bright lighting is preferred in areas where staff performs critical tasks such as medication dispensing.

Medical Errors. Research has found that medication-dispensing errors are lower when the level of work-surface lighting is relatively high, compared to situations with lower levels of lighting. While other areas of the hospital have not been tested, it is logical to infer that bright lighting would also be useful in other places where precision is called for.

Pain. Exposure to natural light has been found to reduce patients' pain and the amount of pain medications that they use. Buildings should be carefully designed so that patient rooms can have abundant natural light.

Patient Sleep. As a major contributor to normal circadian rhythm, the amount of light that patients are exposed to at different times of day can affect sleep quality. During the day, patients should be exposed to adequate natural light or bright artificial lighting when natural light is not available. At nighttime, if possible, the light in patients' rooms should be dimmed long enough to ensure good sleep.

Depression. A considerable body of rigorous evidence indicates that exposure to light—daylight or bright artificial light—is effective in reducing depression and improving mood. These findings underline the importance of building orientation and site planning in new healthcare projects.

Length of Stay. Research on patients suffering from depression found that patients in rooms with more morning daylight had shorter lengths of stay than patients in rooms without morning sunlight.

Communication with Patients and Families. Research on counseling rooms suggests that people feel more comfortable talking and talk longer in rooms with dim lighting as compared to similar rooms with bright lighting.

Patient Satisfaction. Adequate lighting has been identified as one component affecting patients' overall satisfaction with their hospital stays.

Staff Satisfaction. Access to sufficient natural light is one of the few physical environmental attributes that

HERD VOLUME 1, NUMBER 3, PP 61-125 COPYRIGHT ©2008 VENDOME GROUP, LLC

has been linked by research with higher staff satisfaction. This finding suggests that natural light is also needed in staff working areas.

Family Zone in Patient Room

While single-patient rooms have the potential to affect the largest number of outcomes in hospital settings, some of the benefits may be facilitated by the availability of appropriate family zones within the room.

Social Support. Evidence indicates that single-patient rooms encourage family presence by providing more space and privacy and accommodating patient-family interactions, compared with multibed rooms. It is important to make sure that single-patient rooms include appropriate family zones and comfortable furniture to encourage family members to stay longer and provide more social support to patients.

Patient Falls. Providing family zones can encourage family members to remain longer in patient rooms. As a result, timely help is available from family members to assist patients with getting in and out of the bed, which may reduce the frequency of patient falls.

Noise-Reducing Finishes

Hospitals are noisy places with numerous sources of noise, and historically they have been designed with sound-reflecting surfaces that worsen acoustic conditions and enable noises to echo and propagate over large areas. Research has found that the use of noise-reducing finishes such as high-performance sound-absorbing ceiling tiles can reduce the noise in hospitals and benefit both patients and staff.

Patient Sleep. Getting a good night's sleep is very important to patients' healing processes. Studies have found that the noise level in many hospitals is quite high even at night and that noise is a major cause of awakenings and poor sleep. For this reason, measures should be taken to reduce the reverberation time, sound propagation, and noise intensity level in patient rooms.

Patient Privacy. The use of sound-absorbing materials can also enhance patient privacy by reducing sound propagation and privacy breaches. When single-bed rooms are not available, as in many EDs, hard-wall partitions rather than curtains should be used to separate bed spaces; these should be extended all the way up to the support ceiling or deck to protect speech privacy.

Patient Satisfaction. Noise is one of the factors of the ambient environment that patients complain about most frequently. Research found that a reduced noise level in patient rooms has a positive impact on patient satisfaction. Patients treated in spaces with good acoustic performance considered staff attitude and care quality to be much better than those in spaces with poor acoustics.

Patient Stress. In addition to worsening sleep quality, noise elevates psychological and physiological stress in patients. The use of sound-absorbing materials in patient rooms, in combination with reducing noise sources, can create a less stressful environment for patients.

Staff Stress. Limited research has focused on the effects of noise on staff. A recent study found that improved room acoustics (facilitated by using sound-absorbing materials) positively affected the staff's perception of work demands and lowered their work pressure and strain.

Views of Nature

Consierable research has examinined the psychological and physiological effects of viewing real and simulated nature. Most available evidence is related to the impact of nature views on patients. There is also limited evidence suggesting that staff experience restorative benefits from views of nature or exposure to gardens.

Pain. Nature has been determined to be an effective positive distraction, which can reduce the perception of pain and thereby reduce the use of pain medications. Some studies combined simulated views of nature with nature sounds or classical music; these studies demonstrated greater impact on pain reduction, compared with when auditory distraction was not available.

Length of Stay. A direct relationship between exposure to nature views and reduced length of stay in a study

of patients recovering from abdominal surgery was found in one study. More research in diverse settings with various types of patient populations is needed to examine the contribution of nature views to the overall healing process and their effect on length of stay.

Patient Stress. Strong studies have found that exposing patients to nature lessens stress and anxiety.

Minimizing Negative Distractions for Healthcare Workers

Whereas positive distractions such as nature can help alleviate patient pain and stress, negative distractions (such as noise) in healthcare staff workplaces will lower work efficiency and possibly increase the incidence of medical errors.

Staff Effectiveness. Distractions during surgery can slow the progress of procedures. Interruptions from staff can result in delays in activities and thereby reduce the productivity of an already stressed staff.

Medical Errors. Distractions during critical tasks, such as preparing medications, can result in errors, which ultimately affect patients. However, the evidence shows that design strategies such as using sound-absorbing materials to reduce noise, and providing bright lighting at work stations can help minimize distractions, reduce medical errors, and improve work efficiency.

Acuity-Adaptable Rooms

There is increasing interest in acuity-adaptable rooms, but their use in real projects is still limited. As the number of hospitals with acuity-adaptable rooms grows, there will be greater opportunity to study their impact on patients and staff. Evaluation of the concept and its implementation suggest that these rooms reduce transfers, and may reduce the incidence of patient falls and medical errors and increase patient satisfaction.

Patient Falls. Acuity-adaptable patient rooms can minimize the need for costly patient transfers.

Medical errors. Some medical errors originate from the delays, communication discontinuities, loss of information, and changes in computers or systems associated with the patient transfer process. The use of acuity-adaptable rooms can lessen the number of patient transfers and the medical errors that may occur during transfer.

Patient Satisfaction. In some recent studies, the provision of acuity-adaptable rooms was accompanied by improvements in predictive indicators of patient satisfaction. There were also improvements in quality of care and operational cost.

Looking Forward

EBD is a rapidly evolving and increasingly rigorous field. Hospital owners and designers have to make very important decisions about how hospitals will be built based on the information and knowledge available. It is clear from this review that there is a growing amount of sound research to support the application of certain specific design characteristics to improve healthcare outcomes. This paper is intended to make that evidence more accessible to practitioners, and to identify needs and directions for future research.

The Role of the Physical Environment in the Hospital of the 21st Century: A Once-in-a-Lifetime Opportunity

A visit to a U.S. hospital is dangerous and stressful for patients, families and staff members. Medical errors and hospital-acquired infections are among the leading causes of death in the United States, each killing more Americans than AIDS, breast cancer, or automobile accidents (Institute of Medicine, 2000; 2001). According to the Institute of Medicine in its landmark *Quality Chasm* report: "*The frustration levels of both patients and clinicians have probably never been higher. Yet the problems remain. Health care today harms too frequently and routinely fails to deliver its potential benefits*" (IOM, 2001). Problems with U.S. health care not only influence patients; they impact staff. Registered nurses have a turnover rate averaging 20 percent (Joint Commission on Accreditation of Healthcare Organizations, 2002).

At the same time, the United States is facing one of the largest hospital building booms in US history. As a result of a confluence of the need to replace aging 1970s hospitals, population shifts in the United States, the graying of the baby boom generation, and the introduction of new technologies, the United States will spend more than $16 billion for hospital construction in 2004, and this will rise to more than $20 billion per year by the end of the decade (Babwin, 2002). These hospitals will remain in place for decades.

This once-in-lifetime construction program provides an opportunity to rethink hospital design, and especially to consider how improved hospital design can help reduce staff stress and fatigue and increase effectiveness in delivering care, improve patient safety, reduce patient and family stress and improve outcomes and improve overall healthcare quality.

Just as medicine has increasingly moved toward "evidence-based medicine," where clinical choices are informed by research, healthcare design is increasingly guided by rigorous research linking the physical environment of hospitals to patients and staff outcomes and is moving toward "evidence-based design" (Hamilton, 2003). This report assesses the state of the science that links characteristics of the physical setting to patient and staff outcomes:

- What can research tell us about "good" and "bad" hospital design?
- Is there compelling scientifically credible evidence that design genuinely impacts staff and clinical outcomes?
- Can improved design make hospitals less risky and stressful for patients, their families, and for staff?

In this project, research teams from Texas A&M University and Georgia Tech combed through several thousand scientific articles and identified more than 600 studies—most in top peer-reviewed journals—that establish how hospital design can impact clinical

outcomes. The team found scientific studies that document the impact of a range of design characteristics, such as single-rooms versus multi-bed rooms, reduced noise, improved lighting, better ventilation, better ergonomic designs, supportive workplaces and improved layout that can help reduce errors, reduce stress, improve sleep, reduce pain and drugs, and improve other outcomes. The team discovered that, not only is there a very large body of evidence to guide hospital design, but a very strong one. A growing scientific literature is confirming that the conventional ways that hospitals are designed contributes to stress and danger, or more positively, that this level of risk and stress is unnecessary: improved physical settings can be an important tool in making hospitals safer, more healing, and better places to work.

RESEARCH PROCESS

The research teams searched through scores of databases and in libraries at Texas A&M, Georgia Institute of Technology, University of Michigan, and elsewhere. The team was looking for studies that are:

- Rigorous, in that they use appropriate research methods that allow reasonable comparisons, and discarding of alternative hypotheses. The research studies were assessed on their rigor, quality of research design, sample sizes, and degree of control.

- High impact, in that the outcomes they explore are of importance to healthcare decision-makers, patients, clinicians, and society.

In 1998, Haya Rubin and her colleagues Amanda Owens and Greta Golden found 84 studies produced since 1968 that met similar criteria (Rubin, Owens, & Golden, 1998). Reviewing the research literature six years later, the team estimated that they would find around 125 rigorous studies. We found more than 600.

RESULTS

The research team found rigorous studies that link the physical environment to patient and staff outcomes in four areas:

1. Reduce staff stress and fatigue and increase effectiveness in delivering care
2. Improve patient safety
3. Reduce stress and improve outcomes
4. Improve overall healthcare quality

I. Reduce Staff Stress and Fatigue and Increase Effectiveness in Delivering Care

There is a growing nurse shortage, and this directly threatens patient safety. And the existing hospital-based nursing force is aging. Registered nurses in the United States average more than 43 years old and will average 50 by 2010 and have a turnover rate

averaging 20 percent per year (JCAHO, 2002). The Joint Commission on Accreditation of Healthcare Organizations (JCAHO), in their 2002 report, *Health Care at the Crossroads: Strategies for Addressing the Evolving Nursing Crisis*, noted that a shortage of nurses in America's hospitals is putting patient lives in danger. JCAHO examined 1,609 hospital reports of patient deaths and injuries since 1996 and found that low nursing staff levels were a contributing factor in 24 percent of the cases. The JCAHO report and surveys of nursing found that physical working conditions, along with support and compensation, are key contributors to turnover and burnout. Environmental support for work has become more critical as the typical patient is more seriously ill, patient loads increase, technology changes, and documentation requirements increase.

While reducing staff stress and fatigue through a healing and supportive environment seems like an obvious goal, there are relatively few studies that have dealt with this issue in any detail. More attention has been given to patient outcomes. However, the following sections review several studies that do document (a) effects of healthcare environments on staff health and safety and (b) improving workplaces to increase staff effectiveness, reduce errors, and increase staff satisfaction. Each section also suggests directions for further research.

Improve Staff Health and Safety through Environmental Measures

Nurses, physicians, and other healthcare employees work under extremely stressful physical conditions. Several studies deal with healthcare employees' risk of contracting infectious diseases from patients due to airborne and surface contamination (Jiang et al., 2003; Kromhout et al., 2000; Kumari et al., 1998; Smedbold et al., 2002). A recent study conducted in the wake of the SARS epidemic in China found that isolating SARS cases in wards with good ventilation could reduce the viral load of the ward and might be the key to preventing outbreaks of SARS among healthcare workers, along with strict personal protection measures in isolation units (Jiang et al., 2003). Another study in Norway found correlations between environmental factors and nasal symptoms of 115 females who worked at 36 geriatric nursing departments. They found significant decrease in nasal inflammation in relation to presence of *Aspergillus fumigatus* in ventilation supply and elevated room temperatures (Smedbold et al., 2002). An evaluation of 17 acute-care or university hospitals in Canada shows that tuberculosis (TB) infection among healthcare workers was associated with ventilation of general or nonisolation patient rooms of less than two air exchanges per hour. The evaluation included all personnel who worked at least two days per week in the respiratory and physiotherapy departments (Menzies, Fanning, Yuan, & Fitzgerald, 2000). This study, like the others, supports the importance of adequate ventilation with good maintenance for ensuring both staff and patient safety in hospitals. Several good studies demonstrating the risk of the sick building syndrome in hospitals also have been compiled within the 2003 *Guidelines for Environmental Infection Control in Healthcare Facilities* by the US Centers for Disease Control and Prevention (CDC) and the Healthcare Infection Control Practices Advisory Committee (HICPAC) (Sehulster & Chinn, 2003).

Nursing staff members are also open to risk of injury from medical equipment such as high-intensity surgical-light sources. One study found that a light source used during surgery could potentially cause retinal damage in surgical staff (Fox & Henson, 1996). Much research has examined the effects of noise on patients, but comparatively few studies are available for healthcare staff. There is evidence that staff perceive higher sound levels as stressful (Bayo, Garcia, & Garcia, 1995; Norbeck, 1985). Importantly, noise-induced stress in nurses correlates with reported emotional exhaustion or burnout (Topf & Dillon, 1988). A recent study by Blomkvist et al. (in press, 2004) examined the effects of higher versus lower noise levels on the same group of coronary intensive-care nurses over a period of months. Lower noise levels were linked with a number of positive effects on staff, including reduced perceived work demands, increased workplace social support, improved quality of care for patients, and better speech intelligibility.

Poor ergonomic design of patient beds and nurses' stations leads to back stress, fatigue, and other injuries among nursing staff. In one nursing home study, Garg and Owen evaluated manual tasks deemed stressful by nursing staff and used the information to select patient-transferring devices and to modify toilets and shower rooms. This nursing intervention resulted in a reduction of back injuries of almost 50 percent, from 83 per 200,000 work hours to 47 per 200,000 work hours. Also, in the four months after the intervention, there were no injuries resulting in lost or restricted workdays (Garg & Owen, 1992).

Thus, reducing staff stress by ergonomic interventions, as well as careful consideration of other issues such as air quality, noise, and light, can have significant impact on staff health. In addition, it is also likely to send a message that maintaining health and safety of staff members is an important goal for the organization.

Increase Staff Effectiveness, Reduce Errors, and Increase Staff Satisfaction by Designing Better Workplaces

Jobs by nurses, physicians, and others often require a complex choreography of direct patient care, critical communications, charting, filling meds, access to technology and information, and other tasks. Many hospital settings have not been rethought as jobs have changed, and, as a result, the design of hospitals often increases staff stress and reduces their effectiveness in delivering care. While much research in the hospital setting has been aimed at patients, there is a growing and convincing body of evidence suggesting that improved designs can make the jobs of staff much easier.

Nurses spend a lot of time walking. According to one study, almost 28.9 percent of nursing staff time was spent walking (Burgio, Engel, Hawkins, McCorick, & Scheve, 1990). This came second only to patient-care activities, which accounted for 56.9 percent of observed behavior. At least four studies have shown that the type of unit layout (e.g. radial, single corridor, double corridor) influences amount of walking among nursing staff (Shepley, 2002; Shepley & Davies, 2003; Sturdavant, 1960; Trites, Galbraith, Sturdavant, & Leckwart, 1970), and two studies showed that time saved walking was translated into more time spent on patient-care activities and interaction with family

members. Sturdavant (1960) found that fewer trips were made to patient rooms in radial units as nurses were able to better supervise patients visually from the nursing station, though the average time spent with patients was the same in radial as well as single-corridor designs. Shepley and colleagues (2003) found that nursing staff in the radial unit walked significantly less than staff in the rectangular unit (4.7 steps per minute versus 7.9 steps per minute). However, Shepley and her colleagues noted that radial designs might provide less flexibility in managing patient loads. Trites and colleagues (1970) found that a decrease in the percentage of time spent walking by staff in radial units was correlated to an increase in the percentage of time spent in patient-care activities. Also, the majority of the staff surveyed preferred to work in the radial units. Hendrich's research showed that decentralized nurses stations reduced staff walking and increased patient-care time, especially when supplies also were decentralized and placed near the nurses' station (Hendrich, 2003; IOM, 2004). Centralized location of supplies, however, could double staff walking and substantially reduce care time irrespective of whether nurses stations were decentralized (Hendrich, 2003)

Workplace design that reflects a closer alignment of work patterns and the physical setting, such as redesign of a pharmacy layout, has been shown to improve work flow and reduce waiting times, as well as increase patient satisfaction with the service (Pierce, Rogers, Sharp, & Musulin, 1990). Other studies that compared delivery times in decentralized and centralized pharmacy systems found medication delivery times are reduced by more than 50 percent by using decentralized drug-dose distribution systems (Hibbard, Bosso, Sward, & Baum, 1981; Reynolds, Johnson, & Longe, 1978).

Other aspects of the environment, such as lighting levels and auditory or visual distractions, can also affect staff effectiveness while performing critical tasks such as dispensing medical prescriptions. There are relatively few studies that have examined the effect of environmental factors on medication errors, though this is clearly an area of great interest and future research potential. This is discussed in greater detail in the following section.

II. Improve Patient Safety

Hospital-Acquired Infections

One critically important way that evidence-based design improves safety is by reducing risk from hospital-acquired infections. The research team identified more than 120 studies linking infection to the built environment of the hospital. Transmission of infection to patients occurs through two general routes: airborne and contact. The research literature shows that the design of the physical environment strongly impacts hospital-acquired infection rates by affecting both airborne and contact transmission routes. The literature suggests a clear pattern wherein infection rates are lower when there is very good air quality and patients are in single-bed rather than multi-bed rooms. Also, there is some evidence that providing numerous, easily accessible alcohol-based hand-rub

dispensers or hand washing sinks can increase hand washing compliance and thereby reduce contact contamination.

Reducing Infections Caused by Airborne Pathogens

Evidence from many studies leaves no doubt that hospital air quality and ventilation play decisive roles in affecting air concentrations of pathogens such as fungal spores (*Aspergillus*) and, in this way, have major effects on infection rates.

Source of airborne infections: Well-conducted research has linked all of the following to air quality and infection rates: type of air filter, direction of airflow and air pressure, air changes per hour in room, humidity, and ventilation system cleaning and maintenance (Lutz, 2003; McDonald et al., 1998). For example, in one study where six patients and one nurse were involved with an outbreak of epidemic methicillin-resistant *Staphylococcus aureus* (EMRSA-15), an environmental source was suspected, and the ventilation grilles in two patient bays were found to be harboring EMRSA-15 (Kumari et al., 1998). The ventilation system, at that time, was working on an intermittent cycle from 4:00 p.m. to 8:00 p.m. Daily shutdown of the system created negative pressure, sucking air in from the ward environment into the ventilation system and contaminating the outlet grilles. The contaminated air blew back into the ward when the ventilation system was started. In another case, the source of infection was the exhaust ducting of the adjacent isolation room ventilation system that allowed the contaminants to enter the unit via a partially open window positioned above a particular bed.

Several studies have identified hospital construction and renovation activities as the sources of airborne infection outbreaks due to dust or particulate generation (Humphreys et al., 1991; Iwen, Davis, Reed, Winfield, & Hinrichs, 1994; Loo et al., 1996; Opal et al., 1986; Oren, Haddad, Finkelstein, & Rowe, 2001). In one study, high spore counts were found within and outside construction sites in a hospital. After control measures were instituted, no further cases of disseminated aspergillosis were identified (Opal et al., 1986). In another study, a nosocomial (hospital-induced) outbreak of invasive pulmonary aspergillosis (IPA) occurred in acute leukemia patients treated in a regular ward with natural ventilation during extensive hospital construction and renovation. The observed infection rate was 50 percent. At this point, some of the patients were moved to a new hematology ward with high-efficiency particulate air (HEPA) filters. During the following three years, none of the patients hospitalized exclusively in the hematology ward developed IPA, although 29% of leukemia patients still housed in the regular ward contracted IPA (Oren et al., 2001).

Controlling and preventing airborne infection: There is convincing evidence that immunocompromised and other high-acuity patient groups have lower incidence of infection when housed in a HEPA-filtered isolation room (Passweg et al., 1998; Sherertz, et al., 1987; Sherertz & Sullivan, 1985). In one study, bone-marrow transplant recipients were found to have a tenfold greater incidence of nosocomial *Aspergillus* infection, compared to other immunocompromised patient populations, when assigned beds outside of a HEPA-filtered environment (Sherertz, et al., 1987). Air contamination is least in

laminar airflow rooms with HEPA filters, and this approach is recommended for operating-room suites and areas with ultraclean room requirements such as those housing immunocompromised patient populations (Alberti et al., 2001; Arlet, Gluckman, Gerber, Perol, & Hirsch, 1989; Dharan & Pittet, 2002; Friberg, Ardnor, & Lundholm, 2003; Hahn et al., 2002; Sherertz, et al., 1987). (Laminar flows are very even, smooth, low velocity airflows that are used in cleanrooms and other settings where high quality ventilation is critical. But laminar flows are relatively expensive and difficult to achieve because furnishings, vents and other features can create turbulence.) HEPA filters are suggested for healthcare facilities by the CDC and HICPAC, but are either required or strongly recommended in all construction and renovation areas (Sehulster & Chinn, 2003).

Effective prevention or control measures during construction and renovation activities include, for example, portable HEPA filters, installing barriers between the patient care and construction areas, negative air pressure in construction/renovation areas relative to patient-care spaces, and sealing patient windows. There is strong evidence of the impact of using HEPA filters for air intakes near construction and renovation sites (Loo et al., 1996; Mahieu, De Dooy, Van Laer, Jansens, & Ieven, 2000; Opal et al., 1986; Oren et al., 2001). A strong study by Humphreys (1991) demonstrates that HEPA filters are not *by themselves* an adequate control measure, and must be employed in conjunction with other measures such as enhanced cleaning, the sealing of windows, and barriers. Cornet et al. (1999) concludes that carefully directed airflow (e.g. laminar airflow) is important, however, we were unable to find and document cost-benefit analysis in the literature to justify the expense versus effectiveness of laminar airflow for patient-care areas near construction and renovation sites

Reducing Infections by Increasing Hand Washing

Although infection caused by airborne transmission poses a major safety problem, most infections are now acquired in the hospital via the contact pathway (Bauer, Ofner, Just, Just, & Daschner, 1990; IOM, 2004). It is well-established that the hands of healthcare staff are the principal cause of contact transmission from patient to patient (Larson, 1988). The importance of assiduous hand washing by healthcare workers, accordingly, cannot be overemphasized for reducing hospital-acquired infections. In this context, the fact that rates of hand washing by healthcare staff are low represents a very serious patient safety challenge. Several studies of hand washing in high-acuity units with vulnerable patients have found that as few as one in seven staff members wash their hands between patients: compliance rates in the range of 15 percent to 35 percent are typical; rates above 40 percent to 50 percent are the exception (Albert & Condie, 1981; Graham, 1990). Hand washing compliance tends to be consistently lower in units that are understaffed and have a high patient census or bed-occupancy rate (Archibald, Manning, Bell, Banerjee, & Jarvis, 1997).

Education programs to increase hand washing adherence have yielded disappointing or, at best, mixed results. Some investigations have found that education interventions generate no increase at all in hand washing. Even intensive education or training

programs (classes, group feedback, for example) produce only transient increases in hand washing (Conly, Hill, Ross, Lertzman, & Louie, 1989; Dorsey, Cydulka, & Emerman, 1996; Dubbert, Dolce, Richter, Miller, & Chapman, 1990). Given the tremendous morbidity and mortality associated with high rates of hospital-acquired infections, there is an urgent need to identify more effective ways for producing sustained increases in hand washing. Is there evidence suggesting improved hospital design can be effective in elevating hand washing?

Effect of number and location of sinks/dispensers on hand washing: The research team identified six studies that examined whether hand washing is improved by increasing the ratio of the number of sinks or hand-cleaner dispensers to beds and/or by placing sinks or hand-cleaner dispensers in more accessible locations (Cohen, Saiman, Cimiotti, & Larson, 2003; Graham, 1990; Kaplan & McGuckin, 1986; Muto, Sistrom, & Farr, 2000; Pittet et al., 2000; Vernon, Trick, Welbel, Peterson, & Weinstein, 2003). These studies, on balance, offer support, though limited, for the notion that providing numerous, conveniently located alcohol-rub dispensers or washing sinks can increase compliance. In particular, the evidence suggests that installing alcohol-based hand-cleaner dispensers at bedside usually improves adherence. As an example, a study by Pittet et al. (2000) found that a combination of bedside antiseptic hand-rub dispensers and posters to remind staff to clean their hands substantially increased compliance. Cohen et al. (2003) likewise reported improved adherence in association with the installation of numerous alcohol-gel dispensers. By contrast, Muto et al. (2000) reported that placing alcohol-gel dispensers next to the doors of patient rooms did not increase adherence. Two other investigations focusing on sinks (water/soap) identified a positive relationship between observed frequency of hand washing and a higher ratio of sinks to beds (Kaplan & McGuckin, 1986; Vernon et al., 2003). Providing automated water/soap sinks, however, appears not to increase hand washing rates compared to traditional non-automated sinks (Larson, et al., 1991; Larson, Bryan, Adler, & Blane, 1997).

Further, three studies offer convincing and important evidence that providing single-patient rooms with a conveniently located sink in each room reduces nosocomial infection rates in intensive care units, such as neonatal intensive care (NICU) or burn units, compared to when the same staff and comparable patients are in multibed open units with few sinks (Goldmann, Durbin, & Freeman, 1981; McManus, A. T., Mason, McManus, & Pruitt, 1994; McManus, A. T., McManus, Mason, Aitcheson, & Pruitt, 1985; Mulin et al., 1997). Although hand washing frequency was not measured in these studies, the investigators posited that increased hand washing was an important factor in reducing infections in the units with single rooms and more sinks. A comparison of an ICU converted from an open unit with few sinks to single rooms with one sink per room found a nonsignificant tendency for hand washing to increase (from 16 percent to 30 percent) but no decline in infection incidence (Preston, Larson, & Stamm, 1981). These results are perhaps explainable by the fact that several sinks in the single-bed unit were placed in comparatively inaccessible or inconvenient locations, such as behind doors or away from staff work paths.

Despite the encouraging overall pattern of findings in these studies, it is not clear how much of the effectiveness in terms of increased hand washing or reduced infection rates can be attributed to the installation of more numerous and/or accessible sinks and alcohol-gel dispensers. Future research should include controlled experiments that systematically vary the number and location of hand-cleaning stations or dispensers. There is also a conspicuous need for studies that define *accessible* locations for hand-cleaning stations in an evidence-based manner—that is, on the basis of empirical analysis of staff movement paths, visual fields, interactions with patients and families, and work processes. In this regard, the neglect of *human factors* knowledge and research methods is a major weakness of the hand washing research and, more generally, of the infection control literature. Research teams should include a human factors specialist and often an environmental psychologist. The urgent need to increase hand washing frequency underscores the high priority that should be accorded this research direction.

Reducing Infections with Single-Bed Rooms

The research team identified at least 16 studies relevant to the question of whether nosocomial infection rates differ between single-bed and multi-bed rooms. The findings collectively provide a strong pattern of evidence indicating that infection rates are usually lower in single-bed rooms. Different mechanisms or factors have been identified or implicated as contributing to lower infection incidence in single rooms. One clear set of advantages relates to reducing airborne transmission through air quality and ventilation measures such as HEPA filters, negative room pressure to prevent a patient with an aerial-spread infection from infecting others, or maintaining positive pressure to protect an immunocompromised patient from airborne pathogens in nearby rooms. A strong study by Passweg et al. (1998) found that the combination of room isolation and HEPA filtration reduced infection and mortality in bone marrow transplant patients and significantly increased their one-year survival rates. Research studying burn patients also has shown that single rooms and good air quality substantially reduce infection incidence and reduce mortality (McManus, A. T. et al., 1994; McManus, A.T., Mason, McManus, & Pruitt, 1992; Shirani et al., 1986; Thompson, Meredith, & Molnar, 2002). Studies of cross-infection for contagious airborne diseases (influenza, measles, TB, for example) have found, as would be expected, that placing patients in single rooms is safer than housing them in multibed spaces (Gardner, Court, Brocklebank, Downham, & Weightman, 1973; McKendrick & Emond, 1976).

Severe Acute Respiratory Syndrome (SARS) outbreaks in Asia and Canada dramatically highlighted the shortcomings of multibed rooms for controlling or preventing infections both for patients and healthcare workers. SARS is transmitted by droplets that can be airborne over limited areas. Approximately 75 percent of SARS cases in Toronto resulted from exposure in hospital settings (Farquharson & Baguley, 2003). The pervasiveness in Canadian and Asian hospitals of multibed spaces in emergency departments and ICUs, together with the scarcity of isolation rooms with negative pressure, severely hindered treatment and control measures. Toronto hospitals were forced to create additional negative-pressure isolation rooms by quickly constructing wall barriers to replace bed curtains and making airflow and pressure adaptations (Farquharson & Baguley, 2003).

In addition to clear advantages in reducing airborne transmission, several studies show that single-bed rooms also lessen risk of infections acquired by contact. As background for understanding how single rooms can lessen contact spread, it should first be mentioned that many environmental surfaces and features become contaminated near infected patients. Examples of surfaces found to be contaminated frequently via contact with patients and staff include: overbed tables, bed privacy curtains, computer keyboards, infusion pump buttons, door handles, bedside rails, blood pressure cuffs, chairs and other furniture, and countertops (Aygun et al., 2002; Boyce, Potter-Bynoe, Chenevert, & King, 1997; Bures, Fishbain, Uyehara, Parker, & Berg, 2000; Devine, Cooke, & Wright, 2001; Neely & Maley, 2001; Noskin, Bednarz, Suriano, Reiner, & Peterson, 2000; Palmer, 1999; Roberts, Findlay, & Lang, 2001; Rountree, Beard, Loewenthal, May, & Renwick, 1967; Sanderson & Weissler, 1992; Williams, Singh, & Romberg, 2003). These and other contaminated surfaces and features act as pathogen reservoirs that increase cross-infection risk. Boyce et al. (1997) found that in the rooms of patients infected with methicillin-resistant *Staphylococcus aureus* (MRSA), 27 percent of all environmental surfaces sampled were contaminated with MRSA

Compared to single-bed rooms, multi-bed rooms are far more difficult to decontaminate thoroughly after a patient is discharged, and therefore worsen the problem of multiple surfaces acting as pathogen reservoirs. Because different staff members who enter a room can touch the same contaminated surfaces, the risk of a nurse unknowingly becoming contaminated should be greater in multioccupancy rooms. Circumstantial support for this point is provided by research on contamination of nurses in units having patients infected by MRSA. Boyce et al. (1997) found that 42 percent of nurses who had no direct contact with an MRSA patient but had touched contaminated surfaces contaminated their gloves with MRSA.

In a study of MRSA infections in NICUs, Jernigan et al. (1996) reported that risk was lowered by isolation in single-bed rooms; high risk was associated with spatial proximity to an infected patient and shared exposure to caregivers. Ben-Abraham et al. (2002) found that nosocomial infection frequency was much lower in a single-bed pediatric intensive care unit than a unit with multi-bed rooms. The investigators tentatively concluded that single-bed rooms helped to limit person-to-person spread of pathogens between pediatric patients. Having a roommate has been identified as a risk factor for nosocomial diarrhea and gastroenteritis (Chang, V. T. & Nelson, 2000; Pegues & Woernle, 1993).

To summarize briefly, there is a convincing pattern of evidence across many studies indicating that single-bed rooms lower nosocomial infection rates. Singles appear to limit person-to-person and person-surface-person spread of infection in part because they are far easier to decontaminate thoroughly than multibed rooms after patients are discharged. Also, single rooms with a conveniently located sink or alcohol-gel dispenser in each room may heighten hand washing compliance compared to multibed rooms with few sinks. Finally, single rooms are clearly superior to multi-bed rooms with respect to reducing airborne transmission of pathogens.

Reducing Medication Errors

The research team identified three rigorous studies that link environmental factors, such as lighting, distractions, and interruptions, with errors in prescribing or dispensing medications (Booker & Roseman, 1995; Buchanan, Barker, Gibson, Jiang, & Pearson, 1991; Flynn et al., 1999). Although there are relatively few studies in this area, the findings suggest a promising research direction that merits further exploration, considering the vital importance of preventing medical errors in hospitals. Results from a large-scale study of the effects of different illumination levels on pharmacists' prescription-dispensing error rates strongly suggested that such errors are reduced when work-surface light levels are relatively high (Buchanan et al., 1991). In this study, three different illumination levels were evaluated (450 lux, 1,100 lux, 1,500 lux). Medication-dispensing error rates were significantly lower (2.6 percent) at an illumination level of 1,500 lux (highest level), compared to an error rate of 3.8 percent at 450 lux. Two investigations of medication dispensing errors by hospital pharmacists found that error rates increased sharply for prescriptions when an interruption or distraction occurred, such as a telephone call (Flynn et al., 1999; Kistner, Keith, Sergeant, & Hokanson, 1994). Thus, lighting levels, frequent interruptions or distractions during work, and inadequate private space for performing work can be expected to worsen medication errors. The process of improving systems and processes to reduce medication errors in hospitals should include an assessment of the environment in which staff members perform their activities. Additional research is required to confirm the findings from studies as well as to identify ways to design better working environments that may reduce or prevent the likelihood of such errors occurring.

There is mounting evidence that the transfer of patients between rooms or different units is a source of medication errors (Cook, Render, & Woods, 2000). Reasons why errors plague room transfers include delays, communication discontinuities among staff, loss of information, and changes in computers or systems. The solution implied is to create an acuity-adaptable care process and patient rooms that substantially reduce transfers. When Methodist Hospital in Indianapolis, Indiana, changed from two-bed rooms in coronary intensive care to acuity-adaptable single-bed rooms, transfers declined 90 percent and medication errors were lowered by 67 percent (Hendrich, Fay, & Sorrells, 2002; 2004). Reducing transfers also saves much staff time, shortens patient stays, and reduces costs (IOM, 2004). Further studies and demonstration projects are needed to ascertain the safety advantages of acuity-adaptable rooms for other types of units and patient categories.

Reduce Patient Falls

There is a very large literature that looks at the causes and risk factors involved in patient falls in hospitals. This is an area of great importance because patients who fall incur physical injuries, psychological effects, and have greater lengths of stay in the hospital (Brandis, 1999). It is estimated that the total cost of fall injuries for older people was

around $20.2 billion per year in the United States in 1994, and is projected to reach $32.4 billion (in 1994 U.S. dollars) in 2020 (Chang, 2004). While the role of the environment in causing or preventing patient falls is widely accepted, there is not yet evidence conclusively tying environmental interventions with reduced falls. Available studies usually examine the location of fall incidents retrospectively or discuss environmental-modification programs such as improving lighting, securing carpeting, and so on. However, a meta-analysis and systematic review of randomized controlled trials of fall-prevention interventions found that there was no clear evidence for the independent effectiveness of environmental-modification programs (Chang, 2004).

Nonetheless, several studies have shown that most patient falls occur in the bedroom, followed by the bathroom, and that comprehensive fall-prevention programs can have an effect. Brandis (1999) reported transfers to and from bed as the cause of 42.2 percent of inpatient falls. Design faults identified in the bathroom and bedroom areas included slippery floors, inappropriate door openings, poor placement of rails and accessories, and incorrect toilet and furniture heights. After the fall-prevention program (which included identifying high-risk patients, management strategies, environmental and equipment modification, and standardization) was implemented, there was an overall decrease of 17.3 percent in falls. Thus, fall-prevention strategies that have included environmental modification have worked in the past. However, it is not clear how much of the effectiveness of such strategies can be attributed to environmental factors alone.

An innovative and promising environmental strategy for reducing falls has its origins in evidence suggesting that many falls occur when patients attempt to get out of bed unassisted or unobserved (Uden, 1985; Vassallo, Azeem, Pirwani, Sharma, & Allen, 2000). It should be mentioned that considerable evidence has shown that bedrails are ineffective for reducing the incidence of falls and may increase the severity of fall injuries from beds (Capezuti, Maislin, Strumpf, & Evans, 2002; Hanger, Ball, & Wood, 1999; van Leeuwen, Bennett, West, Wiles, & Grasso, 2001). To increase observation and improve assistance for patients and thereby reduce falls, Methodist Hospital in Indianapolis, Indiana, changed from a coronary critical care unit with centralized nurses stations and two-bed rooms to one having decentralized nurses stations and large single-bed rooms designed to support family presence (Hendrich, et al., 2002). Comparison of data from two years prior and three years after the new unit design showed that falls were cut by 2/3—from six-per-thousand patients to two-per-thousand. Given that falls are a critical safety problem, additional research is needed to understand the effectiveness of this approach for designing patient-care units.

Improve Patient Confidentiality and Privacy

Confidentiality has emerged as a priority issue in light of research showing that physicians and nurses very frequently breach patient confidentiality and privacy by talking in spaces where they are overhead by other patients or persons (Ubel, Zell, & Miller, 1995). The seriousness of the problem is underscored, for example, by a study of an emergency department at a university hospital that showed that 100 percent of physicians and other clinical personnel committed confidentiality and privacy breaches

(Mlinek & Pierce, 1997). HIPAA, the Health Insurance Portability and Accountability Act of 1998, has further elevated the importance of providing reasonable safeguards to protect the confidentiality of staff conversations with and about patients.

Although the importance of the built environment for patient confidentiality may seem self-evident, only a few studies have directly examined the role of unit design or architecture. A study by Barlas et al. (2001) compared auditory and visual privacy for emergency department patients assigned to either multibed spaces with curtain partitions or rooms with solid walls. Those with curtains reported having far less auditory and visual privacy than patients with walls. An important finding was that 5 percent of the patients in curtained spaces reported they withheld portions of their medical history and refused parts of their physical examination because of lack of privacy (Barlas et al., 2001). None of the patients in rooms with walls reported withholding information. The fact that some emergency department patients with curtains withheld information suggests that lack of privacy can reduce patient safety. Additional convincing evidence of the importance of the emergency department physical environment comes from a study that documented frequent breaches of auditory and visual privacy and confidentiality in areas with curtains compared to rooms with solid walls (Mlinek & Pierce, 1997). A recent questionnaire study of staff in four West Coast hospitals found that nurses overwhelmingly judged single rooms to be superior to double rooms for examining a patient (85 percent) and for collecting a patient's history (82 percent) (Chaudhury, Mahmood, & Valente, 2003).

There is a clear need for additional studies that examine privacy and confidentiality breaches associated with the physical environment in single versus double rooms, multibed spaces in ICUs and other types of units, and in spaces such as waiting rooms and nurses' stations. As well, priority should be accorded to generating more research that investigates how the quality of communication and information *from* patients *to* physicians and nurses is affected by the unit architecture.

Analysis of patient satisfaction data made available by Press Ganey (2003) for this report leaves no doubt that patients in single-bed rooms, compared to those with a roommate, are consistently much more satisfied with "concern for your privacy." The satisfaction data were obtained from 2,122,439 patients who received care during 2003 in 1,462 healthcare facilities (Press Ganey, 2003). Fifty-six percent of the patients were in single rooms; 44 percent had a roommate. Greater satisfaction with privacy in single rooms was evident across all major patient categories and types of unit and across different age and gender groups. Satisfaction with privacy was 4.5 percent higher on average nationally in single rooms than doubles—a substantial difference considering that it can be difficult for hospitals to increase satisfaction scores by even 1 percent to 2 percent.

III. Reduce Stress and Improve Outcomes

Reduce Noise

The research team identified more than 130 references focusing on noise in hospitals in the research literature. Studies tend to fall into three broad categories: those that measure noise levels in hospital spaces but do not assess outcomes, studies of the effectiveness of environmental and/or organizational interventions in reducing noise, and investigations of the effects of noise on outcomes.

World Health Organization guideline values for continuous background noise in hospital patient rooms are 35 dB, with nighttime peaks in wards not to exceed 40 dB (Berglund, Lindvall, & Schwela, 1999). These guidelines notwithstanding, many studies have shown that hospital background noise levels fall in far higher ranges. Background noise levels typically are 45 dB to 68 dB, with peaks frequently exceeding 85 dB to 90 dB (Aaron et al., 1996; Allaouchiche, Duflo, Debon, Bergeret, & Chassard, 2002; Blomkvist et al., in press, 2004; Falk & Woods, 1973; Hilton, 1985; McLaughlin, McLaughlin, Elliott, & Campalani, 1996; Robertson, Cooper-Peel, & Vos, 1998). In judging these noise levels, it is worth noting that the decibel scale is logarithmic; each 10 dB increase represents approximately a doubling in the perceived sound level. A 60 dB sound, accordingly, is perceived as roughly four times as loud as a 40 dB sound. Medical equipment and staff voices often produce 70 dB to 75 dB levels measured at the patient's head, which approach the noise level in a busy restaurant (Blomkvist et al., in press, 2004). Noises from alarms and certain equipment exceed 90 dB (for example, portable X-ray machine), which is comparable to walking next to a busy highway when a motorcycle or large truck passes. A study in a NICU measured peak levels once per minute and found that 31 percent of peaks exceed 90 dB (Robertson et al., 1998). Noise peaks in hospitals can be extraordinarily loud. A recent study recorded 113 dB during shift changes at a large hospital (Cmiel, Karr, Gasser, Oliphant, & Neveau, 2004). Operating room noises from drills, saws, and other equipment are in the range of 100 dB to 110 dB, presenting a significant risk for noise-induced hearing loss (Hodge & Thompson, 1990; Love, 2003; Nott & West, 2003).

The research reviewed suggests that hospitals are excessively noisy for two general reasons (Ulrich, Lawson, & Martinez, 2003). First, noise sources are numerous, often unnecessarily so, and many are loud. Well-documented examples include paging systems, alarms, bedrails moved up/down, telephones, staff voices, ice machines, pneumatic tubes, trolleys, and noises generated by roommates. Second, environmental surfaces—floors, walls, ceilings—usually are hard and sound-reflecting, not sound-absorbing, creating poor acoustic conditions. Sound-reflecting surfaces cause noise to propagate considerable distances, traveling down corridors and into patient rooms, and adversely affecting patients and staff over larger areas. Sound-reflecting surfaces typical of hospitals cause sounds to echo, overlap, and linger or have long reverberation times (Blomkvist et al., in press, 2004; Ulrich et al., 2003).

Environmental interventions that have proven especially effective for reducing noise and improving acoustics in hospital settings include: installing high-performance sound-absorbing ceiling tiles, eliminating or reducing noise sources (for example, adopting a noiseless paging system), and providing single-bed rather than multibed rooms. In general, studies of the effectiveness of noise-reduction measures suggest that environmental or design interventions are more successful than organizational interventions such as staff education or establishing quiet hours (Gast & Baker, 1989; Moore, 1998; Walder, Francioli, Meyer, Lancon, & Romand, 2000).

A clear-cut finding in the literature is that noise levels are much lower in single-bed than multi-bed rooms. Studies of multi-bed rooms in acute care and intensive care units have shown that most noises stem from the presence of another patient (staff talking, staff caring for other patients, equipment, visitors, patient sounds such as coughing, crying out, rattling bed rails) (Baker, 1984; Southwell & Wistow, 1995; Yinnon, Ilan, Tadmor, Altarescu, & Hershko, 1992). A study of multi-bed bays in a children's hospital concluded that noise levels were so high that consideration should be given to abolishing open bay rooms (Couper et al., 1994). Further, patient satisfaction data provided for this report by Press Ganey (2003) unequivocally show that patients in single-bed rooms, compared to those with a roommate, are vastly more satisfied with the "noise levels in and around your room." The satisfaction data, as noted in an earlier section, were obtained from 2,122,439 patients who received care during 2003 in 1,462 healthcare facilities (Press Ganey, 2003). Far higher satisfaction with noise levels in single rooms was evident across all major patient categories and types of unit and across different age and gender groups. Satisfaction with noise level was 11.2 percent higher on average nationally in single rooms than doubles—a huge difference. As was noted above, it can be difficult for hospitals to achieve even 1 percent to 2 percent increases in patient satisfaction scores. The combination of findings from noise-level measurement studies and patient-satisfaction surveys highlight the great advantage of providing single rooms, compared to two-bed rooms, with respect to reducing noise.

A considerable body of research has documented negative effects of noise on patient outcomes. Several studies have focused on infants in NICUs, finding that higher noise levels, for example, decrease oxygen saturation (increasing need for oxygen support therapy), elevate blood pressure, increase heart and respiration rate, and worsen sleep (Johnson, 2001; Slevin, Farrington, Duffy, Daly, & Murphy, 2000; Zahr & de Traversay, 1995). Much research on adults and children has unequivocally shown, as might be expected, that noise is a major cause of awakenings and sleep loss (Blomkvist et al., in press, 2004; Gabor et al., 2003; Meyer et al., 1994; Parthasarathy & Tobin, 2004; Schnelle, Ouslander, Simmons, Alessi, & Gravel, 1993; Topf, 1985; Topf & Davis, 1993; Topf & Thompson, 2001; Yinnon et al., 1992). In multi-bed rooms, noises stemming from the presence of other patients often are the major cause of sleep loss. Berg (2001) found, by monitoring brain activity, that even relatively low decibel levels—38 dB to 40 dB—when coupled with longer reverberation times (sound-reflecting ceiling) significantly fragmented and worsened sleep of volunteers in patient rooms. Berg's (2001) findings have disturbing implications because most hospitals have nighttime sound peaks exceeding those of the patient rooms in his study.

Apart from worsening sleep, there is strong evidence that noise increases stress in adult patients, for example, heightening blood pressure and heart rate (Baker, 1992; Morrison, Haas, Shaffner, Garrett, & Fackler, 2003; Novaes, Aronovich, Ferraz, & Knobel, 1997; Topf & Thompson, 2001). A recent study by Blomkvist et al. (in press, 2004) examined the effects of poor versus good sound levels and acoustics on coronary intensive-care patients by periodically changing the ceiling tiles from sound-reflecting to sound-absorbing tiles. When the sound-absorbing ceiling tiles were in place, patients slept better, were less stressed (lower sympathetic arousal), and reported that nurses gave them better care. There were also indications in this study that the incidence of re-hospitalization was lower if patients had experienced the sound-absorbing rather than sound-reflecting ceiling during their hospital stay (Hagerman et al., in press, 2004). More studies are needed such as that by Blomkvist et al. (in press, 2004), which use experimental research designs and systematically vary noise conditions. Future research should also investigate the effects of noise on re-hospitalization rates and other outcomes. In sum, the main message from the research review is clear: new hospitals should be much quieter, and effective design strategies for quieting hospitals are available.

Improve Sleep

The above section reviewed many studies showing that noise levels are high in hospitals and that noise is a major cause of poorer sleep in patients. Interventions that reduce hospital noise have been found to improve sleep and reduce patient stress. As noted earlier, environmental interventions found to be most effective for reducing noise in hospital settings include: providing single-bed rather than multi-bed rooms, installing high-performance, sound-absorbing ceiling tiles, using sound-absorbing flooring where possible, and eliminating or reducing noise sources (for example, use noiseless paging, locate alarms outside patient rooms).

Reduce Spatial Disorientation

Wayfinding problems in hospitals are costly and stressful and have particular impacts on outpatients and visitors, who are often unfamiliar with the hospital and are otherwise stressed and disoriented. In a study conducted at a major regional 604-bed tertiary-care hospital, the annual cost of the wayfinding system was calculated to be more than $220,000 per year in the main hospital or $448 per bed per year in 1990. Much of this cost was the hidden costs of direction giving by people other than information staff, which occupied more than 4,500 staff hours, the equivalent of more than two full-time positions (Zimring, 1990). While almost all hospitals strongly feel the problems associated with a complicated building and poor wayfinding system, it is usually difficult to tackle this problem with a piecemeal approach. A wayfinding system, as the name implies, is not just about better signage or colored lines on floors. Rather, hospitals are seeking to provide integrated systems that include coordinated elements such as visible and easy-to-understand signs and numbers, clear and consistent verbal directions, consistent and clear paper, mail-out and electronic information and a legible physical

setting (Carpman, 1993). A wayfinding system includes four main components that work at different levels: administrative and procedural levels, external building cues, local information and global structure

Administrative and procedural information: Mail-out maps, electronic information available on the Web and at kiosks and verbal directions are organizational strategies aimed at providing key information to patients to prepare them for their hospital visit. This is not dealt with in this review.

***External building cues*:** Signs and cues that lead to the hospital, especially the parking lot, need to be considered carefully, as they are the first point of contact of the patient with the hospital (Carpman, Grant, & Simmons, 1985). For example, Carpman, Grant and Simmons conducted a video simulation study to assess the relative role of signs and seeing a destination. The hospital wanted to direct most traffic to a parking structure rather than a drop-off lane. When the researchers showed prospective visitors a simulated video showing a design alternative that allow arriving drivers to see the main pavilion with the drop-off lane, 37 percent of the respondents said that they would turn into the drop circle when they could see the entry to the garage, ignoring the signs. As a consequence, the hospital chose to redesign the entry.

***Local information*:** Once patients find their way to the building from the parking lot, they are faced with the prospect of identifying the destination. Informational handouts, information desks, you-are here maps, directories, and signage along the way are critical wayfinding aids (Carpman, Grant, & Simmons, 1983-84; Levine, Marchon, & Hanley, 1984; Nelson-Shulman, 1983-84; Wright, Hull, & Lickorish, 1993). In an experimental study, researchers found that patients who had the benefit of an information system (welcome sign, hospital information booklet, patient letter, orientation aids) upon reaching the admitting area were more self-reliant and made fewer demands on staff. In contrast, uninformed patients rated the hospital less favorably and were found to have elevated heart rates (Nelson-Shulman, 1983-84).

Information provided in you-are-here maps can be useful. However, you-are-here maps should be oriented so that the top signifies the direction of movement for ease of use. When the maps were aligned in directions other than the forward position, people not only took much longer to find their destination, but were significantly less accurate (Levine et al., 1984). Another study found that people who used signs found their destination faster than those who only used maps (Butler, Acquino, Hissong, & Scott, 1993). However, people who were given a combination of handheld maps and wall signs reached their destination more often than those who just used wall signs (Wright et al., 1993).

It is critical to design signage systems with logical room numbering and comprehensible nomenclature for departments (Carpman & Grant, 1993; Carpman, Grant, & Simmons, 1984). For example, inpatients, outpatients, and visitors to a hospital preferred simple terms such as *walkway* or *general hospital* over more complex or less-familiar terms such as *overhead link, medical pavilion* or *health-sciences complex*.

Contrary to the belief that fewer signs in hospital hallways means less clutter and hence less confusion, an experimental study in a hospital found that patients who had access to more number of signs along the way to the destination were faster, less hesitant, asked for directions a fewer number of times, and reported lower levels of stress (Carpman et al., 1984). Based on this study, the authors suggest that directional signs should be placed at or before every major intersection, at major destinations, and where a single environmental cue or a series of such cues (e.g. change in flooring material) convey the message that the individual is moving from one area into another. If there are no key decision points along a route, signs should be placed approximately every 150 feet to 250 feet.

***Global structure*:** In addition to local properties of the spaces that people move through, there are specific characteristics of the overall structure of the system of rooms and corridors that impact the paths people take (Haq & Zimring, 2003; Peponis, Zimring, & Choi, 1990). People tend to move toward spaces and through corridors that are more accessible from a greater number of spaces. Based on observations of search patterns of study participants in a hospital and use of objective measures that quantify spatial characteristics, researchers found that participants tended to move along more "integrated" routes—routes that are, on average, more accessible because they are fewer turns from all other routes in the hospital. This research suggests that it may be important to identify such integrated routes in the plan while placing important facilities and key points such as the entrance (Peponis et al., 1990).

The research supports the value of a systems approach to wayfinding. Wayfinding continues to be a pervasive problem in hospitals because it is not sufficient to consider one or two components separately. Well-designed signs are likely to be quite ineffective in a building that is highly complicated and does not provide simple cues that enable natural movement. While there are more than 17 studies that look at wayfinding in hospitals and other buildings (Brown, Wright, & Brown, 1997; Carpman & Grant, 1993; Carpman et al., 1983-84, 1984; Carpman et al., 1985; Christensen, 1979; Grover, 1971; Haq & Zimring, 2003; Levine et al., 1984; Moeser, 1988; Nelson-Shulman, 1983-84; Ortega-Andeane & Urbina-Soria, 1988; Passini, Rainville, Marchand, & Joanette, 1995; Peponis et al., 1990; Schneider, L. F. & Taylor, 1999; Weisman, 1981; Wright et al., 1993; Zimring & Templer, 1983-84), it is quite difficult to isolate single influences of design on wayfinding performance or of wayfinding on outpatient or visitor stress. The problem is exacerbated by the fact that most hospitals have existing complex buildings upon which they try to superimpose a signage system to make things work. This strategy is ineffective in most cases.

There are some very good studies that deal with designing better signage, optimal spacing and location of signage, types of information that are most effective in way finding, and so on. Similarly, other studies at the global scale have looked at the properties of the building layout that facilitate or impede movement. It is essential that these different pieces of information come together while designing new hospitals where there is opportunity to develop an effective wayfinding system at multiple levels. Additional

studies are needed to ascertain the magnitude of stress that wayfinding problems have on outpatients and family.

Reduce Depression

Several studies strongly support that bright light—both natural and artificial—can improve health outcomes such as depression, agitation, sleep, circadian rest-activity rhythms, as well as length of stay in demented patients and persons with seasonal affective disorders (SAD). At least eleven strong studies suggest that bright light is effective in reducing depression among patients with bipolar disorder or SAD. Further, seven studies show that exposure to morning light is more effective than exposure to evening light in reducing depression (Beauchemin & Hays, 1996; Benedetti, F., Colombo, C., Barbini, B., Campori, E., & Smeraldi, E., 2001; Lewy et al., 1998; Lovell, Ancoli-Israel, & Gevirtz, 1995; Terman, Terman, Lo, & Cooper, 2001; Van Someren, Kessler, Mirmiran, & Swaab, 1997; Wallace-Guy et al., 2002). An experimental study that compared the effect of morning and evening light on patients with winter depression found that morning light was *twice* as effective as evening light in treating SAD (Lewy et al., 1998). Exposure to bright morning light has been shown to reduce agitation among elderly patients with dementia. When elderly patients with dementia were exposed to 2,500 lux for two hours in the morning for two ten-day periods, their agitation reduced. Patients were significantly more agitated on non-treatment days (Lovell et al., 1995).

There is also strong evidence that exposure to bright light improves sleep and circadian rhythms. When the daytime environmental illumination level was increased in different living spaces of a dementia unit, it was found that, during increased illumination periods, the stability of the rest-activity rhythm increased in patients with intact vision, but not in visually impaired patients (Van Someren et al., 1997).

It has also been shown that patients in brightly lit rooms have a shorter length of stay compared to patients in dull rooms. Beauchemin and Hays (1996) found that patients hospitalized for severe depression reduced their stays by an average of 3.67 days if assigned to a sunny rather than a dull room overlooking spaces in shadow.

A recent randomized prospective study assessed whether the amount of sunlight in a hospital room modifies a patient's psychosocial health, quantity of analgesic medication used, and pain medication cost (Walch et al., 2004, in press). Patients undergoing elective cervical and lumbar spinal surgeries were admitted to the bright or the dim side of the inpatient surgical ward postoperatively. The outcomes measured included the standard morphine equivalent of all opioid medication used postoperatively by patients and their subsequent pharmacy cost. This strong study found that patients exposed to an increased intensity of sunlight experienced less perceived stress, less pain, took 22 percent less analgesic medication per hour and had 20 percent less pain medication costs.

Using light as an intervention to reduce depression in clinically depressed as well as non-depressed patients is a relatively inexpensive intervention that has been shown to yield consistently positive results. While many studies deal with the effects of artificial light,

natural daylight in patient rooms has also been found effective in reducing depression, reducing length of stay, and reducing intake of pain medication. Thus, an important consideration while designing hospital layouts may be to optimize exposure to morning light in patient rooms by using an east-facing orientation. This research further implies the possibility that depression might be worsened by architectural designs that block or sharply reduce natural daylight in patient rooms. A hypothetical example would be a hospital having patient-room windows looking out into a roofed atrium with few skylights and little natural daylight. In this example, deprivation of natural daylight could be extreme if patient windows were tinted to prevent users of the atrium from looking into patient rooms and violating privacy.

Provide Nature and Positive Distraction

Positive distractions refer to a small set of environmental features or conditions that have been found by research to effectively reduce stress. Distractions can include certain types of music, companion animals such as dogs or cats, laughter or comedy, certain art, and especially nature (Ulrich, 1991). The focus here is on the last, nature. (There is an additional large research literature on music, but this is not covered in this review.)

As background relevant to assessing the credibility of nature findings in healthcare environments, it should be mentioned that many studies of populations other than hospital patients have produced strong evidence that even fairly brief encounters with real or simulated nature settings can elicit significant recovery from stress within three minutes to five minutes at most (Parsons & Hartig, 2000; Ulrich, 1999). Investigators have consistently reported that stress-reducing or restorative benefits of simply viewing nature are manifested as a constellation of positive emotional and physiological changes. Stressful or negative emotions such as fear or anger diminish while levels of pleasant feelings increase. Laboratory and clinical studies have shown that viewing nature produces stress recovery quickly evident in physiological changes, for instance, in blood pressure and heart activity (Ulrich, 1991). By comparison, considerable research has demonstrated that looking at built scenes lacking nature (rooms, buildings, parking lots) is significantly less effective in fostering restoration and may worsen stress.

Questionnaire studies have found that bedridden patients assign especially high preference to having a hospital window view of nature (Verderber, 1986). Mounting research is providing convincing evidence that visual exposure to nature improves outcomes such as stress and pain. For example, a study in a Swedish hospital found that heart-surgery patients in ICUs who were assigned a picture with a landscape scene with trees and water reported less anxiety/stress and needed fewer strong doses of pain drugs than a control group assigned no pictures (Ulrich, 1991). Another group of patients assigned an abstract picture, however, had worsened outcomes compared to the control group. Ulrich (1984) found that patients recovering from abdominal surgery recovered faster, had better emotional well-being, and required fewer strong pain medications if they had bedside windows with a nature view (looking out onto trees) than if their windows looked out onto a brick wall.

Recently, strong studies using experimental designs have produced additional convincing evidence that viewing nature reduces patient pain as well as stress. These investigations also support the interpretation that nature serves as a positive distraction (Ulrich, 1991) that reduces stress and diverts patients from focusing on their pain or distress. A randomized prospective investigation found that adult patients undergoing a painful bronchosopy procedure reported less pain if they were assigned to look at a ceiling-mounted nature scene rather than a control condition consisting of a blank ceiling (Diette, Lechtzin, Haponik, Devrotes, & Rubin, 2003). Another controlled experiment that used volunteers in a hospital assessed the effect on pain of viewing a soundless nature videotape in contrast to a static blank screen (Tse, Ng, Chung, & Wong, 2002). Subjects who watched the nature scenes evidenced a higher threshold for detecting pain and had substantially greater pain tolerance. Two studies of female cancer patients have shown that taking a virtual reality nature walk while in bed or a hospital room (through a forest with bird sounds) reduced anxiety and symptomatic distress (Schneider, S. M., Prince-Paul, Allen, Silverman, & Talaba, 2004). Research on patients suffering intense pain because of severe burns found that exposing patients to a videotape of scenic nature (forest, flowers, ocean, waterfalls) during burn dressing changes significantly reduced both anxiety and pain intensity (Miller, Hickman, & Lemasters, 1992).

The possibility that nature can improve outcomes even in patients with late-stage dementia, including Alzheimer's disease, has received some support from a quasi-experimental study that found reduced levels of agitated aggressive behavior associated with a shower bath when recorded nature sounds (birds, babbling brook) and color pictures were present (Whall et al., 1997). A well-controlled study of blood donors in a waiting room found that blood pressure and pulse were lower on days when a wall-mounted television displayed a nature videotape, compared to days with continuous daytime television programs (Ulrich, Simons, & Miles, 2003). More research is needed to identify conditions under which television can either be a stress-reducing positive distraction or a stressor in hospitals.

Gardens in healthcare environments*:* Hospital gardens not only provide restorative or calming nature views, but can also reduce stress and improve outcomes through other mechanisms, for instance, fostering access to social support and providing opportunities for positive escape and sense of control with respect to stressful clinical settings (Cooper Marcus & Barnes, 1995; Ulrich, 1999). Based on postoccupancy evaluations of four hospital gardens in California, Cooper-Marcus and Barnes (1995) concluded that many nurses and other healthcare workers used the gardens for achieving pleasant escape and recuperation from stress. Other postoccupancy studies indicate that patients and family who use hospital gardens report positive mood change and reduced stress (Whitehouse et al., 2001). These reports also suggest that gardens and nature in hospitals can heighten patient and family satisfaction with overall quality of care.

Art in healthcare environments: A small number of studies on art in hospitals has yielded findings parallel to those from nature research. Results suggest a consistent pattern wherein the great majority of patients respond positively to representational

nature art, but many react negatively to chaotic abstract art (Ulrich & Gilpin, 2003). For example, Carpman & Grant (1993) studied the preferences of 300 randomly selected inpatients and concluded that the patients consistently preferred nature images but disliked abstract art. Although nature pictures and other emotionally appropriate art elicit positive reactions, there is also evidence that inappropriate art styles or image subject matter can increase stress and worsen other outcomes (Ulrich, 1991). It should not be expected that all art is suitable for high-stress healthcare spaces, as art varies enormously in subject matter and style, and much art is emotionally challenging or provocative.

The pitfalls of displaying emotionally challenging art in healthcare environments are revealed by a study of psychiatric patients (Ulrich, 1991). The unit was extensively furnished with a diverse collection of wall-mounted paintings and prints. Interviews with patients indicated strongly negative reactions to artworks that were ambiguous, surreal, or could be interpreted in multiple ways. The same patients, however, reported having positive feelings and associations with respect to nature paintings and prints.

Provide Social Support

Many studies of several different categories of patients have indicated that social support reduces stress and improves, for example, recovery outcomes in myocardial infarction patients. Considering the well-established importance of social support, it is unfortunate that there is only a moderate amount of research concerning how hospital design can facilitate or hinder access to social support. Most studies have focused on psychiatric units and nursing homes. There is strong evidence that levels of social interaction can be increased—and presumably beneficial social support as well—by providing lounges, day rooms, and waiting rooms with comfortable movable furniture arranged in small flexible groupings. A few well-designed studies in psychiatric wards and nursing homes have found that appropriate arrangement of movable seating in dining areas enhances social interaction and also improves eating behaviors, such as increasing the amount of food consumed by geriatric patients (Melin & Gotestam, 1981; Peterson, Knapp, Rosen, & al., 1977). Much research on day rooms and waiting areas has shown that the widespread practice of arranging seating side-by-side along room walls inhibits social interaction (Holahan, 1972; Sommer & Ross, 1958). A novel study by Harris (2000) found that family and friends stayed substantially longer during visits to rehabilitation patients when patient rooms were carpeted rather than covered with vinyl flooring.

Much evidence indicates that single rooms are markedly better than multi-bed rooms for supporting or accommodating the presence of family and friends. Some research suggests that open-plan multibed rooms deter family presence and accordingly reduce social support (Sallstrom, Sandman, & Norberg, 1987). Multibed rooms greatly reduce privacy for patient-family interactions compared to single rooms and are much more likely to have restricted visiting hours. A clear advantage of single rooms in fostering social support stems from the fact they provide more space and furniture than double rooms to accommodate family presence (Chaudhury et al., 2003). A survey of staff in four hospitals that each had a mix of single and double rooms found that nurses gave high

ratings to single rooms for accommodating family members but accorded double rooms low scores (Chaudhury et al., 2003). Further, patient-satisfaction data obtained from 2,122,439 patients who received care during 2003 provide overwhelming evidence that patients in single-bed rooms, compared to those with a roommate, are much more satisfied with "accommodations and comfort for family and visitors" (Press Ganey, 2003).

Do patients sharing the same room provide each other with stress-reducing social support? While some patients find roommates provide comforting social support, findings from several studies indicate that the presence of a roommate usually is a source of stress rather than social support. In most cases, roommates are linked to stressors, for example, loss of privacy or having a roommate who is unfriendly, has too many visitors, or is seriously ill (Van der Ploeg, 1988; Volicer, Isenberg, & Burns, 1977). An earlier section emphasized that noise is a much greater problem in double rooms than singles, and that noises stemming from the presence of other patients are a major cause of sleep loss.

Improve Communication to Patients

Good staff communication helps reduce patient and family anxiety, promotes better care at home after discharge, and in other ways can improve outcomes. Good communication also tends to be the single most important factor affecting overall satisfaction with care across different patient categories (Press Ganey, 2003). Data obtained from 2,122,439 patients nationally in 2003 show that patients consistently report significantly higher satisfaction with communication from nurses and physicians when they are in single rooms compared to when they have one or more roommates (Press Ganey, 2003). To explain this clear and important advantage of single rooms, Kaldenburg (1999) has proposed that staff in multibed rooms are reluctant to discuss patient issues or give information within hearing of a roommate, out of respect for privacy. Growing concern for patient confidentiality and HIPAA are certain to increase the already major advantages of single rooms with respect to communication.

IV. Improve Overall Healthcare Quality

Provide Single-Bed Patient Rooms

Based on an extremely large and varied body of research reviewed in earlier sections, there can be no question that single-bed rooms have several major advantages over double rooms and open bays. To summarize briefly, these advantages include: lower nosocomial infection rates, fewer patient transfers and associated medical errors, far less noise, much better patient privacy and confidentiality, better communication from staff to patients and from patients to staff, superior accommodation of family and consistently higher satisfaction with overall quality of care.

Reduce Length of Stay

Climate and sunlight influences length of hospital stay as well as sleep-wake patterns among hospitalized patients (Beauchemin & Hays, 1996; Benedetti, Francesco, Colombo, Cristina, Barbini, Barbara, Campori, Euridice, & Smeraldi, Enrico, 2001; Federman, Drebing, Boisvert, Penk, 2000; Hebert, Dumont, & Paquet, 1998; Kecskes et al., 2003; Kinnunen, Saynajakangs, Tuuponen, & Keistinen, 2002). One research group studied the impact of the amount of natural light on the length of hospitalization of patients with unipolar and bipolar disorder. The researchers found that bipolar patients randomly assigned to the brighter, eastern rooms (exposed to direct sunlight in the morning) had a mean 3.67-day shorter hospital stay than patients in west-facing rooms (Benedetti, Francesco et al., 2001). Patients recovering from abdominal surgery had shorter stays if they had a bedside window view of nature rather than if their windows looked out onto a brick wall (Ulrich, 1984).

The large research literature on infection reviewed in an earlier section indicated that the design of the physical environment strongly impacts hospital-acquired infection rates by affecting both airborne and contact transmission routes. Evidence-based design measures, by reducing nosocomial infection rates, play a key role in shortening hospital stays.

Increase Patient Satisfaction with Quality of Care

There is strong evidence that design changes that make the environment more comfortable, aesthetically pleasing, and informative relieve stress among patients and increases satisfaction with the quality of care provided. Renovating a traditional waiting area in a neurology clinic by making small changes to the general layout, color scheme, furniture, floor covering, curtains, and providing informational material and information displays resulted in more positive environmental appraisals, improved mood, altered physiological state, and greater reported satisfaction among waiting patients (Leather, Beale, Santos, Watts, & Lee, 2003).

Patients in well-decorated and well-appointed hotel-like rooms rated their attending physicians, housekeeping, and food-service staff, the food, and the hospital better than patients in standard rooms (typical hospital beds, inexpensive family sitting chairs, and no artwork) in the same hospital. Also, they had stronger intentions to use the hospital again and would recommend the hospital to others (Swan, Richardson, & Hutton, 2003). In another study, it was found that environmental satisfaction was a significant predictor of overall satisfaction, ranking only below perceived quality of nursing and clinical care (Harris, P. B., McBride, Ross, & Curtis, 2002). Several post-occupancy evaluation studies have examined patient and staff satisfaction with the different elements of the healthcare environment such as gardens, individual wards, and patient rooms (Brown, Wright, & Brown, 1997; Heath & Gifford, 2001; Shepley, 1995, 2002; Shepley & Davies, 2003; Shepley & Wilson, 1999; Whitehouse et al., 2001). These studies yield rich context-specific data that describe which aspects of the environment were effective. Some studies show quite clearly that tacit, as well implicit, staff and organizational practices and policies influence how an environment actually functions and is perceived

by patients and staff members. The qualitative and quantitative data provided by such studies are very important in understanding the nature of the problem (e.g. why are the gardens not being used as intended?) as well in developing solutions to tackle the problem. Future research that looks at satisfaction among hospital patients should consider using these multi-method post-occupancy evaluations that use different methods to obtain objective and subjective evaluations of use and satisfaction.

CONCLUSIONS

The research team found more than 600 rigorous studies linking a range of aspects of the built environment of hospitals to staff stress and effectiveness, patient safety, patient and family stress and healing, and improved overall healthcare quality and cost. This deep and wide base of evidence suggests that, parallel to evidence-based medicine, we can move to evidence-based design (EBD). EBD refers to a process for creating healthcare buildings, informed by the best available evidence, with the goal of improving outcomes and of continuing to monitor the success of designs for subsequent decision-making. While it is difficult to conduct rigorous research on the impacts of the healthcare environment—hospitals are complex systems where it is difficult to isolate the impact of single factors and the building industry conducts little impact-based research—The Center for Health Design and other groups have made considerable progress in developing a knowledge base of evidence.

EBD is not about hospitals that are simply nicer or fancier than traditional hospitals. Rather, the focus of evidence-based design is to create hospitals that actually help patients recover and be safer, and help staff do their jobs better. EBD is a process for creating health care buildings informed by the best available evidence concerning how the physical environment can interfere with or support activities by patients, families, and staff, and how the setting provides experiences that provide a caring, effective, safe, patient-centered environment. Many of the improvements suggested by EBD are only slightly more expensive than traditional solutions, if they are more expensive at all.

The large research literature surveyed in this report point to several actions we can take immediately:

- Provide single-bed rooms in almost all situations. Adaptable-acuity single-bed rooms should be widely adopted. Single rooms have been shown to lower hospital-induced nosocomial infections, reduce room transfers and associated medical errors, greatly lessen noise, improve patient confidentiality and privacy, facilitate social support by families, improve staff communication to patients, and increase patients' overall satisfaction with health care.
- New hospitals should be much quieter to reduce stress and improve sleep and other outcomes. Noise levels will be substantially lowered by the following combination of environmental interventions: providing single-bed rooms, installing high-performance sound-absorbing ceilings, and eliminating noise sources (for example, using noiseless paging).

- Provide patients stress reducing views of nature and other positive distractions.
- Develop wayfinding systems that allow users, and particularly outpatients and visitors, to find their way efficiently and with little stress.
- Improve ventilation through the use of improved filters, attention to appropriate pressurization, and special vigilance during construction.
- Improve lighting, especially access to natural lighting and full-spectrum lighting.
- Design ward layouts and nurses stations to reduce staff walking and fatigue, increase patient care time, and support staff activities such as medication supply, communication, charting, and respite from stress.

Bloodstream Infections

RAQUEL M. MARTINEZ[1] and DONNA M. WOLK[1]
[1]Department of Laboratory Medicine, Geisinger Health System, Danville, PA 17822

ABSTRACT Bacteremia and sepsis are conditions associated with high mortality and are of great impact to health care operations. Among the top causes of mortality in the United States, these conditions cause over 600 fatalities each day. Empiric, broad-spectrum treatment is a common but often a costly approach that may fail to effectively target the correct microbe, may inadvertently harm patients via antimicrobial toxicity or downstream antimicrobial resistance. To meet the diagnostic challenges of bacteremia and sepsis, laboratories must understand the complexity of diagnosing and treating septic patients, in order to focus on creating algorithms that can help direct a more targeted approach to antimicrobial therapy and synergize with existing clinical practices defined in new Surviving Sepsis Guidelines. Significant advances have been made in improving blood culture media; as yet no molecular or antigen-based method has proven superior for the detection of bacteremia in terms of limit of detection. Several methods for rapid molecular identification of pathogens from blood cultures bottles are available and many more are on the diagnostic horizon. Ultimately, early intervention by molecular detection of bacteria and fungi directly from whole blood could provide the most patient benefit and contribute to tailored antibiotic coverage of the patient early on in the course of the disease. Although blood cultures remain as the best means of diagnosing bacteremia and candidemia, complementary testing with antigen tests, microbiologic investigations from other body sites, and histopathology can often aid in the diagnosis of disseminated disease, and application of emerging nucleic acid test methods and other new technology may greatly impact our ability to bacteremic and septic patients, particularly those who are immunocompromised.

INTRODUCTION

Bloodstream infections (BSIs) and sepsis rank among the top reasons for human mortality for hospitalized patients. The full breadth of sepsis syndromes are particularly dangerous to any immunocompromised patient. Sepsis is one of the oldest of medical syndromes and dates back to the time in which Hippocrates characterized it as a clinical syndrome (1). Worldwide estimates of sepsis prevalence exceed 19 million cases per year, with over 750,000 in the United States (2). While only 2% of patients are admitted to the hospital with severe sepsis, they represent at least 10% of all ICU admissions in the U.S. (3).

In this article, we will review the human impact of BSIs in the immunocompromised host, as well as standard definitions of clinical criteria, symptoms, predisposing factors linked to the development of bacteremia and fungemia, and common modes of bacterial pathogenesis. We will review current literature to describe the presence of nonculturable BSIs, such as those caused by some viruses, parasites, and other nonculturable microbes. We will also review key aspects of the Surviving Sepsis Campaign guidelines (4) and approaches for diagnosis, therapy, and resuscitation from the septic event. Finally, we will highlight key laboratory roles and responsibilities to support the diagnosis of sepsis as part of today's interdisciplinary health care teams, detail the new Laboratory Medicine Best Practice guidelines for blood culture collection (5), and summarize the meta-analysis describing the impact of rapid diagnostics that identify bloodstreams pathogens (6). We will show that expansion of the laboratory's role, rapid diagnostics, and understanding of the complexities related to diagnosing and treating sepsis can not only improve patient survival, but also can limit the financial impact of sepsis on health care systems worldwide.

PATHOPHYSIOLOGY OF INFECTIONS

Pathophysiology of Sepsis

Due to the widespread immune response (7) when the human immune system is faced with infectious agents in the bloodstream, symptoms are widely variable and include fever, chills, hypotension, hypothermia (especially in the elderly), diaphoresis, apprehension, change in mental status, tachypnea, tachycardia, hyperventilation, reduced vascular tone, and the possibility of organ dysfunction. Hematologic findings include neutrophilic leukocytosis, thrombocytopenia, toxic granulations of neutrophils, or disseminated intravascular coagulation. Other metabolic findings include respiratory alkalosis; renal signs, such as acute tubular necrosis, oliguria or anuria; gastrointestinal signs such as upper gastrointestinal bleeding; cholestatic jaundice, increased transaminase levels, or hypoglycemia.

Despite modern advances, sepsis is one of the leading causes of death worldwide (8). If left untreated, sepsis can transform to septic shock (sepsis complicated by either hypotension that is refractory to fluid resuscitation or by hyperlactatemia), and eventually to organ dysfunction and death (3). There are several consensus definitions that define sepsis. For all conditions, the diagnosis primarily relies upon clinical recognition of symptoms, later confirmed by laboratory testing (4).

1. Bacteremia is defined as the presence of viable bacteria in the bloodstream.
2. Systemic inflammatory response syndrome is a systemic inflammatory response to bodily harm (e.g., from infection, burns, or trauma) that requires some of the following conditions:
   a. Fever or hypothermia
   b. Tachycardia
   c. Tachypnea
   d. Leukocytosis or leukopenia
   e. Elevated C-reactive protein
   f. Elevated plasma procalcitonin
   g. Altered mental status
   h. Significant edema or positive fluid balance
   i. Hyperglycemia
   j. Arterial hypotension
   k. Organ dysfunction
   l. Hyperlactatemia
   m. Decreased capillary filling or mottling
   Nonspecific causes of inflammation can cause systemic inflammatory response syndrome and must be considered in assessment of patients who present with inflammatory symptoms.
3. Sepsis is defined as the presence (probable or documented) of infection together with systemic manifestations of infection. Sepsis includes organ dysfunction (i.e., low blood pressure, reduced urine output, intestinal paralysis, reduced circulation, increased creatinine, reduced oxygen in the blood, elevated lactate, elevated bilirubin, abnormal coagulation, or metabolic acidosis).
4. Septic shock is a condition in which the patient exhibits refractory arterial hypotension or hypoperfusion despite adequate intravascular fluid resuscitation. Hypoperfusion may be manifested as lactic acidosis, oliguria, or mental status changes.

Management of sepsis and septic shock is generally driven by clinical care bundles, detailed in the International Surviving Sepsis Campaign (4). Early recognition of the disease is essential, and treatment includes stabilization of blood pressure (early fluid management and vasopressors) and treatment of infection (immediate administration of antibiotics), driven by evidence that for every hour a septic patient is not appropriately treated, mortality increases by approximately 7% (9, 10). Ideally, blood cultures are obtained from the patient prior to the administration of antimicrobials, and empiric therapy with broad-spectrum antimicrobial agents is initiated within the first hour of diagnosis.

Along with administration of antimicrobial therapy, attention is keenly focused on identifying and treating any ongoing foci of infections and/or reactivation of latent infections, a process known as source control. Identifying the source of the infection (urinary tract, respiratory, wound, etc.) is crucial to proper management. Control measures are meant to reduce or eliminate the source of infection, such as an infected device (e.g., hardware, catheters, lines, etc.), removal or drainage of an abscess, or debridement of infected tissue. Once the source of the infection is identified, microbial cultures can be obtained and targeted therapy can be administered based on the culture results. Other key definitions related to BSIs include the following:

- **Endocarditis** is an infection of a natural or prosthetic heart valve.
- **Nosocomial BSI** is defined as a BSI occurring >48 h following admission to hospital or <48 h if the patient has been hospitalized within the previous 2 weeks (11).
- **Community-acquired BSIs** are present on admission (POA).

Downloaded from https://journals.asm.org/journal/spectrum on 02 June 2025 by 194.9.109.109.

- **Endogenous asymptomatic bacteremia** (candidemia, fungemia) represents bacteremia that originates inside the host but that is not yet causing classic symptoms of BSI.
- **Acute bacteremia** (candidemia, fungemia) indicates the presence of microbes in the bloodstream with concomitant symptoms of bacteremia.
- **Transient bacteremia** represents sporadic and commonly asymptomatic bacteremia that is thought to occur under rare but normal circumstances. It occurs in a wide variety of procedures and manipulations, particularly those associated with mucous membrane trauma. It may also occur with such daily functions as tooth brushing and bowel movements. These intermittent and brief forms of bacteremia are especially common in tooth extraction and other dental procedures and can occasionally give rise to infective endocarditis in the susceptible patient.
- **Persistent bacteremia** is defined as bacteremia sustained for 3 days or longer, contributing to many *Staphylococcus aureus* bacteremia episodes and increasingly recognized among hospitalized patients.

Several scoring systems are commonly used to assess the severity and prognosis of a septic event. The Sequential Organ Failure Assessment (SOFA) score predicts intensive care unit (ICU) mortality based on laboratory results and clinical data. The Acute Physiological Assessment and Chronic Health Evaluation Score (Apache II Score) estimates ICU mortality based on laboratory values and patient signs, taking both acute and chronic disease into account. The use of the new "quickSOFA" (qSOFA) scores is described in the "Risk Factors and Outcomes" section of this article.

The Systemic Inflammatory Response Syndromes and Sepsis

BSIs can lead to sepsis, in the following manner. At onset, a bacterial cell triggers the host immune response. For Gram-negative pathogens, the bacterial endotoxin, a lipopolysaccharide from the cell wall, initiates the human inflammatory response. For Gram-positive pathogens, lipoteichoic acid, peptidoglycan, and extracellular products (toxins) trigger the response. An inflammatory response follows, mounting vascular, cellular, and chemical responses designed to stop injury with edema, which dilutes toxins, and with phagocytosis, which removes bacteria and cell debris.

The Role of the Human Immune Response in Sepsis

Classically immunocompromised patients have high mortality and can present with a wide variety of offending pathogens and common or unusual infections. While immunocompromised patients may sometimes die of infection due to their lack of ability to mount an effective immune response, in an immunocompetent host, the immune response is actually implicated in the disease symptoms; therefore, patient survival is dependent on whether the patient immune response to microbial pathogens is sufficient and can be ultimately balanced to regain immune homeostasis (12).

The pathogenesis of sepsis involves proinflammatory mediators, anti-inflammatory mediators, and vasoinflammatory mediators. There are several important inflammatory responses, which are linked to several different human cells that respond to bacterial invasion: 1) phagocytes (monocytes/macrophages, neutrophils, eosinophils); 2) mast cells, which are induced by lipopolysaccharide and complement (C3a and C5a) to release immune mediators; and 3) natural killer cells, which cause lysis of target cells and production of cytokines, like gamma interferon (IFN-γ) and tumor necrosis factor alpha (TNF-α), in a process called cell-mediated cytotoxicity. Other physiological changes include reduced protein C activity, microplugging of vessels, cellular necrosis (ischemic injury), the inhibition of fibrinolysis, apoptosis, leukocyte-mediated tissue injury, endothelial dysfunction, and cytopathic hypoxia (12).

Sepsis is a complicated and variable condition and has a prolonged host immune response. During the immune response, human proinflammatory responses, aimed at eliminating pathogens, combine with the anti-inflammatory responses, aimed at limiting tissue injury. Unfortunately, the same immune responses contribute to concurrent organ injury and susceptibility to secondary infections, respectively (12), and can vary widely during the clinical course of the disease. The immune response depends on various factors, including the causative pathogen (microbial density and relative virulence), the host (genetic characteristics, immunologic condition, comorbidities, and other concurrent infection), and the therapeutic regimen(s) (Fig. 1).

The Host's Innate Immune System

As part of the host's innate immunity, pathogens activate immune cells by interacting with pattern-recognition receptors, which recognize pathogen-associated molecular patterns that are conserved among microbial species. Binding of pathogen-associated molecular patterns

Downloaded from https://journals.asm.org/journal/spectrum on 02 June 2025 by 194.9.109.109.

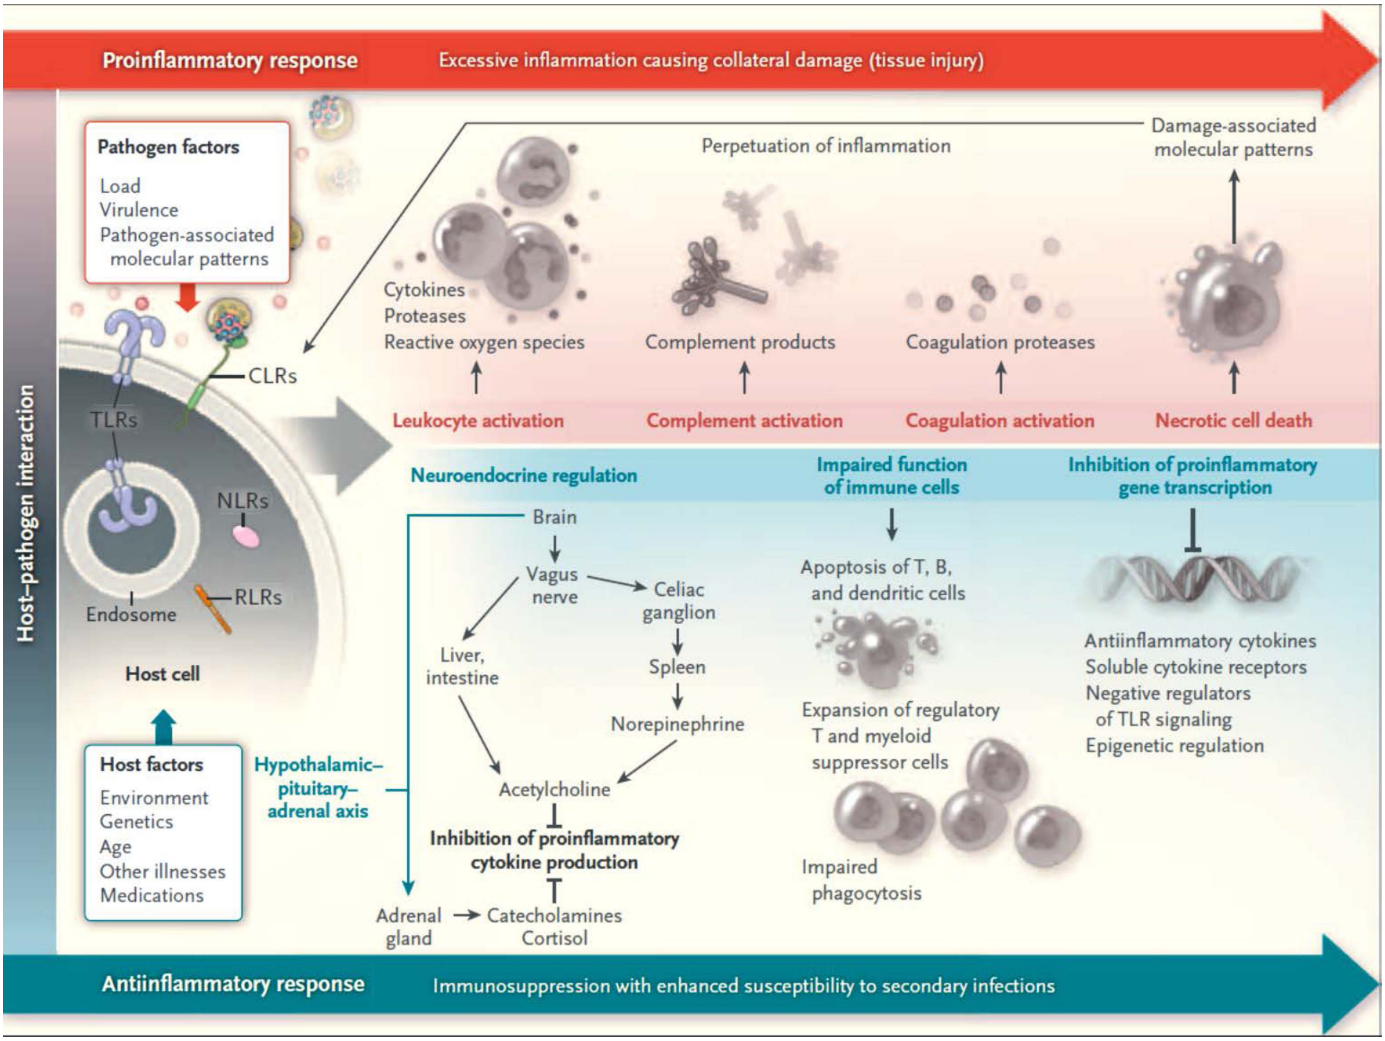

FIGURE 1 The host response in severe sepsis. The host response to sepsis is characterized by both proinflammatory responses (top of panel, in red) and anti-inflammatory immunosuppressive responses (bottom of panel, in blue). The direction, extent, and duration of these reactions are determined by both host factors (e.g., genetic characteristics, age, coexisting illnesses, and medications) and pathogen factors (e.g., microbial load and virulence). Inflammatory responses are initiated by interaction between pathogen-associated molecular patterns expressed by pathogens and pattern-recognition receptors expressed by host cells at the cell surface (toll-like receptors [TLRs] and C-type lectin receptors [CLRs]), in the endosome (TLRs) or in the cytoplasm (retinoic acid inducible gene 1-like receptors [RLRs] and nucleotide-binding oligomerization domain-like receptors [NLRs]). The consequence of exaggerated inflammation is collateral tissue damage and necrotic cell death, which results in the release of damage-associated molecular patterns, so-called danger molecules that perpetuate inflammation at least in part by acting on the same pattern-recognition receptors that are triggered by pathogens. Reprinted from reference (3), with permission.

to the human pattern-recognition receptors results in the upregulation of inflammatory gene transcription and initiation of the innate immune system. Human pattern-recognition receptors are categorized into four main classes: toll-like receptors, C-type lectin receptors, retinoic acid-inducible gene 1-like receptors, and nucleotide-binding oligomerization domain-like receptors, which partially act in protein complexes called inflammasomes (Fig. 1) (3, 13). The receptors are also capable of sensing molecules called damage-associated molecular patterns or alarmins, which are released from injured cells. Examples of alarmins include the high-mobility-group

Downloaded from https://journals.asm.org/journal/spectrum on 02 June 2025 by 194.9.109.109.

protein B1, S100 proteins, as well as extracellular RNA, DNA, and histones (3). Since alarmins are also released during trauma and other sterile tissue injury, the prevailing concepts that describe the pathogenesis of multiple organ failure in sepsis are not intrinsically different from those found in some noninfectious critical illnesses (3).

Organ Dysfunction

Although reduced oxygen supply to human organs is clearly an important contributor to tissue damage, inflammation can also cause dysfunction of the vascular endothelium and can contribute to cell death and loss of cell integrity, giving rise to subcutaneous and body-cavity edema (14). In parallel, injured mitochondria release alarmins, which include mitochondrial DNA and formyl peptides that can activate neutrophils and cause further tissue injury (15). Oxidative stress also damages mitochondria, and other mechanisms impair cellular oxygen use. Mechanisms that contribute to oxygen reduction include hypotension, reduced red-cell deformability, and microvascular thrombosis (16).

Coagulation Abnormalities Related to Tissue Injury

Four subtypes of protease-activated receptors (PARs) form a link between inflammation and coagulation. PAR1 is particularly important; it exerts cytoprotective effects when stimulated by activated protein C or low-dose thrombin, but it exerts disruptive effects on endothelial-cell barrier function when activated by high-dose thrombin (17, 18). Because of these interactions, human coagulation is commonly altered during sepsis (3) (Fig. 2), and the disruption can lead to disseminated intravascular coagulation. In disseminated intravascular coagulation, the coagulation cascade drives excess fibrin deposition through depression of the fibrinolytic system, which triggers fibrin removal, and via activation of a transmembrane glycoprotein, which is expressed by various cell types because of impaired anticoagulant mechanisms (including the protein C system and antithrombin) (18).

Immunosuppression and Its Association with Anti-inflammatory Processes

The immune system is composed of humoral, cellular, and neuroinflammatory mechanisms that mitigate the harmful effects of the human proinflammatory cytokines and the proinflammatory response (Fig. 1). Phagocytes can switch to an anti-inflammatory phenotype, combining with regulatory T cells, myeloid-derived suppressor cells, and neural mechanisms to promote tissue repair and reduction of inflammation (3, 12, 19). By nature of the septic event itself, patients who survive early sepsis but remain under intensive care have evidence of immunosuppression, partly from reduced expression of HLA-DR on myeloid cells (20). Reduced responsiveness of leukocytes, functional impairment of splenocytes, and immunosuppression in the spleen and lungs are all associated with sepsis (12, 20). In addition, epigenetic regulation of gene expression may also contribute to sepsis-associated immunosuppression (21) and apoptosis, especially of B cells, $CD4^+$ T cells, and follicular dendritic cells. Sepsis-associated immunosuppression has been implicated in sepsis-associated immunosuppression and death (22, 23).

Agents of Bloodstream Infections

In an immunocompromised host, the spectrum of microbes that cause BSIs has changed over the last decade, shifting from Gram-negative to Gram-positive organisms (24). Reasons for the change can be found in recent changes in clinical practice that include antimicrobial therapy, changes to immunosuppressive or chemotherapeutic regimens, and significant increases in the use of long-term indwelling devices. In addition, emerging antimicrobial resistance impacts the epidemiology of BSIs found in immunocompromised hosts (24).

Historically, patients with hematologic malignancies and febrile granulocytopenia constituted the majority of immunocompromised hosts (24, 25); however, there are currently many other types of immunocompromised hosts, including those with hematopoietic stem cell and solid organ transplants, as well as a wide variety of other immunosuppressive states, detailed later in this article. Today, many of these patients have concurrent intravascular catheters and are besieged with Gram-positive microorganisms, especially staphylococci, which have become the most frequent cause of BSIs. Additionally, BSIs caused by nontuberculous mycobacteria (NTM) and non-*Candida* yeasts are on the rise. Unfortunately, blood cultures are not a fully reliable diagnostic test—in some populations, only one-third of sepsis cases result in positive blood cultures (3).

Gram-positive and Gram-negative bacteria

Severe sepsis can be the result of either community-acquired or health care-associated infections, but it can also follow dissemination of primary infections. Primary infections such as pneumonia, urinary tract, and intra-abdominal infections are often the source of BSIs and can lead to sepsis and septic shock (8). Common causative bacterial agents of BSIs include *Staphylococcus*

Downloaded from https://journals.asm.org/journal/spectrum on 02 June 2025 by 194.9.109.109.

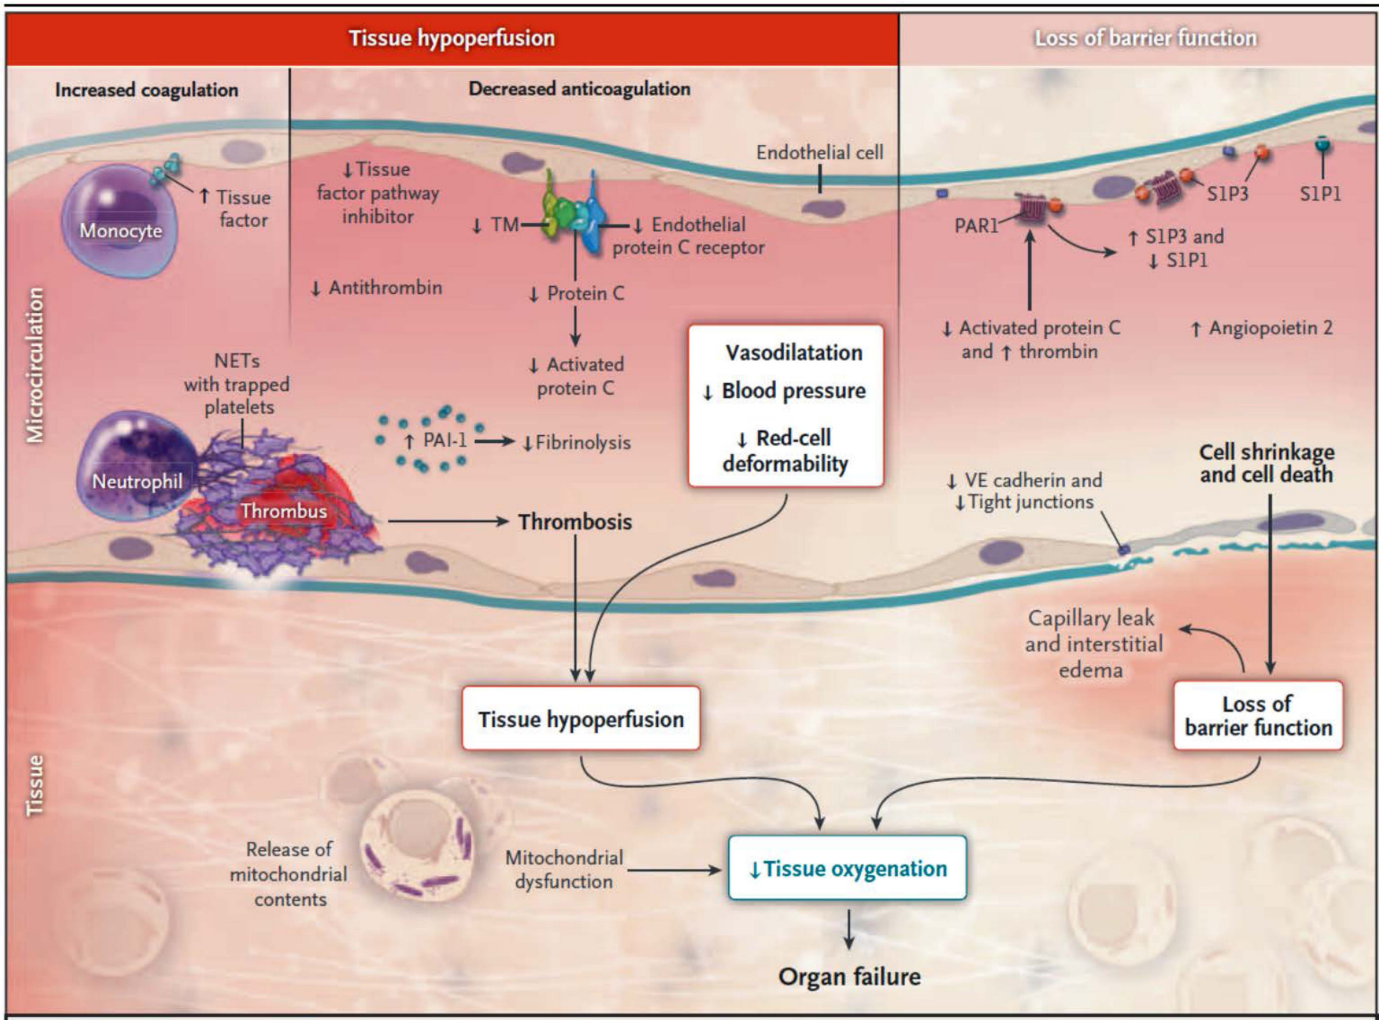

FIGURE 2 Organ failure in severe sepsis and dysfunction of the vascular endothelium and mitochondria. Sepsis is associated with microvascular thrombosis caused by concurrent activation of coagulation (mediated by tissue factor) and impairment of anticoagulant mechanisms as a consequence of reduced activity of endogenous anticoagulant pathways (mediated by activated protein C, antithrombin, and tissue factor pathway inhibitor), plus impaired fibrinolysis owing to enhanced release of plasminogen activator inhibitor type 1 (PAI-1). The capacity to generate activated protein C is impaired at least in part by reduced expression of two endothelial receptors: thrombomodulin (TM) and the endothelial protein C receptor. Thrombus formation is further facilitated by neutrophil extracellular traps (NETs) released from dying neutrophils. Thrombus formation results in tissue hypoperfusion, which is aggravated by vasodilatation, hypotension, and reduced red-cell deformability. Tissue oxygenation is further impaired by the loss of barrier function of the endothelium owing to a loss of function of vascular endothelial (VE) cadherin, alterations in endothelial cell-to-cell tight junctions, high levels of angiopoietin 2, and a disturbed balance between sphingosine-1 phosphate receptor 1 (S1P1) and S1P3 within the vascular wall, which is at least in part due to preferential induction of S1P3 through protease-activated receptor 1 (PAR1) as a result of a reduced ratio of activated protein C to thrombin. Oxygen use is impaired at the subcellular level because of damage to mitochondria from oxidative stress. Reprinted from reference (3), with permission.

Downloaded from https://journals.asm.org/journal/spectrum on 02 June 2025 by 194.9.109.109.

aureus, *Staphylococcus epidermidis*, *Enterococcus* spp., *Streptococcus pneumoniae*, *Escherichia coli*, *Pseudomonas aeruginosa*, and *Klebsiella* spp.

Not only does the range of disease and pathogens vary greatly, but the way in which an individual responds to sepsis also depends on the immune condition of the host and on the pathogenic characteristics (virulence factors and bacterial load). For example, the absence of specific host immune responses such as B-cell depletion from rituximab or complement deficiency in systemic lupus erythematosus may predispose a patient to a BSI. In many instances, the underlying reason for immunosuppression provides clues to the type of microorganism causing infection. For example, a complement-depleted patient with systemic lupus erythematosus who presents with sudden onset of septic shock is at increased risk for a bloodstream infection with *Neisseria meningitidis* (26). Similarly, unusual pathogens such as *Vibrio vulnificus* may cause BSIs in patients with severe liver disease or liver transplantation. When anatomic barriers such as skin or mucosa are compromised from graft-versus-host disease or cytotoxic chemotherapy, patients are more likely to become infected with microorganisms colonizing the skin or oropharyngeal and gastrointestinal tracts. The recovery of *Leptotrichia* spp. or *Capnocytophaga* spp. from blood culture may suggest disruption of the mucosal integrity from the oropharynx or gastrointestinal tract in a granulocytopenic patient with severe mucositis.

Anaerobic bacteria

Anaerobic bacteremia is an important consideration in any patient, particularly in the immunocompromised and vulnerable populations. Anaerobic infections in the general population are most frequently related to pelvic, abdominal, and skin/soft-tissue infections, in 50 to 70%, 5 to 20%, and 5 to 20% of cases, respectively. Publications in the immunocompromised population exist but are limited in number (27–29). The *Bacteroides fragilis* group and *Clostridium* spp. are the most frequent anaerobic blood culture isolates (28), and associated conditions include cancer and malignant tumors, diabetes mellitus, post-surgery status, and advancing age. Older persons are at higher risk of mortality with anaerobic bacteremia (25 to 44%) (30, 31). In general, the risk of mortality for anaerobic BSIs is high and the prevalence of anaerobic bacteremia is increasing (30, 31). As antimicrobial resistance is also increasing among anaerobes, there is a need for more rapid and easier anaerobic antimicrobial susceptibility testing (AST) methods to be deployed.

Mycobacteria

For the diagnosis of disseminated *Mycobacterium tuberculosis* infections or NTM infections, such as *Mycobacterium chelonae* and *Mycobacterium haemophilum*, it is necessary to consider collection of specimens, like sputum or skin lesions, to improve diagnostic yield over that of blood cultures alone (32, 33). There are case reports of septicemia caused by *M. chelonae* complex, in which appropriate therapy is likely delayed, resulting in significant morbidity and multiple hospital admissions (34). Gram staining of these organisms from blood culture should not be confused with debris or with *Corynebacterium* spp. For immunocompromised individuals, the identification of a Gram-positive bacillus that is not able to be identified by phenotypic methods should prompt an acid-fast bacilli stain to distinguish between *Bacillus* spp. and the rapidly growing mycobacteria. Likewise, rapidly growing NTM, while considered rare pathogens, can cause central line-associated BSIs and have been associated with hospital-associated outbreaks in hematology–oncology wards. *Mycobacterium mucogenicum* and *Mycobacterium canariasense* were identified in patients with acute myeloid leukemia, acute lymphocytic leukemia, and aplastic anemia. In this case report, environmental surveillance cultures detected genetically similar *M. mucogenicum* and *M. canariasense* in the water supply of the hematology–oncology ward (35).

Depending on local geography and CD4 count, HIV patients commonly present with mycobacteremial infections ranging from *Mycobacterium avium-intracellulare* to *Mycobacterium tuberculosis* (36, 37). Infections caused by NTM are rapidly emerging among all hosts with altered immune responses and often are associated with an intravascular catheter (33, 38).

Fungi

Yeasts

Candidemia is frequently observed among immunocompromised hosts receiving broad-spectrum or prolonged antibiotic therapy, parenteral nutrition, intravascular catheters, or renal failure, and in those with prolonged stays in an intensive care unit (39–41). *Candida* spp. rank fourth among common causes of BSIs in some groups of hospitalized patients (42, 43). Over 95% of all candidemia is caused by 5 species: *C. albicans*, *C. glabrata*, *C. tropicalis*, *C. parapsilosis*, and *C. krusei* (43). Other yeasts include *Cryptococcus* spp., *Trichosporon* spp., *Geotrichum* spp., *Rhodotorula* spp., and *Hansenula* spp., all of which have emerged as important bloodstream pathogens in the immunocompromised host (44,

Downloaded from https://journals.asm.org/journal/spectrum on 02 June 2025 by 194.9.109.109.

45). All yeasts, except *Cryptococcus* spp., are often related to the presence of indwelling devices (45).

Standard blood culture bottles will recover many medically important yeasts without the need for special fungal blood bottles (46); however, performance studies show that traditional blood cultures are able to identify medically important yeasts with only varied sensitivity, which can be as low as 38 to 80% when compared to molecular methods (47). For those reasons, special broth formulations, adapted for optimal fungal recovery, are warranted for patients at high risk for candidemia and fungemia.

Nosocomial candidiasis is a life-threatening condition in both critically ill and immunocompromised patients (48). The frequency of infection and the associated mortality have not decreased over the past two decades (48). These findings highlight the difficulties encountered when diagnosing *Candida* infection in high-risk patients and the challenges in administering adequate and appropriate antifungal therapy despite the introduction of several extended-spectrum triazole and echinocandin antifungal agents (48). Moreover, the criteria for initiating antifungal therapy are not completely standardized and often result in administration of antifungal therapy with the associated risks of toxicity, development of antifungal resistance, and high costs (48).

Many yeasts are emerging as new causes of disease. *Kodameae ohmeri* (formerly *Pichia*) is a yeast that is an emerging pathogen in patients with compromised immunity, like cancer patients and premature neonates, with fatal outcomes (49, 50). A rare case of fungemia due to *Trichosporon mucoides* in a diabetes mellitus patient adds to an emerging list of trichosporonosis infections (51). *Rhodotorula* spp. are emerging opportunistic pathogens found in immunocompromised hosts (52, 53). Within the *C. glabrata* complex, *Candida nivariensis* and *Candida bracarensis* are important, since both species have lower susceptibility to fluconazole, but they may be difficult to identify (54).

Molds

Aspergillus spp. (*A. fumigatus*, *A. flavus*, *A. niger*, *A. terreus*), hyaline molds (*Fusarium* spp. and *Scedosporium* spp.), and a wide variety of dematiaceous fungi can cause invasive BSIs (55–58) and are associated with high mortality (59, 60). Most patients with invasive aspergillosis have underlying hematological diseases or have undergone hematopoietic stem cell transplantation. Recognized risk factors for infection are graft-versus-host disease, receipt of steroids, secondary neutropenia, age >40 years, and a stem cell source (61). In contrast, invasive mold infections are unusual in patients with human immunodeficiency virus (62).

Invasive mold infections are especially challenging among patients receiving chemotherapy for hematological malignancies, hematopoietic stem cell transplant recipients (57), HIV patients (63) and solid organ transplant recipients (64, 65). Even *Acremonium* spp. are implicated in systemic fungal diseases, with a case of *Acremonium kiliense* fungemia with proven involvement of the lungs in an allogeneic hematopoietic stem cell patient (66). *Saprochaete capitata* (formerly known as *Geotrichum capitatum* and *Blastoschizomyces capitatus*) has been known to produce serious opportunistic infections in patients with hematological malignancies (67).

Traditional blood culture methods can recover some molds (68), but depending on the species, broth culture has low sensitivity for recovering fungi when compared with molecular methods. The recovery of *Aspergillus* spp. from specific fungal blood culture bottles is infrequent despite disseminated disease (including endocarditis), owing to tissue tropism and limitations in traditional broth culture technology. Vessel invasion and skin infarcts can limit mold recovery from the bloodstream. In contrast, some molds and dematiaceous fungi such as *Fusarium* spp. (69), *Paecilomyces* spp. (70), and *Wangiella* (*Exophiala*) *dermatitidis* (71) have been successfully cultivated from patients, especially those with indwelling catheters.

Viruses

Many viruses are well-known sources of sepsis in immunocompromised hosts; however, these syndromes and their associated test methods are well covered elsewhere and therefore will not be reiterated here; rather, we provide a summary table with a list of relevant publications and rare or miscellaneous pathogens (Table 1).

Other fastidious pathogens

Immunocompromised patients are susceptible to invasive infections with fastidious pathogens that may require unique incubation procedures. Microorganisms such as HACEK (species of *Haemophilus*, *Actinobacillus*, *Cardiobacterium*, *Eikenella*, and *Kingella*) bacteria can be recovered within 5 days of incubation in currently available automated blood culture systems; extended incubation is not deemed necessary (72, 73).

Legionella spp. grow poorly in routine blood culture media; they require blind subculture from blood culture bottles and special supplementation for growth on solid media (74). *Legionella bozemanae* has been reported to cause pneumonia in immunocompromised patients (75). Some *Campylobacter* spp., *Helicobacter* spp., and

Capnocytophaga spp. may also grow poorly or not at all but are important in the immunocompromised population (76, 77). Laboratories may consider performing acridine orange staining for bottles that flag positive but do not show microbes via the Gram stain (78).

Care must be taken when interpreting the Gram stain to avoid false positives that may occur due to Gram stain precipitate. Telemicroscopy is becoming feasible in microbiology and can drastically reduce the number of errors for Gram stain interpretation made by nonmicrobiologists during night shifts or by generalists, for whom competency remains a challenge due to limited exposure to the practice (79).

With improved blood culture systems, the ability to detect *Bartonella* spp. has also improved, but it still requires a prolonged incubation period of up to 6 weeks followed by subculture to freshly prepared media (80). For other microbes, the addition of supplemental agar or different incubation conditions can help support the growth. These additional considerations are well worth

the effort for immunocompromised patients and should be included in standard culture algorithms (Fig. 3).

PREDISPOSING FACTORS FOR BLOODSTREAM INFECTION

Risk Factors and Outcomes

Immune changes are the main risk factors for developing sepsis. It is important to assess the patient's predisposition for infection and how likely it is for a patient to develop organ dysfunction. Much is known about immunosuppression-related sepsis risk factors, and they are discussed in greater detail later in this article. Although less is known about the risk factors leading to organ dysfunction, it is important to document the patient's baseline organ function (overall health status) and any inherited risk factors (3). Age, sex, and race contribute to and influence the prevalence of sepsis. For example, severe sepsis occurs more frequently in infants and elderly individuals, is more common among males than females, and has a greater incidence rate in African Americans than in Caucasians (81). Genetic characteristics may contribute to the host's susceptibility to sepsis and are currently of great interest (82–87).

As with all medical conditions that suppress immunity, the major risk factors for acquiring a life-threatening infection, such as BSI, include two major concepts: pathogen exposure and the immune status of the individual (33). Depending on the predisposing factor (HIV, organ transplant, diabetes, etc.) different risk factors can occur. In addition to underlying immunosuppression, immunocompromised patients have increased risk for infections from unusual or multidrug-resistant (MDR) microorganisms, owing to chemoprophylaxis regimens, extended hospitalizations, or prolonged stays in intensive care units.

Improvements in the management of patients with sepsis and septic shock have increased the survival rate from 20% to over 70% in some populations (3, 88); however, as septic shock is the most severe facet of sepsis, it is not surprising that it has the highest mortality rate, still approximately 50% in some studies (88). Mortality seems to be associated with a poor prognosis when

Downloaded from https://journals.asm.org/journal/spectrum on 02 June 2025 by 194.9.109.109.

attributed to Gram-negative organisms or yeast, as opposed to Gram-positive organisms (88).

Even after discharge, patients who survive sepsis are less likely to live long-term, and sequelae such as impaired biological functions, exacerbation of chronic conditions (chronic kidney disease or cardiovascular disease), emergence of new chronic conditions, and neurocognitive dysfunction lower their overall quality of life (3). Refer to Table 2 for a summary of risk factors.

Critical care and surgery

Sepsis can be a fatal outcome for postsurgical patients in a variety of settings, including transplantation, wound surgery, splenectomy, intra-abdominal surgery, and cancer surgery (89–91).

Cancer

An estimated 5% of cancer patients acquire severe sepsis, and hospitalized patients with cancer are more than 5 times more likely to die (37.8%) than cancer patients without sepsis. The use of cytotoxic agents is largely responsible for immune suppression in these patients, and their therapies predispose them to BSIs. In addition, malignant neoplasms can provide entry for bacteria into the bloodstream. Even more risk comes for patients with hematologic cancers, who are 15 times more likely than the average person to suffer from severe sepsis (92).

Long-term immunosuppressive therapy for cancer is linked to development of life-threatening complications, including BSIs. Central line-associated BSIs are common among these patients with febrile neutropenia following cytotoxic chemotherapy due to translocation of intestinal organisms (*E. coli*, *E. faecium*, and *Streptococcus* spp.) (93). Further studies on enterococcal bacteremia show a high global mortality rate (42%) in patients with hematological malignancies (94). Poor outcomes are associated with age >50 years, underlying disease (leukemia, lymphoma, myeloma, etc.), pneumonia, and shock (94). Other risk factors include long hospital stays (average of 25 days), the presence of a central venous catheter, and the urinary tract as a source of infection (94). One study established that previous use of carbapenem antibiotics increased the risk of acquiring hospital-associated vancomycin-susceptible *E. faecium* BSI, which can be problematic if vancomycin resistance emerges, as that will limit therapy options (95).

TABLE 2 Predisposing factors that contribute to immunosuppression

Therapy
Immunosuppressive
Antimicrobial (i.e., broad-spectrum)
Antifungal
Bacterial colonization
Staphylococcus aureus (i.e., MRSA)
Distortions in normal bacterial microbiota (due to antimicrobial prophylaxis)
Immune deficiency
Autoimmune disease
Devitalized tissue, fluid collections
Neutropenia, lymphopenia
Medical Comorbidities
Uremia
Malnutrition
Diabetes
Alcoholism with cirrhosis
Peripheral vascular disease
Congestive heart failure
Renal and liver disease
Infection with immunomodulating viruses
CMV
EBV
HBV
HCV
HIV
Surgical and/or invasive procedure
Catheterization (i.e., urinary tract, central venous, central line-associated BSIs)

Age

Age over 40 is a risk factor for sepsis (7, 96), and the poorest outcomes occur in patients older than 85 years, with an associated mortality rate of over 38.4% (81). People over 65 years old account for only 1/8 of the U.S. population but account for 66% of all sepsis cases. At the other end of the age spectrum, children, particularly neonates, share elevated mortality rates (97). Infections are more frequent identified in elderly patients (aged ≥65 years) due to preexisting comorbidities, an impaired integumentary system, reduced mechanisms of clearance, and diminished immune response (i.e., immunosenescence, which is more marked in women than in men). Because elderly patients have a decreased immune response, the clinical presentation of infection can be atypical or subtle, which often makes infection difficult to diagnose in those with increased age. Persons over the age of 85 have the highest risk for hospitalization and mortality (98). The increased risk of hospitalization alone puts them at risk for infection (99).

In 2012, the number of elderly persons in the U.S. was 43.1 million (13.7% of the total population), mostly due to the aging of the baby boomer generation; it is estimated that that number will increase to nearly 84

Downloaded from https://journals.asm.org/journal/spectrum on 02 June 2025 by 194.9.109.109.

million by 2050 (20.9% of the total population) (100). As the elderly population increases, health care providers should not only be prepared for increased hospitalization rates in the years to come, but they should focus efforts to reduce infection rates in the elderly. Survival rates do appear to be positively influenced by public health campaigns and behavioral changes, e.g., reductions in smoking and obesity (100).

The most frequent cause of BSIs in the elderly population is urinary tract infection, especially with MDR uropathogens; depression of immunity plays a role in their predisposition to infection (101–103). Bacteremic urinary tract infection is defined as the isolation of the same organism from both the blood and urine within 48 h (104). The majority of urosepsis cases in the elderly are community-acquired (approximately 80%, of which nearly 90% of the Gram-negative infections are due to *E. coli*) (104). Non-*E. coli* Gram-negative organisms are more common among hospital-acquired infections. Gram-positive microbes are associated with male patients with chronic urinary catheter insertion.

At the other end of the age spectrum, at birth, infants have little immunity of their own and are susceptible to infections (105–107). Similar to elderly sepsis, the diagnosis of neonatal sepsis is difficult due to nonspecific signs and symptoms. In 2015, 45% of neonatal sepsis-related deaths (died within 28 days of birth) were due to infectious etiologies (108).

Hospitalization

Risk factors for health care-associated infections (recent hospitalization, extended-care facility, dialysis, or regular home care or hospital clinic visits) predispose patients to BSIs and sepsis. Common etiologies of health care-associated infections are methicillin-resistant *S. aureus* (MRSA), vancomycin-resistant enterococci, *Acinetobacter baumannii*, *Pseudomonas aeruginosa*, extended-spectrum β-lactamase-producing *K. pneumoniae*, and extended-spectrum β-lactamase-producing *E. coli* (109). Patients receiving prophylaxis with fluoroquinolones, common in hospitals, are at risk for BSIs with methicillin-resistant *S. aureus* (110) and MDR Gram-negative bacilli (111).

HIV

Advances in antiretroviral therapy (ART) have extended the life expectancy of people with HIV, and because infection is related to immunosuppression, the incidence of opportunistic infections in HIV-infected persons has been reduced. Moreover, just as the epidemic has evolved, so has the spectrum of HIV-associated opportunistic infections. For example, people with HIV are more likely to be admitted to the ICU for sepsis than for *Pneumocystis* pneumonia, as was more common in the past (112). The incidence of a community-acquired bacterial BSI is higher in HIV-positive patients (20% in adults and 30% in children) than in HIV-negative adults and children (9%) (113). Although causative agents vary by geographic region, HIV-infected persons worldwide are particularly susceptible to developing nontyphoidal salmonellae and *S. pneumoniae* bacteremia. Other pathogens such as *E. coli* and *S. aureus* are common causes of BSI among HIV-positive and HIV-negative individuals. Moreover, patients who receive ART are less likely to be hospitalized for a BSI, with an incidence rate of 0.63 pre-ART and 0.2 post-ART (113).

Regardless, a low CD4 count is the main risk factor for the development of BSIs in HIV-infected persons. Mortality rates vary from 7% to 46% worldwide, with Europe and the U.S. at 16% to 18% and 25% to 43%, respectively, and Africa at 7% to 46% (113). Although data are limited, no studies have yet shown a difference in mortality rates between HIV-positive and HIV-negative patients with community-acquired BSI (113).

Transplant

BSIs are a major cause of morbidity and mortality after solid organ transplant and hematopoietic stem cell transplantation, with the highest incidence rate (7.4% to 14%) within the first 30 days (114–116). When coupled with septic shock, the mortality rate of posttransplant BSI is approximately 50% (117). The transplantation type (i.e., kidney, kidney–pancreas, liver, etc.) also plays a role in incidence rate, and liver transplantation was associated with the highest risk of BSI (118). Although etiologic agents vary between studies, most Gram-negative BSIs are caused by *E. coli*, and the Gram-positive BSIs are largely due to *Staphylococcus* spp. (115, 116). Moreover, the Gram-negative isolates mainly consists of multidrug-resistant organisms (115, 116), thus necessitating the use of a more aggressive empiric agent, such as a carbapenem.

Risk factors for BSI posttransplantation include age >50 years, nosocomial infection, pulmonary source (117), urinary tract sources (115), and central venous catheters (119). In one study, for 27% of liver transplant BSIs, urosepsis began with catheter-related infections (115). Certain causative agents are also associated with poor outcomes. For example, *Candida* spp., enteric Gram-negative bacteria other than *E. coli*, and MDRO non-lactose-fermenting Gram-negatives (e.g., *P. aeruginosa*) (117, 119) are associated with increased mortality. Moreover, the prophylactic antimicrobials used to mini-

Downloaded from https://journals.asm.org/journal/spectrum on 02 June 2025 by 194.9.109.109.

mize opportunistic infection in high-risk patients inadvertently increase the rate of resistant microorganisms isolated. Increasing resistance rates of MDR organisms complicate treatment options and continue to be a concern in transplant patients.

Steroid use

Glucocorticoids, also known as corticosteroids, play an important role in regulating the immune response, and as one would expect, disruption in their levels can destabilize a sepsis patient. Glucocorticoids function to inhibit the inflammatory response, thus creating an immunosuppressive effect. During sepsis, cortisol and glucocorticoid production are reduced, which causes individuals to experience exaggerated and uncontrolled inflammatory responses. Therefore, glucocorticoids are frequently used to treat patients with severe sepsis or septic shock as a means to stabilize their immune imbalances. New data suggest that glucocorticoids serve to reprogram immune cells, which balances homeostasis and restores organ function for improved patient outcomes (120). On the other hand, high random cortisol levels are a marker of disease severity and a poor prognostic marker (120, 121). Not surprisingly, an uncontrolled immune response during sepsis disrupts homeostasis, causing metabolic chaos. For example, hyperglycemia is one clinical characteristic of sepsis that becomes an important therapeutic factor to manage in septic patients. The use of corticosteroids, such as hydrocortisone, during sepsis has the ability to stabilize blood glucose levels. However, current studies show limited to no benefit of the use of corticosteroids as sepsis therapy, and the lack of evidence-based data keep this a controversial topic (121).

Nutrition (malnourished, diabetic)

Many metabolic and nutritional deficiencies are linked to increased risk of infections and to increased severity and mortality of BSIs (122, 123). A variety of metabolic and vitamin deficiencies predispose hosts to infections and are linked to higher incidence and severity of BSIs. Vitamin D, selenium, iron, amino acids, and hormone deficiencies have all been linked to higher risks and severity of disease (124–136).

B-cell depletion

B lymphocytes produce antibodies, which function to inhibit infections by eliminating microorganisms. B-cells also regulate the immune response by producing specialized signaling molecules called cytokines. In BSIs, proinflammatory cytokines, such as TNF, interleukin-1 (IL-1), interleukin-6 (IL-6), and interleukin-8 (IL-8), function to provide response to human infection. When produced and released, the proinflammatory cytokines induce a systemic inflammatory response. Anti-inflammatory cytokines, such as interleukin-10 (IL-10), transforming growth factor-beta (TGF-β), and INF-γ, function to limit tissue injury.

B-cell dysfunction obviously alters the host's immune response, but so does B-cell depletion, a type of therapy utilized for the treatment of autoimmune diseases (i.e., lupus, rheumatoid arthritis, multiple sclerosis) and B-cell malignancies (i.e., Hodgkin lymphoma, chronic lymphocytic leukemia). Depletion therapy alters the host immune response, and treatment with rituximab, an anti-CD20 antibody, is associated with induced hypogammaglobulinemia, which predisposes patients to increased infections.

Neutropenia

Neutropenia predisposes patients to BSIs and sepsis, and febrile neutropenia represents one of the biggest diagnostic challenges (137–146). Like depletion therapy, treatment-related neutropenia can have severe consequences and is associated with a variety of common and rare microbes (141, 147). The situation is similar for autoimmune cytopenia (148) and other causes of granulocytopenia (107, 143, 149–153).

Intensive care unit

In critical care settings, the definitions of sepsis and septic shock were last revised in 2012. Experts from a variety of fields (154, 155) introduced changes in sepsis definitions, because previous definitions were thought to include an excessive focus on inflammation and the misleading model that sepsis follows a continuum through severe sepsis to shock. In addition, the inadequate specificity and sensitivity of systemic inflammatory response syndrome criteria was addressed and led to removal of the term "severe sepsis," which was deemed to be redundant (154, 155). In an ICU setting, sepsis is now defined as life-threatening organ dysfunction, which is caused by a dysregulated host response to infection. Organ dysfunction can be represented by an increase of 2 points or more in the SOFA score, which is associated with an in-hospital mortality of greater than 10% (154, 155). These updated definitions and clinical criteria now replace previous definitions and facilitate earlier recognition and more timely management of patients with sepsis or patients at risk of developing sepsis (154, 155).

Septic shock is now defined as a subset of sepsis in which profound circulatory, cellular, and metabolic abnormalities are associated with a greater risk of mor-

Downloaded from https://journals.asm.org/journal/spectrum on 02 June 2025 by 194.9.109.109.

tality than with sepsis alone (154). The presence of septic shock is associated with hospital mortality rates greater than 40%. Patients with septic shock are identified by the need for use of vasopressor therapy in order to maintain their mean arterial pressure at ≥65 mm Hg, and a serum lactate level greater than 2 mmol/liter (>18 mg/dl) in the absence of hypovolemia, a decreased volume of circulating blood.

In outpatient settings, emergency departments, or general hospital ward settings, adult patients with suspected infection can be rapidly identified as being more likely to have poor outcomes typical of sepsis if they have at least 2 of the following clinical criteria, which together constitute a new bedside clinical score termed "quickSOFA" (qSOFA): respiratory rate of ≥22/min, altered mental status, or systolic blood pressure of ≤100 mm Hg.

Nosocomial BSI

Besides the classically known health care-associated infection BSIs, such as *Staphylococcus* spp. (156), *Enterococcus* spp., and MDRO Gram-negative infections, emerging pathogens are becoming more prevalent in health care-associated infection transmissions and outbreaks (156–168). Indeed, due to hospital-associated drug-resistant infections, the simple act of hospitalization increases risk for BSIs and sepsis. Therefore, clinicians and microbiologists must stay keenly aware of novel pathogens and their incidence among their patient populations to serve as a warning system for potential outbreaks and for device- and infusion-based contamination events.

Other

Introduction of novel monoclonal antibody therapy, such as anti-TNF for common conditions such as Crohn's disease, rheumatoid arthritis, and invasive procedures are all risk factors for development of sepsis (60, 88). Other conditions that can be successfully controlled with iatrogenic immunosuppression, such as diabetes, splenectomy, and congenital immunodeficiency, also impart higher risk (60, 88). In addition, rheumatic or congenital heart disease, surgery, cirrhosis, and chronic diseases (including diabetes, heart failure, chronic renal failure, and chronic obstructive pulmonary disease) add risk. Addictions, such as intravenous drug abuse and alcoholism, also represent risk factors for sepsis. Finally, other infections, such as septic abortion, pelvic infection, severe community-acquired pneumonia, abdominal infection, urinary tract infection, meningitis, and cellulitis will predispose patients to sepsis (60, 88).

DIAGNOSTIC APPROACHES AND INTERPRETATION

Unfortunately, despite the enormous human and financial impact of sepsis, this diagnosis remains largely a clinical one (169), due to the lack of rapid, sensitive, and specific laboratory tests to detect the causative pathogens. In order to provide a more accurate diagnosis, there is a significant need to improve the speed and diagnostic breadth of laboratory detection methods for the causative agents of bacteremia and sepsis and the immune aspects of bloodstream infections. There is a wide variety of diagnostic approaches for the identification and treatment of bacteremia and sepsis.

Radiographic Techniques: MRIs, CT Scans

It is important to determine the source of the infection to eliminate reseeding of the bloodstream from regions that are difficult to penetrate with antimicrobials or that may require drainage or removal. Source control is recommended within the first 12 h after a BSI is diagnosed (4) in order to prevent severe downstream morbidity and mortality. For this purpose, magnetic resonance imaging (MRI), routine radiographs, ultrasound, or computed tomography (CT) scans are useful.

Histopathology

Skin or end-organ biopsy for histopathological and microbiological investigation may be helpful in making early diagnosis of fungemia, particularly in disseminated *Fusarium* spp. or *Candida* spp. infections. *In situ* hybridization methods can be useful to identify pathogens in tissue specimens (170). Surgical pathology, autopsy services, and microbiology sections of the laboratory must work closely together and communicate findings with each other.

Microbiology Procedures

Blood cultures are among the most important cultures performed by the clinical microbiology laboratory (171). During the initial evaluation of an immunocompromised patient with a suspected BSI, blood should be routinely cultured for both aerobic and anaerobic bacteria, as well as for commonly encountered yeasts. If the clinician has a high suspicion of a dimorphic fungus or mycobacteria, then blood bottles specifically designed to recover these microorganisms should be obtained; molds may require additional test methods (172).

Routine blood cultures are collected as a set (one aerobic and one anaerobic bottle), in which the patient's blood (optimally 16 to 20 ml, and in some cases 30 ml) is split and inoculated into the broth medium of each

Downloaded from https://journals.asm.org/journal/spectrum on 02 June 2025 by 194.9.109.109.

bottle. The blood culture is incubated at 35°C and remains in the instrument until growth is detected, usually up to 5 days, or less if the bottle flags positive in the instrument.

Blood from the positive bottle is used to prepare a smear, and a Gram stain or other stains are performed. A variety of agar plates are then inoculated and incubated until microbial colonies can be identified and AST can be performed. The Gram stain is reviewed and resulted by a medical technologist, and this critical result is notified to the providers as soon as possible (optimally within 30 min of the blood culture flagging positive) (173). The laboratory diagnosis of bacteremia or fungemia requires urgent attention so that appropriate antimicrobial therapy can be initiated or targeted once the stain results are known (174).

Rapid detection of BSIs in the critically ill, followed by appropriate antimicrobial therapy, can have a lifesaving impact (6, 173). According to a review of more than 2,600 cases from 15 intensive care units in five U.S. and Canadian cities, the risk of death from sepsis increases by 6 to 10% with every hour that passes, from the onset of septic shock until the start of effective antimicrobial therapy (9, 175). Thus, the development of rapid, sensitive, and accurate molecular diagnostic laboratory methods to identify bacterial and fungal pathogens and characterize associated antimicrobial resistance can benefit diagnosis and therapy for septic patients and can save many lives.

While a variety of historical methods were grandfathered into laboratory protocols prior to CLIA regulations, and new methods are implemented by validating them as laboratory-defined tests, the clinical utility and accuracy of these off-label assays must be reestablished in each laboratory where the method is used. In an *ad hoc* survey conducted with members of the American Society for Microbiology's LISTSERV communities, the clinmicronet and divC in May 2009, the survey participants reported use of the following rapid methods, extrapolated from the published literature: the direct tube coagulase (176, 177), directly inoculated cefoxitin disk test with reduced zones to predict MRSA (176, 178, 179), rapid Oxoid PBP2a latex agglutination test (Thermo Fisher Scientific, Waltham, MA) (176, 180), latex agglutination for streptococci (181), direct germ tube for *Candida albicans* (182), MRSA*Select* Agar (BioRad, Hercules, CA) (183), and Pneumoslide for *S. pneumoniae* (Becton Dickinson, Cockeysville, MD) (184). All were performed directly from positive blood culture bottles. In addition, direct susceptibility testing for bacteria (185, 186) and yeast (187) has been reported.

Despite attempts to rapidly identify pathogens and their associated antimicrobial susceptibilities, these techniques are still not a common practice; patients and their physicians continue to wait for confirmatory results from blood cultures, the gold standard for diagnosis of bacterial sepsis, which can take several days before a pathogen is identified, limiting their usefulness in the management of the acutely ill patient. Moreover, blood cultures frequently remain negative even in severe cases of sepsis. For example, routine methods are relatively ineffective for detection of certain pathogens, such as *Coccidioides* spp., and some *Brucella* spp., which are examples of causes of culture-negative fungemia and bacterial endocarditis, respectively.

Clinicians should cautiously interpret the clinical relevance of recovering molds or NTM from blood cultures drawn through catheters, because of environmental contamination with mold spores or asymptomatic colonization at the site of an indwelling line. Features in the clinical history (e.g., extensive immunosuppressive therapy, prolonged fever, embolic events) may aid clinical differentiation between infection and contamination.

Semiautomated systems as well as manual blood culture systems are still available but have largely been replaced by automated continuous monitoring systems that enhance the detection of microorganisms and improve laboratory work flow (188).

Types of blood culture systems

Automated systems

There are several fully automated, continuous-monitoring broth-based blood culture systems on the market (e.g., BD Bactec FX, bioMérieux's BacT/Alert, and Trek Diagnostics VersaTrek). Aerobic and anaerobic broth formulations allow for recovery of the most common causes of BSIs. The broth contains an anticoagulant (sodium polyanethol sulfonate, SPS), an antiphagocytic agent, and an antimicrobial neutralizing agent (charcoal or resin). Using a variety of indicator systems, the bottle(s) are incubated and continuously monitored by the blood culture instrument for growth. Resin-containing media increases microorganism recovery from patients who are receiving antibiotics at the time of collection (189), and technological advancements include monitoring fill volumes.

Positive growth is detected by changes in volatiles and detected as increased CO_2 (BacT/Alert, Bactec) or by changes in pressure (VersaTrek). The bottles are monitored every 10 minutes. Blood cultures are incubated for up to 5 days (or longer for some fastidious microbes). Most, but not all, pathogen growth will trigger a positive

Downloaded from https://journals.asm.org/journal/spectrum on 02 June 2025 by 194.9.109.109.

instrument reading, which typically indicates the presence of viable microorganisms (false flagging can occur in some systems due to CO_2 metabolism of high white blood cell density in the bottles).

The most common Gram-negative microorganisms isolated are *E. coli* and *Klebsiella* spp.; common Gram-positive microorganisms include staphylococci (*S. aureus* and coagulase-negative staphylococci), streptococci, and enterococci (113, 190).

Interpretation of positive blood cultures

The two most useful parameters that aid in the interpretation of a positive blood culture result include the type of microorganism detected (191) and the number of sets of blood cultures from which a potential pathogen is recovered (192). Collection of two sets of blood cultures from peripheral blood before initiating antimicrobial therapy is the optimal approach for determining clinical relevance of recovered microorganisms. False-positive blood cultures, growing skin contamination introduced during collection, can lead to diagnostic confusion and unnecessary antibiotic use and costs. Therefore, blood cultures should be collected from two different sites, peripherally if possible, prior to the initiation of antimicrobial agents; however, the administration of antimicrobials should not be delayed, as early administration is critical for proper treatment.

False-positive blood cultures can lead to diagnostic confusion and unnecessary antibiotic use for immunocompromised as well as immunocompetent patients. As previously described, the common contaminating microorganisms (e.g., coagulase-negative staphylococci or viridans group streptococci) can be implicated in invasive disease, thus confounding the diagnosis. Conversely, positive blood cultures for yeasts must be assumed to represent disease, whereas negative results do not exclude it. Similarly, because of autolysis of *S. pneumoniae*, negative cultures do not exclude it as a cause of BSI (184, 193). Commercially available blood culture bottles, such as the Bactec Myco/F Lytic medium (Becton Dickinson, Franklin Lakes, NJ) and the BacT/Alert MB medium (bioMérieux, Durham, NC) provide fast and sensitive methods to detect mycobacteria (71).

Isolator

Although continuous-monitoring systems have emerged as the new gold standard, the Isolator system (Wampole Laboratories, Cranbury, NJ) is still optimal for isolating some fastidious microorganisms (*Brucella*, *Bartonella*, mycobacteria, filamentous fungi, *Histoplasma capsulatum*) by lysis and centrifugation (188, 194–196). After centrifugation, the resulting pellet is used to inoculate agar media. Contamination is a known problem due to multiple manual processing steps (197).

Principles of Blood Culture Collection

The importance of rigorously following guidelines for the proper collection of blood cultures such as those published by the Clinical and Laboratory Standards Institute cannot be overemphasized. At the initial evaluation for patients with signs and symptoms suggestive of bloodstream infection, an adequate blood volume must be cultured to achieve overall test sensitivity. For nonfastidious bacterial pathogens in patients with no prior history of antibacterial therapy, one set of blood cultures (i.e., 20 ml of blood) has been shown to detect a bacterial or yeast bloodstream infection in approximately 65 to 91% of cases; two or three sets of blood cultures improve the overall yield of detecting the pathogens, raising the yield to 80 to 99% and 96 to >99% of cases, respectively (198, 199). Medical urgency often dictates prompt initiation of empiric antibacterial therapy in immunocompromised hosts, but two to three sets of blood cultures should be obtained within 5 minutes of each other before initiating therapy. The optimal volume of blood for children can vary based on body weight, but similar to adults, higher volumes of blood increase the likelihood of recovering microorganisms.

There are many factors that contribute to clinically effective blood culture data, including disinfection of draw site and culture bottle tops prior to collection, disinfecting agent (iodine versus chlorhexidine), site of collection (peripheral versus line draw), timing of collection (transient versus persistent bacteremia and before antibiotic initiation), volume of collection (negative versus positive growth), and number of bottles/draws (contamination versus true bacteremia). Because blood cultures are susceptible to contamination, proper sample collection is essential in order to avoid culture misinterpretation and unnecessary antibiotic therapy. If the skin is not adequately cleansed prior to blood collection, then commensal skin microorganisms, such as coagulase-negative staphylococci, are likely to contaminate the culture. Coagulase-negative staphylococci are common causes of bacteremia and often associated with endocarditis (200); therefore, it is important to recognize when a positive blood culture is due to improper collection technique versus infection. One way to differentiate between a skin contaminant and a true pathogen is to begin by collecting two sets of blood cultures, each from different sites (e.g., right and left peripheral draws). Assuming proper collection technique, a contaminant

Downloaded from https://journals.asm.org/journal/spectrum on 02 June 2025 by 194.9.109.109.

will likely only grow in one bottle. If poor collection technique is the issue, then it is likely that more than one bottle will be positive, thus elevating the blood culture contamination rate. Data show that blood culture contamination rates decrease when draws are limited to phlebotomy staff versus nonphlebotomists (5). Likewise, if the septum of the blood culture bottle is not sufficiently decontaminated, then environmental organisms, such as *Bacillus*, can be inadvertently inoculated into the blood culture and grow, triggering a false-positive culture. Therefore, it is not only necessary to disinfect the skin prior to collection, but it is also crucial that the septa of the blood culture bottles are thoroughly disinfected prior to collection.

Aseptic technique in blood culture collection is imperative to prevent contamination from skin and other environmental microbiota. In the U.S., the positivity rate for blood cultures is approximately 10%, and many of these positive results represent contaminating skin microbiota due to inadequate skin preparation or from colonized indwelling vascular catheters (198).

Surface dirt and oils should be removed by thoroughly cleansing the skin with 70% alcohol (isopropyl or ethyl). Chlorhexidine gluconate in alcohol can then be used to disinfect the area prior to venipuncture and has become the new standard in blood culture collection. One must not contaminate the area by touching it after skin preparation (171).

Best practices and chlorhexidine skin preparation can drop the contamination rate to <1% for both phlebotomist and nursing collection rates (DM Wolk, personal communication) (201), as can use of a new skin contaminant diversion device, the SteriPath System (Magnolia Medical Technologies, Seattle, WA). One must remember that assuming a 10% positivity rate, a 3% overall contamination rate would apply to 30% of all positive cultures; therefore, successful use of new products makes a contamination rate of near 0% possible. We recommend <1% contamination as the current goal to optimize patient care and minimize needless costs.

Despite the American College of Physicians recommendation that blood cultures should be obtained through fresh venipunctures rather than indwelling intravascular devices (202), blood cultures frequently are collected from an indwelling central venous catheter in immunocompromised hosts because of restricted access to robust veins in those patients. Several studies have shown that blood cultures drawn from the indwelling catheters are less specific and have lower positive predictive value and higher rates of contamination than those obtained from a peripheral venipuncture (203, 204). The exception is a newly inserted catheter, for which investigators have shown no increase in contamination rates for these catheter-drawn blood cultures (205). The clinical significance of blood cultures collected through an indwelling catheter, particularly when only one set of blood cultures is obtained, cannot be determined reliably; therefore, true bacteremia cannot be distinguished from contaminating microbiota. For example, in a patient presenting with hypotensive shock, physicians may mistakenly infer causality from a single positive blood culture, and that may result in misuse of antibiotics and failure to investigate alternative diagnoses.

Peripheral collection

Peripheral blood is the preferred specimen for blood cultures. One set of blood cultures should be drawn from a single venipuncture, consisting of approximately 20 ml (10 ml per bottle) or such that the specimen provides a blood-to-broth ratio of 1:5 to 1:10 (171). Larger blood-to-broth ratios improve microorganism recovery (206). Additionally, microorganism recovery increases when blood cultures are collected before or during a fever spike (171). Two sets of blood cultures drawn consecutively from different anatomic sites prior to antimicrobial therapy are recommended for the diagnosis of acute sepsis (pneumonia, osteomyelitis, meningitis) (4, 171). If continuous bacteremia (endocarditis or fever of unknown origin) is suspected, then an additional set of blood cultures may improve recovery. For instances in which antimicrobial therapy was initiated, cultures should be collected when the concentration of antimicrobial agent is at its lowest.

Collection via indwelling port

Cultures drawn though an indwelling catheter are not recommended; however, if limited vein access requires the use of an indwelling catheter, then a peripheral site draw must accompany that culture in order to fully evaluate the culture results (207, 208). Comparing the time to detection, also known as time to positivity (209–218), or performing quantitative blood cultures (219, 220), may be used to diagnose catheter-related sepsis. Catheter tip cultures may also be useful in the diagnosis of a catheter-related infection when paired with blood cultures, but these have fallen from favor as a standard practice.

ANTIMICROBIAL SUSCEPTIBILITY TESTING

Laboratories utilize a combination of solid agars to promote the growth of microorganisms from positive blood cultures. There are different methods for cul-

Downloaded from https://journals.asm.org/journal/spectrum on 02 June 2025 by 194.9.109.109.

turing. A Gram stain-directed approach utilizes media-driven algorithms. For example, if Gram-negative rods are observed on Gram stain, then a MacConkey plate will be inoculated. When a clinically significant microorganism has been isolated from a patient with bacteremia, susceptibility testing should be performed according to the methods described by the Clinical and Laboratory Standards Institute.

In the 24 to 48 h when susceptibility results are not available, clinicians are encouraged to rely on their institution's antibiograms to help guide their selection of antibacterial therapy. In some cases, when there are enough isolates to substratify the data, a location-specific antibiogram for ICU and emergency department may be useful, as is a source-specific substratification of the data (DM Wolk, personal communication). Although some organisms such as viridans-group streptococci have predictable patterns and susceptibility testing may not be performed, clinicians should be aware that unusual resistance patterns can occur among immunocompromised hosts. For example, *Streptococcus mitis* and *Streptococcus salivarius*, two microorganisms considered to be very susceptible to penicillin, have been observed to have high MICs to penicillin when recovered from patients with febrile neutropenia (111). Multidrug-resistant Gram-negative bacillary infections are also becoming a serious problem in immunocompromised hosts (24). Depending on the institution's frequency of resistance owing to extended-spectrum beta-lactamases or *amp*C-mediated mechanisms, empirical therapy with a carbapenem may be warranted. For infections associated with intravascular devices, removal of the catheter often is necessary. Microorganisms can be embedded within a biofilm layer and thereby can be resistant to the activity of antibiotics (59, 221), which thwarts eradication of bloodstream infection without catheter removal (222). The presence of persistent bacteremia should raise suspicion of an endovascular source such as endocarditis or a metastatic focus (e.g., vertebral osteomyelitis or renal abscess). Endocarditis in granulocytopenic patients is unusual, because inflammatory-mediated processes and platelet deposition are critical for bacterial colonization of the endocardium. In other immunocompromised hosts, however, clinical suspicion for bacterial endocarditis should remain high. Further evaluation with transesophageal echocardiography may be required to assess presence or absence of valvular vegetations. Depending on the clinical context, investigations of other metastatic foci may warrant radiological imaging such as a CT scan or an MRI.

Susceptibility testing is appropriate for candidemia, particularly for questions of treatment failure or as supporting evidence that patients may be converted safely from intravenous to oral therapy. While awaiting testing results, susceptibility patterns can often be predicted based on the species of *Candida* isolated and the institution's specific antibiogram profiles. Fluconazole is appropriate as empiric therapy for institutions with low rates of non-albicans candidemia, except for patients with prior triazole exposure. Indications for voriconazole and echinocandins as empirical therapy are dictated by institution-specific trends for recovery of non-albicans yeast. Echinocandins are often very effective for patients with candidemia, but notable exceptions include *Candida guilliermondii*, the non-*Candida* yeast, and *Trichosporon* spp.

CLSI has developed and published approved methods for broth-dilution testing of caspofungin, fluconazole, and voriconazole (CLSI approved standard M27-A3) and for disk diffusion testing (CLSI approved guideline M44-A) of yeast. These methods are accurate and reproducible and are being used in clinical laboratories. Interpretative breakpoints are available for select *Candida* spp. with certain azoles and echinocandins, and the clinical relevance of testing any other organism–drug combination remains uncertain. A "susceptible–dose-dependent" category exists for species with elevated MICs to triazoles and denotes that higher doses may provide clinical efficacy. Susceptibility testing for filamentous fungi has been more challenging to standardize. CLSI has developed methods for MIC testing of filamentous fungi (CLSI document M38-A2), but more clinical data for correlating *in vitro* results with *in vivo* responses are needed. Generally speaking, for filamentous molds, the term "resistance" testing is informally used as a means to predict therapeutic failures.

For fungemia, all central venous catheters should be removed when feasible. All patients should undergo at least one ophthalmologic examination to exclude endophthalmitis, and patients with fungal endocarditis require immediate cardiothoracic surgical evaluation. Breakthrough or persistence of candidemia (or other fungi) on therapy suggests an infected intravascular device, profound immunosuppression, or microbiologic resistance. Duration of antifungal therapy is highly variable, depending on several factors, including the type of microorganism recovered (e.g., *C. albicans* versus *Fusarium* spp.), the degree of underlying immunosuppression, and the presence of metastatic foci.

Rapid Antibiotic Therapy Saves More Lives than Any Other Intervention

In cases of sepsis, rapid intervention with appropriate antimicrobial therapy can be critical to patient survival (223, 224). For aerobes, anaerobes, and fungi, appropriate antibiotic therapy increases survival by approximately 25 to 45%. Eliminating delays in appropriate antibiotic administration increases survival by ~7 to 10% per hour (9, 175). Optimized antibiotic care requires intravenous broad-spectrum antibiotics with daily reevaluation to optimize efficacy, prevent resistance, avoid toxicity, and minimize costs, with the ultimate goal to discontinue broad-spectrum therapy within 3 to 5 days and to continue antibiotics targeted to the causative pathogen (10).

COMMERCIALLY AVAILABLE MOLECULAR METHODS

Recent developments in molecular diagnostics allow for rapid identification of microorganisms directly from positive blood culture bottles, and some can be used on samples directly from the patient.

Peptide Nucleic Acid Fluorescence *In Situ* Hybridization

Peptide nucleic acid fluorescence *in-situ* hybridization (PNA FISH) is a technology to test blood smears made directly from positive blood culture bottles. Results are provided within 2.5 h for the direct identification of Gram-positive organisms (staphylococci and enterococci), Gram-negative organisms (*E. coli*, *K. pneumoniae*, *P. aeruginosa*) and *Candida* spp. from positive blood cultures. Probe kit utilization is driven by the Gram strain result; thus, Gram-positive cocci in clusters would utilize the *Staphylococcus* probe, yeast would utilize the *Candida* probe and Gram-positive cocci in pairs, and chains would utilize the dual *Enterococcus* probe.

PNA molecules contain the same nucleotide bases as DNA and follow standard base-pairing rules for hybridization for the following base pairs: adenine (A), thymine (T), cytosine (C), guanine (G). Differences in the PNA hybridization probes allow for stronger and more specific binding. Furthermore, PNA FISH probes target rRNA in microbial chromosomes, offering the following advantages of a small subunit rRNA (ssRNA) target: 1) sequences are known and unique between species; 2) ssRNA targets are highly abundant, multicopy targets; and 3) PNA probes, due to their small size, can bind in highly conserved regions that are not accessible to larger DNA probes. In addition, the PNA probes confer very low background, which allows the fluorescent signal to be visualized and confers greater sensitivity.

According to product inserts and clinical publications, PNA FISH performance data have demonstrated accuracy. Sensitivity and specificity are as follows: for *S. aureus*, 98.8% and 99.6%, respectively; for *C. albicans*, 99.3% and 100%; for *E. faecalis*, 96.3% and 98.3%; for other *Enterococcus* spp., 93.1% and 99.3% (225–229); for *E. coli*, 100% and 100%; for *K. pneumoniae*, 60% and 100%; for *P. aeruginosa*, 100% and 100%; and overall accuracy for *Enterobacteriaceae* is 94.3% and for non-*Enterobacteriaceae* is 100% (230). The compatibility of these probes has been proven with demonstrated accuracy for various blood culture media, including FAN and resin bottles (226, 227, 231–233).

Several studies have applied PNA FISH as an adjunct to the Gram stain from positive blood culture bottles, and it is clear that when used appropriately with a team involving laboratory, pharmacy, and physicians, PNA FISH can direct therapy, but it also reduces antibiotic and hospital costs and saves lives. Optimal outcomes for rapid intervention with PNA-FISH have been best documented when there is a strong collaborative effort between the laboratory and pharmacy. Holtzman et al. found no impact when their pharmacy was not involved (234). Others found success with physician intervention, including substantial decreases in turnaround time, mortality, and hospital expenditures (235).

The PNA FISH assay (AdvanDx, Woburn, MA) can be utilized to reduce the time required to administer targeted antibiotics therapy (153, 156, 236), to curtail unnecessary antibiotics when blood cultures are contaminated (58, 237), and to support antifungal selection for candidemia (231, 238).

GeneXpert, Xpert MRSA/SA BC Assay

The rapid detection of *Staphylococcus aureus* bacteremia and a swift determination of methicillin susceptibility have serious clinical implications affecting patient mortality. In a multicenter preclinical evaluation, Wolk et al. evaluated the performance of two Cepheid Xpert MRSA/SA assays for detection of MRSA and methicillin-susceptible *S. aureus* (MSSA) (239). Using an integrated DNA extraction process coupled to real-time PCR, MSSA and MRSA are identified directly from positive blood culture bottles in <1 h. A total of 114 wound specimens and 406 blood culture bottles were tested from study sites in the United States and Europe in order to characterize assay performance of these assays in a clinical setting. Newly positive blood culture broths with Gram's stains showing Gram-positive cocci in clusters

Downloaded from https://journals.asm.org/journal/spectrum on 02 June 2025 by 194.9.109.109.

were tested. Broths from each of the following continuous monitoring blood culture instruments were included: bioMérieux BacT/Alert SA standard aerobic, SN standard anaerobic; Bactec Peds Plus/F Medium, Plus Aerobic/F Medium, Plus Anaerobic/F Medium; Standard Anaerobic/F Medium, Standard/10 Aerobic/F Medium, Lytic/10 Anaerobic/F Culture Vials; and VersaTREK Redox 1 (aerobic), Redox 2 (anaerobic). BacT/Alert FAN aerobic and anaerobic broths were not included. The primers and probes in the Xpert MRSA/SA assays detect sequences within the staphylococcal protein A (*spa*) gene, the gene for methicillin resistance (*mecA*), and the staphylococcal cassette chromosome (SCC*mec*) inserted into the SA chromosomal *attB* insertion site (240, 241). Inclusion of both the *attB* insertion site and the *mec*A gene targets enables the assays to identify the presence of SCC*mec* cassette variants with *mec*A gene deletions, thus reducing false-positive results that occur in molecular tests that only target the SCC*mec* cassette (242, 243). For the Xpert MRSA/SA assay performed on the Cepheid GeneXpert system, sensitivity was 97.1% and 98.3% for MRSA in wound and blood culture specimens, respectively. Sensitivity was 100% for *S. aureus* from both specimen types (244).

SmartCycler, BD GeneOhm StaphSR Assay and BD Max

The BD GeneOhm StaphSR assay on the SmartCycler is used for detection of *Staphylococcus aureus* and MRSA directly from positive blood culture bottles. In a study by Stamper et al., a real-time PCR assay, the StaphSR assay (BD GeneOhm, San Diego, CA), was used for the identification of MSSA and MRSA from positive blood culture bottles (n = 300) (245). The sensitivity, specificity, and positive and negative predictive values of the BD GeneOhm StaphSR assay for MSSA detection were 98.9, 96.7, 93.6, and 99.5%, respectively, when compared to phenotypic identification with a variety of reference standards, including oxacillin and cefoxitin Etests (AB Biodisk, Solna, Sweden), penicillin-binding protein 2 (Denka Seiken Co., Tokyo, Japan), and *mecA* PCR. For the detection of MRSA, the BD GeneOhm StaphSR assay was 100% sensitive and 98.4% specific. Inhibition was seen with only one sample, and the issue was resolved upon retesting.

Recently, Grobner et al. evaluated the BD GeneOhm StaphSR assay for its use in the detection of *S. aureus* and MRSA (n = 134). Of 134 samples, five discrepant results arose with this assay due to the presence of methicillin-susceptible, revertant MRSA strains (3/45) and MRSA strains that were not detected by the BD GeneOhm StaphSR assay (2/45) (246).

BioFire Film Array

The FilmArray system (BioFire; Salt Lake City, UT) is a novel and completely integrated real-time multiplex PCR instrument that incorporates multiple singleplex PCR reactions in a disposable pouch (58, 189). New additions to their FDA-cleared menu include a blood culture identification panel for the detection of relevant bacteria and yeasts, as well as antimicrobial resistance bacterial genes. The blood culture identification panel multiplexes 27 different genetic targets. All nucleic acids are extracted and purified directly from the unprocessed sample. During the nested PCR, the FilmArray performs a single, large-volume, multiplexed reaction with primers specific to several targets. Following the multiplex PCR reaction, an individual singleplex second-stage PCR reaction further amplifies the products that amplified during the first round of multiplex PCR. The FilmArray software analyzes and interprets the endpoint melting curve of the amplicons.

GenMark eSensor

The eSensor technology (XT-8) (GenMark; Carlsbad, CA) promotes high assay specificity and sensitivity owing to competitive DNA hybridization and electrochemical detection of the post-PCR target sequence. The technology is not based on fluorescence or optical detection as are the first-generation multiplex assays; thus, the protocols do not require as many of the time-consuming washing and preparation steps required by earlier multiplexing technologies. The XT-8 systems can be used in tandem with up to 3 modules per computer for a throughput of 1 to 24 samples in random access mode.

The eSensor cartridge is preprogrammed with a specific test protocol, lot number, and expiration date on an internal memory chip. In the cartridge, the preamplified target DNA is mixed with the signal probe solution and then analyzed via electrochemical detection. The GenMark pipeline includes a multiplex panel for rapid detection of common bloodstream pathogens. New adaptation of the system toward one requiring less than 60 minutes of hands-on time will make the GenMark system more easily adaptable to routine laboratory settings, and it is expected to be a fully integrated cartridge system with sample-to-answer workflows.

Nanosphere Verigene

Nanosphere's Verigene (Northbrook, IL) system uses a gold nanoparticle probe technology, typically 13 to 20 nanometers in diameter that carries a defined number of target-specific oligonucleotides or antibodies utilized in

Downloaded from https://journals.asm.org/journal/spectrum on 02 June 2025 by 194.9.109.109.

two methodologies, array and amplification, depending on the specific assay. The nanoparticles support increased sensitivity compared to fluorophores. Light scattered from one nanoparticle is reported to be equivalent to the light emitted from one-half million fluorophores.

Automated nucleic acid purification and amplification is performed on the Verigene Processor SP. Inside the Verigene test cartridges, nucleic acid targets are hybridized to capture oligonucleotides on a microarray containing specific oligonucleotides and gold nanoparticle probes. Finally, signal amplification of probes occurs via a silver staining process, with automated qualitative analysis performed on the Verigene Reader. Products for identification of select Gram-positive and Gram-negative pathogens from positive blood cultures, which are probe-based without target amplification (2, 213), are available.

Molecular Testing for Drug Resistance

Rapid and accurate determination of microbial drug susceptibility is actually the most critical challenge; it is essential to facilitate successful antimicrobial therapy for any person, and it is particularly useful for those with immune-function impairment. Rapid testing for genetic resistance markers is an emerging clinical practice that can not only identify the potential for drug resistance, but also help distinguish ambiguous breakpoints associated with susceptibility testing. The application of molecular diagnostic methods to detect drug resistance is evolving for some laboratories. Future methods should facilitate educated choices for therapy, which can be initiated early in diagnosis to impact patient outcomes. Evidence-based studies will be key to the adoption of these new antimicrobial testing paradigms.

Targets for genetic testing require relative genetic stability of the target sequence, a requirement that demands national and international efforts for monitoring genetic mutations in these target regions. Together, MRSA and vancomycin-resistant enterococci are the two most important resistant bacterial pathogens in U.S. hospitals, and their rapid detection remains a critical necessity as antimicrobial resistance continues to increase in the U.S. and worldwide (247, 248). Among bacteria, other useful antimicrobial resistance targets include resistance genes for β-lactams, aminocylitols, aminoglycosides, chloramphenicol, fluoroquinolones, glycopeptides, isoniazide, macrolides, mupirocin, rifampin, sulfonamides, tetracylines, and trimethoprim (249–251). For a list of PCR primers used to target such resistance markers, see Tenover and Rasheed, 2004 (251). For fungi, rapid detection of antifungal resistance is useful, primarily due to the increase in fungal infections among immunocompromised patients. Current antifungal assays rely on fungal susceptibility testing, which is dependent on growth. The practical application of antifungal molecular testing is yet to be seen, as there is still much to learn about the genetic markers which mediate resistance. The genetic information needed to examine fungal resistance at the molecular level is complex; a review of molecular mechanisms of antifungal resistance has been published (252).

The full potential of molecular diagnostics for drug resistance testing in microbiology has not been reached—its application is still in its infancy. As the molecular mechanisms of antimicrobial resistance are described, newer technologies may enhance the utility of such an approach. Furthermore, microarray technology has the promise to impact the rapid and accurate detection of multiple mutations associated with resistant bacteria, mycobacteria, viruses, and fungi. Until the full potential of drug-resistant markers is understood, rapid molecular antimicrobial testing must still be combined with traditional microbial cultivation (247, 248).

DNA Sequencing

Broad-range gene PCR and sequencing from clinical material provides an alternative, culture-independent method for detecting pathogens. The promise of this technique has remained strong, especially for the bacterial domain, but its application has not been reliably reproducible, owing in large part to issues with contamination and inadequate sensitivity (253). The gene target most commonly used to detect bacteria from a blood sample is 16S ribosomal RNA (16 rRNA gene or 16S rDNA), an approximately 1500-base-pair gene that codes for a portion of the 30S ribosome. Although investigators have demonstrated the ability to detect bacteria directly from blood with 16S rRNA gene amplification and sequencing (254), it should not be performed routinely since culture remains a more sensitive diagnostic test. Also, broad-range PCR is associated with contamination, and a positive result must be correlated with clinical history. When fastidious pathogens (*Bartonella* spp. or *Coxiella burnetii*) are suspected as the cause of bacteremia, serology and species-specific PCR from blood are optimal. The advantage of this technology in immunocompromised hosts is its ability to rapidly detect and identify bacterial and fungal pathogens from whole blood samples using broad-range primers. Its primary limitation is sensitivity, and until multicenter clinical trials are performed, these assays should be used as adjunctive tools to routine blood culture.

Downloaded from https://journals.asm.org/journal/spectrum on 02 June 2025 by 194.9.109.109.

Pyrosequencing (Qiagen, Germantown, MD) is a rapid method for sequencing based on the detection of pyrophosphate released during DNA synthesis. Advantages of this technology include speed and ease of use in comparison to traditional sequencing technology; disadvantages include the short lengths of sequences that can be currently analyzed. Pyrosequencing provides short sequence information of roughly 30 to 50 bases; it is useful for short-read DNA and mutation/ single nucleotide polymorphism analysis. After PCR amplification and amplicon cleanup, run times approach 1 h for 96 samples, with approximately 30 to 45 minutes for sequence analysis applications. Jordan et al. evaluated pyrosequencing directly from blood culture bottles to assess the potential of pyrosequencing to differentiate between bacteria commonly associated with neonatal sepsis (255). An informative 15 bases within the 380-bp amplicon was targeted for pyrosequencing following enrichment culture and PCR amplification. A total of 643 bacterial isolates commonly associated with neonatal sepsis, and 15 PCR-positive, culture-positive neonatal whole blood samples were analyzed by pyrosequencing. Results of DNA sequencing and culture identification were compared and were successful at using PCR and pyrosequencing together to accurately differentiate among several bacterial groups, both Gram positive and Gram negative. The system had some difficulty with viridans-group streptococci and *S. pyogenes* (255). The same group evaluated specimens from isolates from neonatal sepsis events, to support species identification that could lead to rapid deescalation or targeting of antibiotic therapy. A total of 643 bacterial isolates and 15 PCR-positive, culture-positive neonatal whole blood samples were analyzed by pyrosequencing. Pyrosequencing was able to provide useful information on the identity of species based on the amplicon generated by PCR (255).

Proteomic Tests: SepsiTyper and VitekMS

Matrix-assisted laser desorption/ionization–time-of-flight mass spectrometry (MALDI-TOF MS) methods leverage the high sensitivity of mass spectrometry with linkage to large microbial databases to provide users with species-specific spectra that can be used to reproducibly identify microorganisms, and these methods can be used for identification of pure isolates or pathogens from positive blood culture bottles (off-label use) (256). The protein biomarkers that are measured in mass spectrometry of microorganisms are highly expressed proteins responsible for housekeeping functions, such as ribosomal components, chaperones, and transcription/translation factors (38).

Relying on identification of protein profiles, (generally measuring mass-to-charge ratios [*m/z*] between 2 and 20 kDa), MALDI-TOF MS derives its information from profiles of highly conserved bacterial proteins. For MALDI-TOF MS, the protein profiles are generated from direct ionization of an intact colony or a bacterial protein extract, after manual extraction. Identification occurs after correlating an isolate's spectral signature to a database of spectra collected from reference strains. In its current form, MALDI-TOF MS requires cultivated microbes and a small quantity of matrix (typically less than 1 μg/sample). The matrix and target spotting plates/ slides are the primary consumables and are relatively inexpensive in disposable or reusable formats. Ongoing costs include the equipment maintenance agreements. MALDI-TOF MS is widely used for its high accuracy, low consumable cost and speed of analysis. A typical process consists of growth of bacteria or yeast, colony selection and placement on a target, addition of matrix, and analysis with MALDI-TOF MS. Mass spectrometry identification has diverse possibilities as it is a fast and sensitive method to measure proteins, lipids, and other targets, and it does not require prior knowledge about the organism. For a thorough review of MALDI-TOF MS technology, we refer the reader to a recent review of the technology (257).

Commercial mass spectrometry systems exist that can integrate with traditional antimicrobial susceptibility systems. Among them, the MALDI Biotyper from Bruker Daltonics is one of the most widely tested and has proven accuracy in the identification of bacteria (135, 258). The system uses a 48-spot MALDI target plate for organism identification and can be interfaced with the BD Phoenix Epicenter software or the Siemens MicroScan instrument to link antimicrobial susceptibility results that pair with bacterial identification. A few reports show promise for the identification of microorganisms using MALDI-TOF MS without subculture from blood culture bottles (66, 160, 194, 217, 240), but the methods were limited by the need for a large number of cells. These adaptations showed successful identification for only approximately 80% of blood cultures. A promising new technology, the MALDI Sepsityper system (Bruker Daltonics), aims to identify bacteria and yeast directly from positive blood culture bottles (118, 145, 217, 259).

T2Dx, Magnetic Resonance

T2 Biosystems (Lexington, MA) offers the T2Dx instrument, a miniature magnetic resonance-based platform that measures water molecules reacting in the presence

Downloaded from https://journals.asm.org/journal/spectrum on 02 June 2025 by 194.9.109.109.

of magnetic fields. The test is the first to use direct sample EDTA whole blood for direct detection of pathogens. The T2MR technology does not require sample preparation because the signal is not disrupted by background in the sample. For target-specific testing, nanoparticles with magnetic properties that enhance the magnetic resonance signals are used. According to the manufacturer, T2Candida detects five species of *Candida* in whole blood specimens in approximately 3 h with a limit of detection as low as 1 CFU/ml (260).

Biomarkers

Studies show that cytokines can serve as biomarkers for early diagnosis of sepsis in neonates (261, 262). Additionally, cytokines appear to be associated with disease severity. Because early diagnosis is critical for targeted therapy and better outcomes, cytokines seem like promising biomarkers for sepsis. Other biomarkers, such as C-C chemokine ligand 3 (CCL3), IL-8, heat shock protein 70 kDa 1B (HSPA1B), granzyme B, and matrix metallopeptidase 8 (MMP8), may function as reliable predictors of mortality in children with septic shock (263). C-reactive protein (CRP) and amyloid A represent other biomarkers, but their specificity is relatively poor as they are nonspecific acute-phase proteins (106).

Procalcitonin

While patients with sepsis are largely identified based upon clinical criteria, there are several biomarkers of inflammation that can help differentiate patients with true bacterial sepsis from patients who suffer from other conditions for which antibiotic therapy is not required. Traditional biomarkers such as the white blood cell count, erythrocyte sedimentation rate, CRP, and other acute-phase reactants are not sufficiently sensitive nor specific to reliably confirm or refute the diagnosis of sepsis, and in the case of erythrocyte sedimentation rate, are slow to rise. In contrast, biomarkers, such as procalcitonin (PCT), are more useful for the diagnosis of severe bacterial infections and sepsis. PCT is used to help support diagnosis, to predict complications, and for therapeutic monitoring. High plasma levels of PCT are observed in situations characterized by the onset of organ dysfunction and other symptoms of "severe sepsis" or "septic shock" (264–266).

PCT is a precursor peptide of the hormone calcitonin that varies with severity of bacterial infections, where its release is induced from parenchymal cells (lung, liver, kidney, adipocytes, and muscle) (267, 268) and contributes to the deleterious effects of systemic infections. PCT rises (1 to 10 ug/liter) early in sepsis (within 3 h) and increases in concentration for up to 6 h. It remains in the bloodstream for up to 48 h but will drop quickly when BSIs are properly treated, but not with administration of steroids, as is the case for CRP.

Procalcitonin has been extensively evaluated as a marker of infection in several populations. Fernandez-Lopez et al. demonstrated improved sensitivity and specificity of PCT compared to CRP in the emergency department to differentiate bacterial from nonbacterial illnesses in febrile infants (269, 270). Van Rossum et al. reviewed a series of studies that demonstrated superior performance of PCT over CRP for both diagnostic and prognostic applications in patients with urinary tract infection and sepsis (271). In addition, PCT has demonstrated superior performance over CRP, lactate, and IL-6 in identifying bacterial sepsis in medical ICU patients (259). Kruger and colleagues demonstrated that PCT could be used as both a diagnostic and prognostic indicator for patients with community-acquired pneumonia, with improved prognostic ability over the CRP and the WBC count (272).

Clinical use of these tests requires rapid turnaround time and places the microbiology laboratory in a position either to provide 24-7 support for these assays or to share medical guidance with a STAT laboratory where testing is performed. Uptake of this test is high in Europe but less so in the U.S., where is it more commonly used for antimicrobial stewardship than diagnosis. Since there are diagnostic limitations with all biomarkers, for example in cases where only a small quantity of PCT is induced and simultaneous induction occurs due to trauma, clinical consultation for interpretation of these results is critical. Therapy may be initiated or altered based on infectious disease biomarkers, and clinical microbiology laboratories will be challenged to expand test menus to accommodate new biomarker technology.

EMERGING TECHNOLOGY

The future of clinical diagnostics is anticipated to include a variety of rapid and multiplex methods. Review of all technologies is beyond the scope of this review; however, several will be discussed, including multiplex-PCR, DNA sequencing, liquid microarrrays, and PCR-electrospray ionization mass spectrometry. It is known that blood culture bottles, positive for bacteria, do not always support cultivation of the pathogen to agar (174, 273); therefore, new molecular methods may allow microbiology laboratories to identify fastidious pathogens

Downloaded from https://journals.asm.org/journal/spectrum on 02 June 2025 by 194.9.109.109.

or those damaged by antibiotics more efficiently. More detailed information about the following techniques may be found in other reviews (274, 275).

Automated Microscopy: ID/AST

A novel combination of automated microscopy paired with electrophoresis of microbes and FISH genetic probes, the Accelerate instrument (Accelerate Diagnostics, Tucson, AZ) utilizes both genomic and phenotypic detection technologies to significantly decrease time to result while sustaining high sensitivity and specificity. This process will occur on a circular cartridge. In a recent report, susceptibility of *S. aureus* was characterized by assessing immobilized live bacterial cells and differentiating them as susceptible or nonsusceptible using as few as 10 growing clones after 4 h of growth, compared to overnight growth required for traditional culture-based methods (193). In this report, 77/77 MRSA phenotypes and 54/54 MSSA phenotypes were correctly identified. In addition, 53/56 clindamycin-resistant and 75/75 clindamycin-susceptible strains were detected, and heterogeneous and inducible resistance was characterized (193).

PCR Mass Spectrometry, Genetic Profiling Directly from Blood Culture Bottles

PCR/electrospray ionization mass spectrometry from Abbott/Ibis has recently been adapted and developed for rapid identification, strain typing, and antibiotic-resistance assessment (276–278), including *S. aureus* genetic targets (239, 279). In a recent publication, Baldwin et al. provided evidence for the technology's ability to identify a broad range of pathogens, such as those that may be encountered in blood cultures (278). With accuracy listed as 91% for the genus level, there is room for improvement; however, the approach shows promise as a rapid method for identification of pathogens.

In this approach, broad-range primers are used to amplify PCR products from groupings of microbes, rather than primers targeted to a single target or species. Electrospray ionization time-of-flight mass spectrometry is used to determine the nucleic base composition (the numbers of A, C, G, and T) of the PCR amplicon, and this base composition signature is used to identify the pathogens present. Unlike nucleic acid probe assays or microarrays, mass spectrometry does not require prior knowledge of the products analyzed; rather, it simply measures the masses of the nucleic acids present in the sample. The platform is significantly different from previous technologies in its ability to detect virtually all microbes from a family and even microbes that have mutated significantly. This technology has the potential for identification of all known human microbial pathogens in 4 to 6 h from blood or sterile body fluids (280, 281). The newest version of this technology, the IRIDICA BAC BSI assay, is currently in FDA clinical trials.

Molzyme SepsiTest

Another PCR method is based on the detection of conserved sequences in whole blood for rapid diagnosis of bacteremia and fungemia. The SepsiTest is not commercially available in the United States. The test uses a universal PCR from the 16S and 18S rRNA genes, with subsequent identification of bacteria and fungi, respectively, from positive samples by sequence analysis of amplicons. The SepsiTest was evaluated in a prospective, multicenter study of 342 blood samples from 187 patients with systemic inflammatory response syndrome, sepsis, or neutropenic fever. Compared to blood culture, the diagnostic sensitivity and specificity of the PCR were 87.0 and 85.8%, respectively, achieving results with improved accuracy over the SeptiFast, and yielding results in a few hours. The concordance of PCR and blood culture for both positive and negative samples was 86.0% despite the indispensability of blood culture diagnostics (282, 283). In another study employing 20 patients with infective endocarditis and 10 patients without infective endocarditis, heart valves and preoperative blood samples were analyzed by blood culture and SepsiTest. The diagnostic sensitivity of the molecular test was 85% and that of blood culture was only 45%, remaining negative in many cases as a result of antibiotic treatment. Also, etiological agents were identified by SepsiTest in 5/10 patients without infective endocarditis, whereas blood cultures were negative (284).

Immunexpress

Immunexpress (Seattle, WA) has developed a multiplex, quantitative real-time PCR and RT-PCR combination (RT1qPCR) in a ready-to-use kit, now in clinical trials in the United States. Their SeptiCyte test was developed to be utilized in the microbiology laboratory using whole blood collected from patients soon after ICU admission. The test analyzes gene expression using RNA extracted from whole blood of patients suspected of having sepsis. The test determines the level of expression of four genes, resulting in an expression profile reflecting several key biological pathways linked to the host response to infection. These genes have been identified from a panel of previously discovered biomarkers identified in gene expression array and RT1qPCR studies. This test, with

Downloaded from https://journals.asm.org/journal/spectrum on 02 June 2025 by 194.9.109.109.

other laboratory findings and clinical information, is intended to aid in the detection and clinical assessment of systemic inflammation due to infection (sepsis) in critical-care patients. The SeptiCyte Lab signature and associated score was validated in a Netherlands-based clinical study, in which sepsis and infection-negative systemic inflammation cohorts were separated with a negative predictive value of 95.5% and positive predictive value of 74.7% (285).

Q-linea

Q-linea's (Uppsala, Sweden) fully automated, ASTrID instrument provides microbial identification of fungi and Gram-negative and Gram-positive bacteria together with resistance marker mapping within one working day. The technology is based on highly specific padlock probes and circle-to-circle isothermal nucleic acid amplification technology. The ASTrID platform is currently under development, with the goal to start CE-IVD validation in 2018 followed by FDA certification shortly thereafter.

SUMMARY

Bacteremia and sepsis are critically important syndromes with high mortality and associated costs. BSIs and sepsis are among the top causes of mortality in the United States, killing over 600 people per day. Many septic patients are treated in emergency medicine departments or critical care units, settings in which rapid administration of targeted antibiotic therapy drastically reduces mortality. Unfortunately, routine blood cultures are too slow to support rapid therapeutic interventions. As a result, empiric, broad-spectrum treatment is common—a costly approach that may fail to effectively target the correct microbe, may inadvertently harm patients via antimicrobial toxicity, and may contribute to the evolution of drug-resistant microbes. To meet these diagnostic challenges, laboratories must understand the complexity of diagnosing and treating septic patients, in order to focus on creating algorithms that help direct targeted antibiotic therapy and synergize with existing emergency medicine department and critical care unit clinical practices put forth in Surviving Sepsis Guidelines. Immunocompromised hosts are particularly impacted by BSIs and sepsis, and there are numerous conditions that compromise patients and increase their risk and decrease their potential for survival.

Several methods for rapid molecular identification of pathogens from blood culture bottles are available. Labs can integrate with overall care to support local Surviving Sepsis campaigns by providing rapid testing to facilitate targeted therapeutic interventions for infections with common pathogens. As a result, empiric, broad-spectrum antibiotic therapy can be shortened to improve survival, reduce health care costs, and decrease antibiotic resistance. More evidence and clinical utility studies are needed to justify the added expense of molecular methods and to determine an appropriate niche in patient populations for which the cost–benefit would be favorable. The PNA FISH methods show much promise for clinical utility and cost-effectiveness; however, the accuracy and cost–benefit of multiplex PCR remains to be fully evaluated. Pyrosequencing and PCR/ESI-MS have proven accuracy and await practical adoption to routine microbiology laboratories. MALDI-TOF MS shows real promise and is currently being adapted to rapid identification of pathogen isolates and potentially for direct detection from positive blood culture bottles.

Molecular diagnostic assays for detection of single pathogens from blood culture bottles have already been shown to have an impact by reducing mortality and decreasing costs. In the future, tests for multiple pathogens that could characterize Gram-positive, Gram-negative, and fungal infections would enable more rapid and targeted antimicrobial interventions for those with severe disease. Targeted drug-resistance gene testing of blood culture bottles will enable risk assessment and guide treatment options for sepsis. Ultimately, early intervention by molecular detection of bacteria and fungi directly from whole blood would provide the most benefit to patients and would contribute to tailored antibiotic coverage of the patient early in the course of the disease, allowing for more effective treatment and better outcomes for patients with sepsis and septic shock.

Over a century has passed since the introduction of blood cultures for the diagnosis of bloodstream infections. Significant advances have been made in improving blood culture media; as yet, no molecular or antigen-based method has proven superior for the detection of bacteremia. Our ability to make a rapid and reliable diagnosis of fungemia, however, remains elusive. Laboratorians can continue to optimize the use of blood cultures for the diagnosis of BSIs and to encourage their clinicians to obtain at least two sets of blood cultures by separate venipuncture before starting antimicrobial therapy. When blood cultures are obtained through indwelling lines or from a single venipuncture, positive blood culture results can be misleading and can result in diagnostic confusion and injudicious use of antimicrobial therapy. Although blood cultures remain the best means of diagnosing bacteremia and candidemia,

Downloaded from https://journals.asm.org/journal/spectrum on 02 June 2025 by 194.9.109.109.

complementary testing with antigen tests, microbiologic investigations from other body sites, and histopathology can often aid in the diagnosis of disseminated disease.

Abstract

Rationale: Cystic fibrosis (CF) is characterized by early structural lung disease caused by pulmonary infections. The nasopharynx of infants is a major ecological reservoir of potential respiratory pathogens.

Objectives: To investigate the development of nasopharyngeal microbiota profiles in infants with CF compared with those of healthy control subjects during the first 6 months of life.

Methods: We conducted a prospective cohort study, from the time of diagnosis onward, in which we collected questionnaires and 324 nasopharynx samples from 20 infants with CF and 45 age-matched healthy control subjects. Microbiota profiles were characterized by 16S ribosomal RNA–based sequencing.

Measurements and Main Results: We observed significant differences in microbial community composition ($P < 0.0002$ by permutational multivariate analysis of variance) and development between groups. In infants with CF, early *Staphylococcus aureus* and, to a lesser extent, *Corynebacterium* spp. and *Moraxella* spp. dominance were followed by a switch to *Streptococcus mitis* predominance after 3 months of age. In control subjects, *Moraxella* spp. enrichment occurred throughout the first 6 months of life. In a multivariate analysis, *S. aureus*, *S. mitis*, *Corynebacterium accolens*, and bacilli were significantly more abundant in infants with CF, whereas *Moraxella* spp., *Corynebacterium pseudodiphtericum* and *Corynebacterium propinquum* and *Haemophilus influenzae* were significantly more abundant in control subjects, after correction for age, antibiotic use, and respiratory symptoms. Antibiotic use was independently associated with increased colonization of gram-negative bacteria such as *Burkholderia* spp. and members of the Enterobacteriaceae bacteria family and reduced colonization of potential beneficial commensals.

Conclusions: From diagnosis onward, we observed distinct patterns of nasopharyngeal microbiota development in infants with CF under 6 months of age compared with control subjects and a marked effect of antibiotic therapy leading toward a gram-negative microbial composition.

At a Glance Commentary

Scientific Knowledge on the Subject: Cystic fibrosis (CF) is characterized by early structural lung disease caused by low-grade asymptomatic pulmonary infections. Potential pathogens such as *Haemophilus influenzae*, *Staphylococcus aureus*, and *Pseudomonas aeruginosa* are most frequently cultured. In the lungs of adults with CF, community complexity and composition are correlated with CF genotype and phenotype, age, and antibiotic exposure. Little is known yet about the moment of onset of these changes in childhood.

What This Study Adds to the Field: This study shows for the first time that, starting directly from diagnosis, nasopharyngeal microbial colonization development profiles, including the commensal flora, are different in infants with CF than in control subjects. Additionally, the first antibiotic courses and prophylaxis early in life significantly alter the respiratory microbiota, with a significant reduction in potential beneficial commensals and an increase in potentially pathogenic gram-negative bacteria.

A substantial proportion of children with cystic fibrosis (CF) have pulmonary disease, which manifests starting from early in life as tissue inflammation and radiological evidence of structural lung damage, even before clinical symptoms occur (1–3). Bacterial and viral infections have been thought to drive these processes. Therefore, there has been growing interest in studying the microbial community composition of the respiratory tract in infants with CF from early in life. A multimodality approach including symptom monitoring, lung function measurements, imaging techniques, and microbial surveillance is recommended to obtain more information regarding the early pathophysiology of CF lung disease (4, 5). Interventions to alter the course of CF disease in infancy (6) include antistaphylococcal prophylaxis (7), which may be prescribed to prevent *Staphylococcus aureus* colonization from birth onward in asymptomatic infants with CF. Longer-term clinical outcomes are not clear, and currently this preventive therapy is commonly used only in the United Kingdom (7–9). The policy in the Netherlands, as well as in most other countries nowadays, is to consider antibiotic prophylaxis only in infants with CF with symptomatic airway disease.

Most of the scarce knowledge on the etiology of pulmonary infections in infants with CF is based on conventional culture. Culture-independent sequencing techniques offer an opportunity to profile whole respiratory microbial communities and to evaluate early microbial side effects of (chronic) use of antibiotic prophylaxis in infants (10, 11). Because infants are incapable of producing an expectorated sputum specimen, and because bronchoalveolar lavage is performed only when there is a compelling clinical reason, upper respiratory tract (URT) cultures are used as a surrogate for bacterial colonization and infection of the lung (12, 13). Evidence of the dynamics of URT colonization in infants with CF during the first months of life may help to improve understanding of the pathophysiology of respiratory infections and to determine ecological targets for future intervention trials. Some of the results of this study have been reported previously in the form of an abstract and poster presentation (14).

Methods

Study Population and Design

We conducted a prospective, two-center cohort study in which we enrolled 20 infants born between 2011 and 2013 who were diagnosed with CF on the basis of newborn screening and/or symptoms. The first 15 infants with CF were individually matched to 45 healthy control subjects by date of birth (range, ±6 wk) and sex (ratio, 1:3). Study population and design information can be found in the online supplement. For the purposes of the present study, we collected nasopharyngeal samples during (home) visits at ages 1, 2, 3, 4, 5, and 6 months and during acute respiratory illnesses (aRIs) from both infants with CF and control subjects. Questionnaires on respiratory symptoms, day care attendance, antibiotic use, and other environmental factors were obtained at all sampling moments.

Ethics Statement

The study (NL10/337) was approved by the pediatric medical ethics committees of the University Medical Center Utrecht and the Erasmus University Medical Center. It was carried out in accordance with European statements on Good Clinical Practice, which include the provisions of the Declaration of Helsinki.

Sampling and Storage Methods

Deep transnasal nasopharyngeal swabs were taken by trained study personnel with an eSwab 484CE nylon flocked flexible sterile swab (Copan Diagnostics, Brescia, Italy) according to standard procedure recommended by the World Health Organization (15). After sampling, swabs of patients and control subjects were immediately inoculated in 1 ml of Amies transport medium and stored within 24 hours at −80°C until analyses.

Viral and Bacterial Detection

aRI samples were tested using real-time polymerase chain reactions (PCRs) (RespiFinder SMART 22 FAST; PathoFinder, Maastricht, the Netherlands) specific for human bocavirus; respiratory syncytial virus types A and B; human influenza virus types A and B; parainfluenza virus; human rhinoviruses, adenoviruses, and bocaviruses; human coronaviruses OC43, NL63, HKU1, and 229E; and human metapneumovirus and enteroviruses (16). Culture and bacterial identification were performed according to standard procedures (12, 17, 18).

Metagenomic Analysis

Bacterial DNA isolation and quantification. DNA was isolated from a 200-μl aliquot of each sample and quantified by quantitative PCR (qPCR) specific for a conserved region of the 16S ribosomal RNA (rRNA) gene as previously described (19, 20). To avoid interference from background DNA, only samples with sufficient overall bacterial loads (i.e., samples with DNA levels ⩾0.3 pg/μl above background) were selected for further sequencing.

Amplicon library preparation. A PCR amplicon library was generated by

A53210128

amplification of the V5–V7 hypervariable region of the 16S rRNA gene as previously described (21), using a 454 GS FLX Titanium sequencer (454 Life Sciences, Hong Kong, China).

Data processing. The raw sequences obtained were processed using QIIME version 1.8 software (22). Barcodes and primers were trimmed off; chimeric sequences were identified and removed using the chimeraslayer utility; and sequences were checked for their quality. Sequences were clustered into operational taxonomic units (OTUs) using the uclust tool at 97% similarity. Aligned sequences were taxonomically annotated using the greengenes 16S rRNA database (version 13.8). In the figures and tables in this article, the numbers associated with the OTU names represent the hierarchical number of the OTU within its genus based on average relative abundance among all samples (e.g., *Corynebacterium* [6] is the sixth most dominant *Corynebacterium* observed). For each sample, α-diversity was determined by calculating diversity indexes (species richness, Shannon diversity, Chao1, and Simpson indexes) at a rarefaction depth of 1,400 sequences per sample (11). The different *Corynebacterium* OTUs were confirmed at the species level by blasting against the National Center for Biotechnology Information GenBank database. Annotation of the most abundant *Streptococcus* OTUs to species level was performed by *LytA* qPCR (23), culture (24), and matrix-assisted laser desorption ionization time-of-flight mass spectrometry (25), consecutively.

Statistical Analysis

Data analyses were performed in either IBM SPSS version 21 (IBM, Armonk, NY) or R version 3.1 software. To assess the statistical significance of differences (in baseline characteristics) between groups, we used either Student's *t* test or the Mann–Whitney *U* (MW) test for continuous data and the χ^2 test for categorical data. The statistical significance of differences in microbial composition between groups was calculated using significance analysis of microarrays in TIGR Multiexperiment Viewer (26). We used a linear multivariate regression model (multivariate analysis [MVA]) to study the independent associations between CF disease (model 1), antibiotic use (model 2), and the $\log_{10} + 1 \times 10^7$–transformed

A53210128

relative abundance of microbiota, corrected for other variables, including potential confounders. We used the Benjamini–Hochberg procedure to correct for multiple testing, and a q value less than or equal to 0.05 was considered statistically significant. We calculated the relative effect sizes of significant associations using the standardized regression coefficients of the multivariate model to indicate the magnitude of differences between groups (21). Nonmetric multidimensional scaling plots based on Bray–Curtis dissimilarity were used to visualize differences between groups, and the statistical significance of these differences in overall microbial community composition was calculated using permutational multivariate analysis of variance (PERMANOVA) (27). PERMANOVA is a nonparametric permutational test used to partition the variance of the Bray–Curtis dissimilarity matrix among independent variables. Hierarchical clustering using average linkage and Bray–Curtis dissimilarity was visualized using the iTol tool (28), and the optimal number of clusters was estimated using the average silhouette width and Calinski–Harabasz index (fpc R package). We created an alluvial diagram in R (package alluvial) to illustrate colonization dynamics during the first half-year of life. Using the Bray–Curtis dissimilarity, we calculated changes in microbial composition over time per time frame (e.g., month 1 to month 2, month 2 to month 3) for each individual, followed by calculation of differences in the average changes over time between groups (CF vs. control subjects; MW test). To study significant nonrandom copresence or mutual exclusion of bacterial OTUs, a network was inferred using the CoNet Cytoscape plugin (29) and the Markov clustering algorithm in the clusterMaker Cytoscape plugin and analyzed using the NetworkAnalyzer Cytoscape plugin.

Results

Study Population

We obtained 324 nasopharyngeal samples from 20 infants with CF and 45 healthy control subjects aged 1 to 6 months. Seventy percent of all infants were included in the first month of life, 15% in the second month of life, and the rest shortly thereafter. During follow-up, only five samples were missed. A total of 313 (92 CF samples and 221 control samples) of 324 nasopharyngeal samples (97%) contained sufficient amounts of DNA to be analyzed by 16S rRNA-based sequencing. The mean numbers of analyzed samples per individual were 4.6 ± 1.6 and 4.9 ± 1.6 for infants with CF and control subjects, respectively. The baseline characteristics of the study subjects are described in Table 1.

Infants with CF and control subjects differed in prior antibiotic use. Compared with control subjects, infants with CF had lower day care attendance rates and fewer siblings. Also, fewer of them were exclusively breastfed, and they had a higher frequency of antibiotic treatment. The patterns of height and weight gain over time were comparable between infants with CF and control subjects. During aRIs, although in

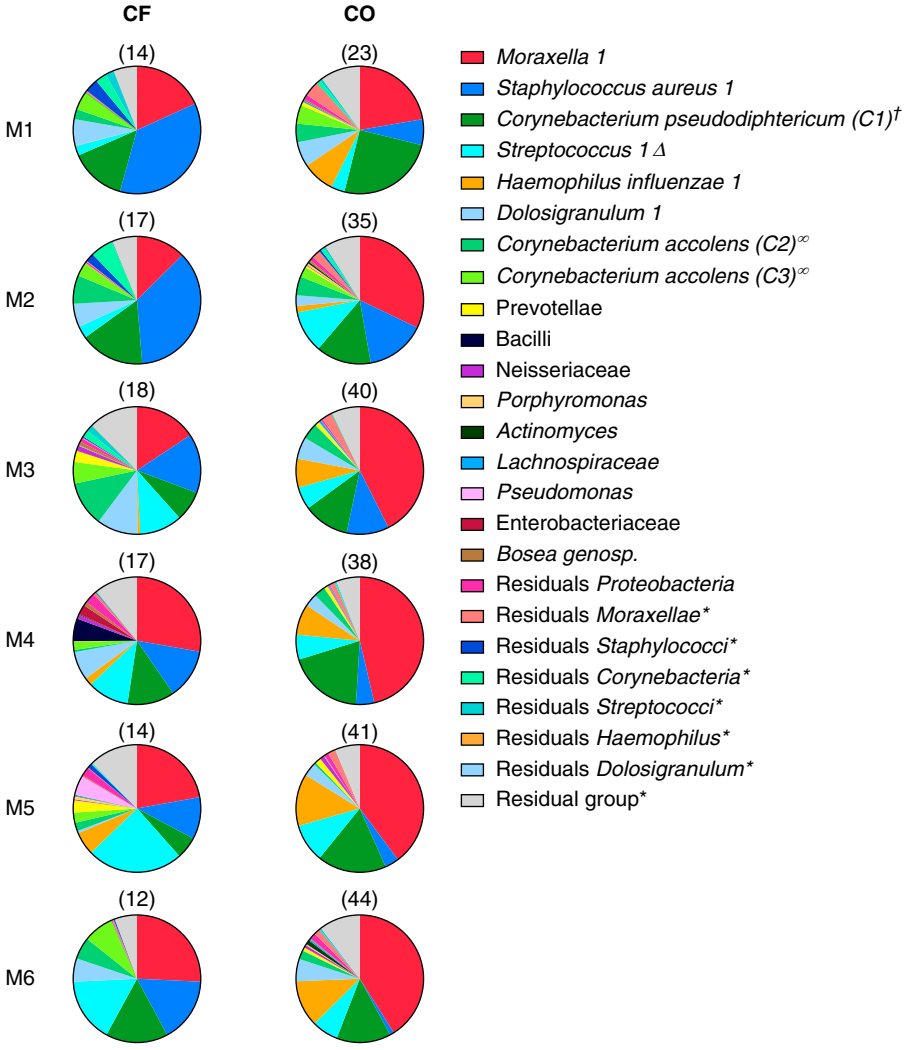

Figure 1. Overall development of microbial community composition over time in infants with cystic fibrosis (CF) and control subjects (CO). The first and second columns of the pie charts show the development of overall microbial community composition (top 35 operational taxonomic units [OTUs]) per month over the first 6 months (M) of life in infants with CF and healthy control subjects, respectively. The total number of samples per month is depicted above the respective pie charts. For ease of visualization, the OTUs of the top 35 belonging to the same genus were merged. †100% homology to *Corynebacterium pseudodiphtericum* and *Corynebacterium propinquum* after blasting. A53210128

both groups the aRIs were mostly diagnosed as upper respiratory infections, coughing ($P = 0.06$) and dyspnea ($P < 0.001$) were observed more often in infants with CF than in control subjects. As part of clinical practice, antibiotic prophylaxis was initiated by the treating physician in 14 (70%) of 20 infants with CF within the first 6 months of life, and this was preceded by one or more short courses of antimicrobial treatment in 6 (43%) of these 14 infants. Five short-course therapies were prescribed for in a total of five control subjects (11%).

Bacterial Density and Diversity

Sequence results, sequence depth, and phylum-level microbial composition of infants with CF and control subjects are described in the RESULTS section of the online supplement. The bacterial density was lower in samples obtained from infants with CF than those from control subjects (median, 62 vs. 197 pg/μl; $P = 0.025$). This was especially true for infants with CF who were 4 months of age and older and was related to antibiotic use (median bacterial density, 27 pg/μl in infants with CF treated with antibiotics vs. 353 pg/μl in those not treated with antibiotics; $P = 0.033$). We observed a trend toward increased density during aRIs (median, 162 vs. 136 pg/μl; $P = 0.08$). With regard to ecological diversity, no major differences in species diversity were observed between infants with CF and control subjects (Figure E1 in the online supplement). We observed no age-related changes in diversity for either group within the first 6 months of life (data not shown).

Microbial Community Composition in Infants with CF Compared with Healthy Control Subjects

Using nonmetric multidimensional scaling based on the Bray–Curtis dissimilarity matrix, we observed significant differences in microbiota composition between infants with CF and healthy control subjects ($R^2 = 0.054$, $P < 0.0002$ by PERMANOVA) (Figure E2). These differences were already explicitly present in the first months of life (i.e., for ages 1–3 mo; $R^2 = 0.052$, $P = 0.0004$).

Average microbiota differences between infants with CF and control subjects aged 1–6 months were determined using univariate analyses (significance analysis of microarrays) and characterized by higher relative abundance of several *S. aureus* OTUs and other staphylococcal species, several *Corynebacterum* spp. (mainly resembling *Corynebacterum accolens* based on BLASTN search), and *Streptococcus*, bacilli, *Acinetobacter*, Enterobacteriaceae, and *Pseudomonas* spp. in infants with CF. Contrarily, we observed a higher abundance of several *Moraxella* and several *Corynebacteria* spp. (mainly resembling *Corynebacterum pseudodiphtericum* and *Corynebacterum propinquum* based on BLASTN search), *Dolosigranulum*, *Haemophilus influenzae*, *Helcococcus*, Pasteurellaceae, and *Prevotella* spp. in control subjects. A subanalysis of samples taken from individuals during the first 3 months of life revealed a significant association already occurring between several staphylococcal OTUs, *Streptococcus*, bacilli, and *Veillonella* spp. in infants with CF, whereas several *Moraxella* spp. and *H. influenzae* were associated with control subjects. Even at this young age, *Corynebacteria* OTUs present in infants with CF were different from those in control subjects.

Microbial community development over the first 6 months of life in infants with CF was markedly different from that in control subjects (Figure 1). Whereas the nasopharyngeal microbiome in infants with CF is initially dominated by *S. aureus* and gradually replaced by *C. pseudodiphtericum* and/or *C. propinquum* and *C. accolens*, a switch to *Streptococcus* spp. and *Moraxella* spp. domination occurs after 3 months of age. In control subjects, however, *Moraxell*a spp., *C. pseudodiphtericum* and/or *C. propinquum* and *H. influenzae* are the most common microbiota members from age 1 month onward, remaining

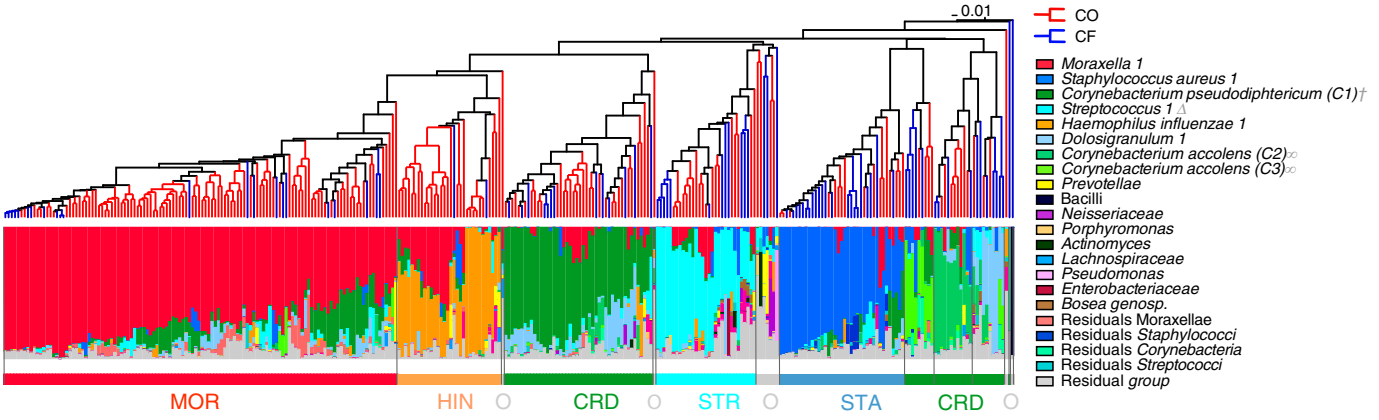

Figure 2. Clustering analysis based on Bray–Curtis dissimilarity and average linkage in infants with cystic fibrosis (CF) and healthy control subjects (CO). Average linkage hierarchical clustering based on the Bray–Curtis dissimilarity matrix is shown in a dendrogram including all 92 and 221 samples of 20 infants with CF and 45 healthy control subjects, respectively. CF samples are depicted with *blue branches* and healthy control subjects with *red branches*. Stacked bar charts show the relative abundance of the top 35 operational taxonomic units. For ease of visualization, the operational taxonomic units of the top 35 belonging to the same genus were merged. Adjacent to the dendrogram branch ends, the *colored line* depicts the clustering of the samples (clusters separated by *gray dotted lines*). Eight clusters comprising four or more samples covered, in total, 91% of all samples. †100% homology to *Corynebacterium pseudodiphtericum* and *Corynebacterium propinquum* after blasting. Δ*Streptococcus mitis* in CF and *Streptococcus pneumoniae* in control subjects by quantitative polymerase chain reaction, matrix-assisted laser desorption ionization time-of-flight mass spectrometry, and culture. ∞99% and 98% homology with *Corynebacterium accolens* after blasting. CRD = *Corynebacterium* and *Dolosigranulum*; HIN = *Haemophilus influenzae*; MOR = *Moraxella*; O = other; STA = *Staphylococcus aureus*; STR = *Streptococcus*.

predominant throughout the first 6 months of life. Because *Streptococcus* spp. cannot be annotated up to species level by 16S rRNA-based sequencing, we tested the Spearman correlation between the abundance of *Streptococcus* 1 OTU with qPCR cycle threshold values for the *Streptococcus pneumoniae*–specific gene *LytA*. We observed a positive correlation for control subjects ($\rho = 0.46$, $P < 0.001$) but not for infants with CF ($\rho = -0.09$; nonsignificant). Culturing of the streptococci, followed by matrix-assisted laser desorption ionization time-of-flight mass spectrometry and optochin testing, confirmed the high *Streptococcus* abundance detected by 16S rRNA-based sequencing to be mostly *S. pneumoniae* in control infants versus exclusively *Streptococcus mitis* in infants with CF. For the other potential respiratory pathogens, the relative abundance of most abundant *Moraxella*, *S. aureus*, and *H. influenzae* OTUs did correlate significantly to corresponding culture data in both infants with CF and control subjects ($P < 0.003$ by MW test).

Individual Microbiota Profiles of Infants with CF and Control Subjects

Clustering of microbial profiles showed eight distinct clusters or profiles containing more than four samples per cluster in total, representing 91% (301 of 331) of all samples (Figure 2). The largest cluster (n = 39), which was characterized by a high mean relative abundance of *S. aureus* (relative abundance, 75% vs. 2% in the remaining clusters), was associated with CF: 24% (22 of 92) of all CF samples and 8% (17 of 221) of control samples belonged to this cluster ($P < 0.001$ by χ^2 test). Two large clusters were strongly associated with control subjects. The first cluster (n = 32) was characterized by dominance of *H. influenzae* (relative abundance, 56% vs. 1% in the remaining clusters) and contained 2% (2 of 92) of all CF samples and 14% (30 of 221) of all control samples ($P = 0.002$). The second cluster (n = 122) was typified by predominance of *Moraxella* (relative abundance, 80% vs. 1% in the remaining clusters) and contained 24% (22 of 92) of CF and 45% (100 of 221) of all control samples ($P < 0.001$). The five remaining clusters, characterized by a high abundance of *C. pseudodiphtericum* and/or *C. propinquum*, *C. accolens*, *Dolosigranulum*, or *Streptococcus*, respectively, were not clearly enriched for either infants with CF or control subjects ($P \geq 0.05$ by χ^2 test).

The dynamics of microbiota development of the individual children over time are shown in Figure 3. In control subjects (Figure 3B), the majority of children started off with a *Corynebacterium*- and/or *Dolosigranulum*-dominated profile (any of the C or D clusters shown in Figure 2) or a *Moraxella*-dominated profile, and a smaller number started off with a *S. aureus*–dominated profile. Over time, the children with a *Moraxella*- and *Corynebacterium*- and/or *Dolosigranulum*-dominated profile remained fairly stable, whereas children with a *S. aureus*–dominated profile quickly developed a *Moraxella*-dominated profile and the *H. influenzae*–dominated profile started to emerge slowly. Children starting with or passing through a *Streptococcus*- or *H. influenzae*–dominated profile rarely kept this profile for longer than 1–2 months.

Of the infants with CF (Figure 3A), the majority started with a *S. aureus*–dominated profile and, to a lesser extent, with a *Corynebacterium*- and/or *Dolosigranulum*- or *Moraxella*-dominated profile. The majority of children in the *S. aureus*–dominated profile developed eventually toward a *Corynebacterium*- and/or *Dolosigranulum*-dominated profile. The children with a *Moraxella*-dominated profile remained fairly stable. Interestingly, compared with control subjects, significantly more infants with CF changed

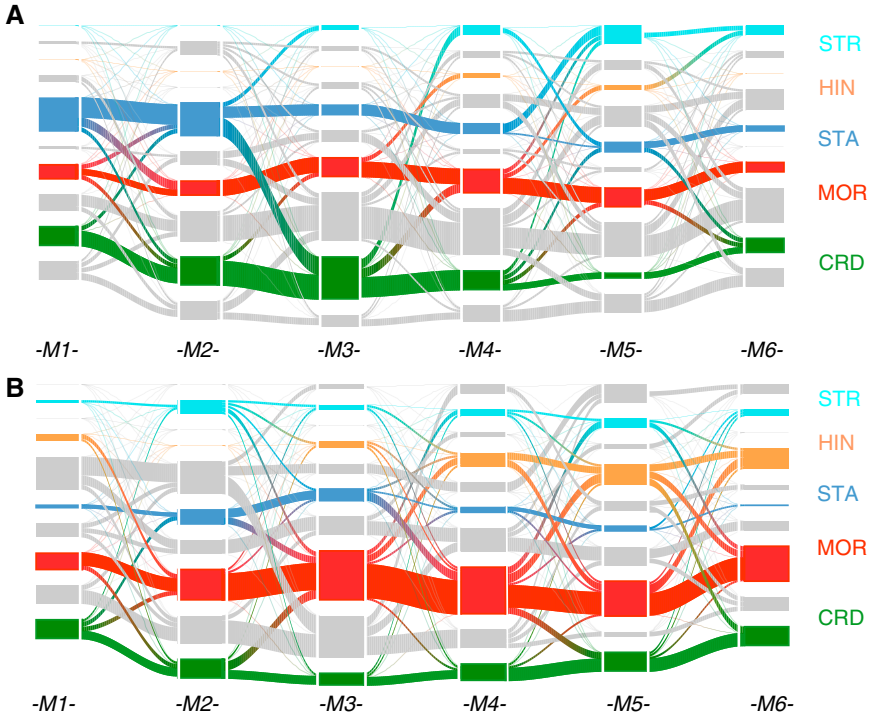

Figure 3. Microbiota colonization patterns over time. This alluvial diagram shows the development of nasopharyngeal microbiota of the individual infants over time. Movements within the eight largest clusters are depicted. Clusters are colored according to the predominant bacterial genus or genera in these clusters. For easier comparison, the diagram is presented in duplicate and colored according to the movement of (*A*) infants with cystic fibrosis (CF) and (*B*) control subjects. To simplify the diagram, we merged the four clusters dominated by *Corynebacterium* 1, 2, and 3 and *Dolosigranulum* into one cluster (*green*). *Lines* between clusters resemble individuals and the development of their microbiota between time points. Only infants with at least three consecutive samples available for analysis are included in this graph (CF, n = 18; control subjects, n = 39). Each infant with CF was given a weight of 2 to more appropriately visualize the relative attribution of colonization patterns of these infants over time. The total number of samples entering and leaving a profile can be dissimilar, owing to (*1*) study inclusion at a different age, (*2*) exclusion of samples from analysis because of low DNA yield, and/or (*3*) visualization of only the eight largest clusters. CRD = *Corynebacterium* and *Dolosigranulum*; HIN = *Haemophilus influenzae*; M = age in months; MOR = *Moraxella*; STA = *Staphylococcus aureus*; STR = *Streptococcus*.

A53210128

microbiota profiles between 4 and 5 months of age ($P < 0.023$ by MW test), resulting in an increase in children with a *Streptococcus*-dominated profile. This sudden shift in microbiota composition was preceded by a steep increase in antibiotic consumption in these children (Figure E3).

Impact of Respiratory Illness, Antibiotic Use, and Breastfeeding on Microbial Community Structure

First, because 70% of infants with CF eventually received antibiotic prophylaxis (mainly trimethoprim-sulfamethoxazole; mean starting point, approximately 4–5 months of age), which was preceded in 30% by a course of therapy (mostly amoxicillin with or without clavulanic acid) for respiratory symptoms, we studied the association between CF and microbiota composition, correcting for antibiotic use, respiratory symptoms, and age, in MVA. The bacteria that remained independently associated with CF are depicted in Figure 4 and Table E1. *Pseudomonas* was positively associated with CF, but with only borderline significane after Benjamini–Hochberg adjustment ($q = 0.057$). However, the difference in *Corynebacterium* spp. colonization between infants with CF and control subjects remained highly significant following MVA.

Second, MVA showed no differences in microbiota community structure between samples collected during aRIs (n = 11 obtained from 9 infants with CF; n = 30 obtained from 21 control subjects) and during regular visits. In addition, clinically symptomatic aRIs were not preceded by shifts in microbiota profiles within individuals (Figure E4). However, respiratory viruses were commonly detected in 78% (7 of 9) and 92% (22 of 24) of aRIs in infants with CF and control subjects, respectively. Human rhino- and coronaviruses were most commonly detected in both groups. Other viruses detected were parainfluenza virus in infants with CF and bocavirus, adenovirus, and respiratory syncytial virus in the healthy control subjects (Table E2). Multiple viruses were detected more frequently in samples of control subjects (46%) than those of infants with CF (11%).

Third, antibiotic treatment and prophylaxis in both groups were independently related to a reduction in Moraxellaceae, *Corynebacterium*, and *Dolosigranulum*, and to an increase in gram-negative bacteria, including Comamonadaceae, *Burkholderia*, and Bradyrhizobiaceae and a trend toward increased Enterobacteriaceae (Figure 5, Table E3), as shown by the MVA. Though not significant, all *S. aureus* OTUs decreased as a result of antibiotic use, whereas several other staphylococcal species increased.

In a subanalysis of the effect of antibiotic course therapy independent of antibiotic prophylaxis, we determined similar trends in microbiota changes with a decrease in *Corynebacterium* spp. ($P = 0.03$ by MW test) and *Dolosigranulum* spp. ($P = 0.03$ by MW test) 1 month after antibiotic course therapy (n = 11 samples of six infants with CF and 5 samples of five control subjects) compared with precourse microbiota (n = 11 samples).

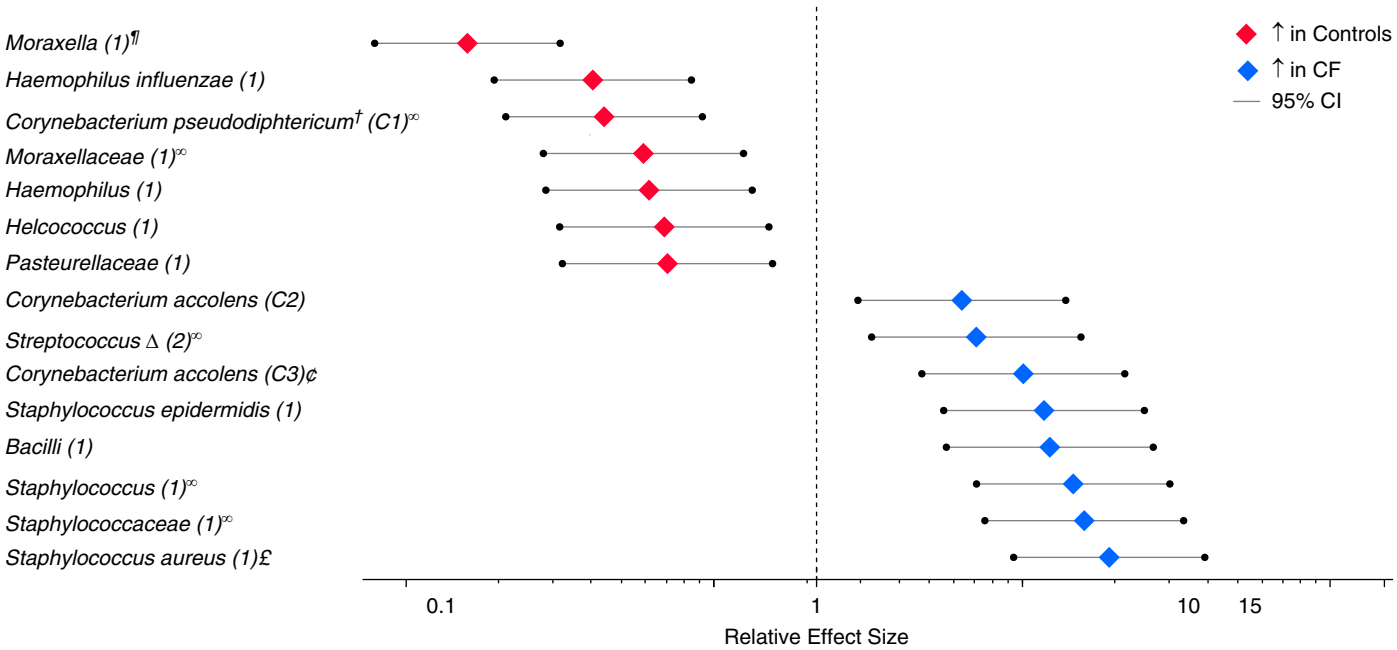

Figure 4. Relative effect size (RES) of operational taxonomic units (OTUs) that were significantly associated with cystic fibrosis (CF) in multivariate analysis. OTUs that were significantly increased (*blue*) or decreased (*red*) in infants with CF compared with control subjects are depicted. Overview of RESs with their 95% confidence intervals (CIs) of operational taxonomic units that were increased (RES >1) or decreased (RES <1) in infants with CF compared with control subjects after correction for age, antibiotic use, and respiratory health in a multivariate model after Benjamini–Hochberg correction. ∞n = 1; ¢n = 2; £n = 5; ¶n = 12; OTU(s) corresponding to the same species/genus are pooled. †100% homology to *Corynebacterium pseudodiphtericum* and *Corynebacterium propinquum* after blasting. Figure 5. Relative effect size (RES) of operational taxonomic units that were significantly associated with antibiotic (AB) use in multivariate analysis. Overview of RESs with their 95% confidence intervals (CIs) of operational taxonomic units that were significantly increased (RES >1) or decreased (RES <1) in (prophylactic) AB users compared with nonusers after correction for age, cystic fibrosis disease, and respiratory health in a multivariate model following Benjamini–Hochberg correction. †100% homology to *Corynebacterium pseudodiphthericum* and *Corynebacterium propinquum*. §Borderline significant.

Finally, on the basis of previous experience (21), we investigated the role of breastfeeding (significantly lower in infants with CF) on microbiota composition in both infants with CF and control subjects, correcting for CF and age in an independent MVA excluding samples obtained during respiratory infections. A positive correlation was found between breastfeeding and *Moraxellaceae* and *Corynebacterium* during the first half-year of life in both groups. In contrast, a higher abundance of *Prevotella melaninogenica*, other *Prevotella*, *Parascardovia*, *H. influenzae*, *Porphyromonas*, and *Actinomyces* was observed in formula-fed infants.

Microbial Inference Network in Infants with CF and Control Subjects

The abundance of individual bacteria most likely affects the presence of others because of ecologic interactions (29). Therefore, a network was constructed to study the cooccurrence and exclusion of various bacteria, which helped us to interpret potential interactions within the microbial community in infants with CF and control subjects (Figure 6). We observed several distinct clusters of bacteria cooccurring with one another. Strong positive associations were observed for *Streptococcus* spp. and gram-negative bacteria such as *Burkholderia* spp. Also, we observed strong negative correlations between the *Corynebacterium* and *Moraxella* clusters and *H. influenzae*, as well as between the cluster containing *Corynebacterium* and the *S. aureus* cluster.

Discussion

The nasopharynx is the major ecological niche for potential pathogens that cause lower respiratory infections. In the present study, we found distinct patterns of nasopharyngeal bacterial colonization in infants with CF and control subjects from the first month of life onward, already starting before first antibiotic course or prophylaxis and/or day care attendance, suggesting differences in microenvironments and host antimicrobial defense between groups (30). Madan and colleagues (2, 3, 31, 32) previously characterized the oral microbiota of infants with CF, concluding that, in particular, *Streptococcus*, *Veillonella*, and *Prevotella* were the most common genera in the oropharynges of infants with CF. In our present study, we showed increased abundance of *S. aureus* in the nasopharynges of infants with CF early in life, which might be explained by a defect in early innate immune defense against *S. aureus* in infants with CF (5, 33). Furthermore, *S. aureus* is suggested to better survive in the CF ecosystem owing to its ability to grow in facultative anaerobic conditions (4, 34). Importantly, recent studies have shown that increased respiratory colonization with *S. aureus* (35), in particular small colony variants (36), is associated with worse respiratory outcome, even in infants with CF who are clinically stable (37, 38). Together, this information suggests a nonbeneficial role for this bacterium in the respiratory ecocystem of infants with CF. However, on the basis of studies of healthy infants, it is also known that *S. aureus* presence is associated with decreased cocolonization of other potential pathogens, such as *S. pneumoniae* and *H. influenzae* (24, 39). This is in line with our finding that, in parallel with increased *S. aureus* colonization, the presence of *H. influenzae* and *S. pneumoniae* were decreased in infants with CF.

Despite the fact that *H. influenzae* is often reported to be a CF pathogen of infancy and childhood (40), we observed

A53210128

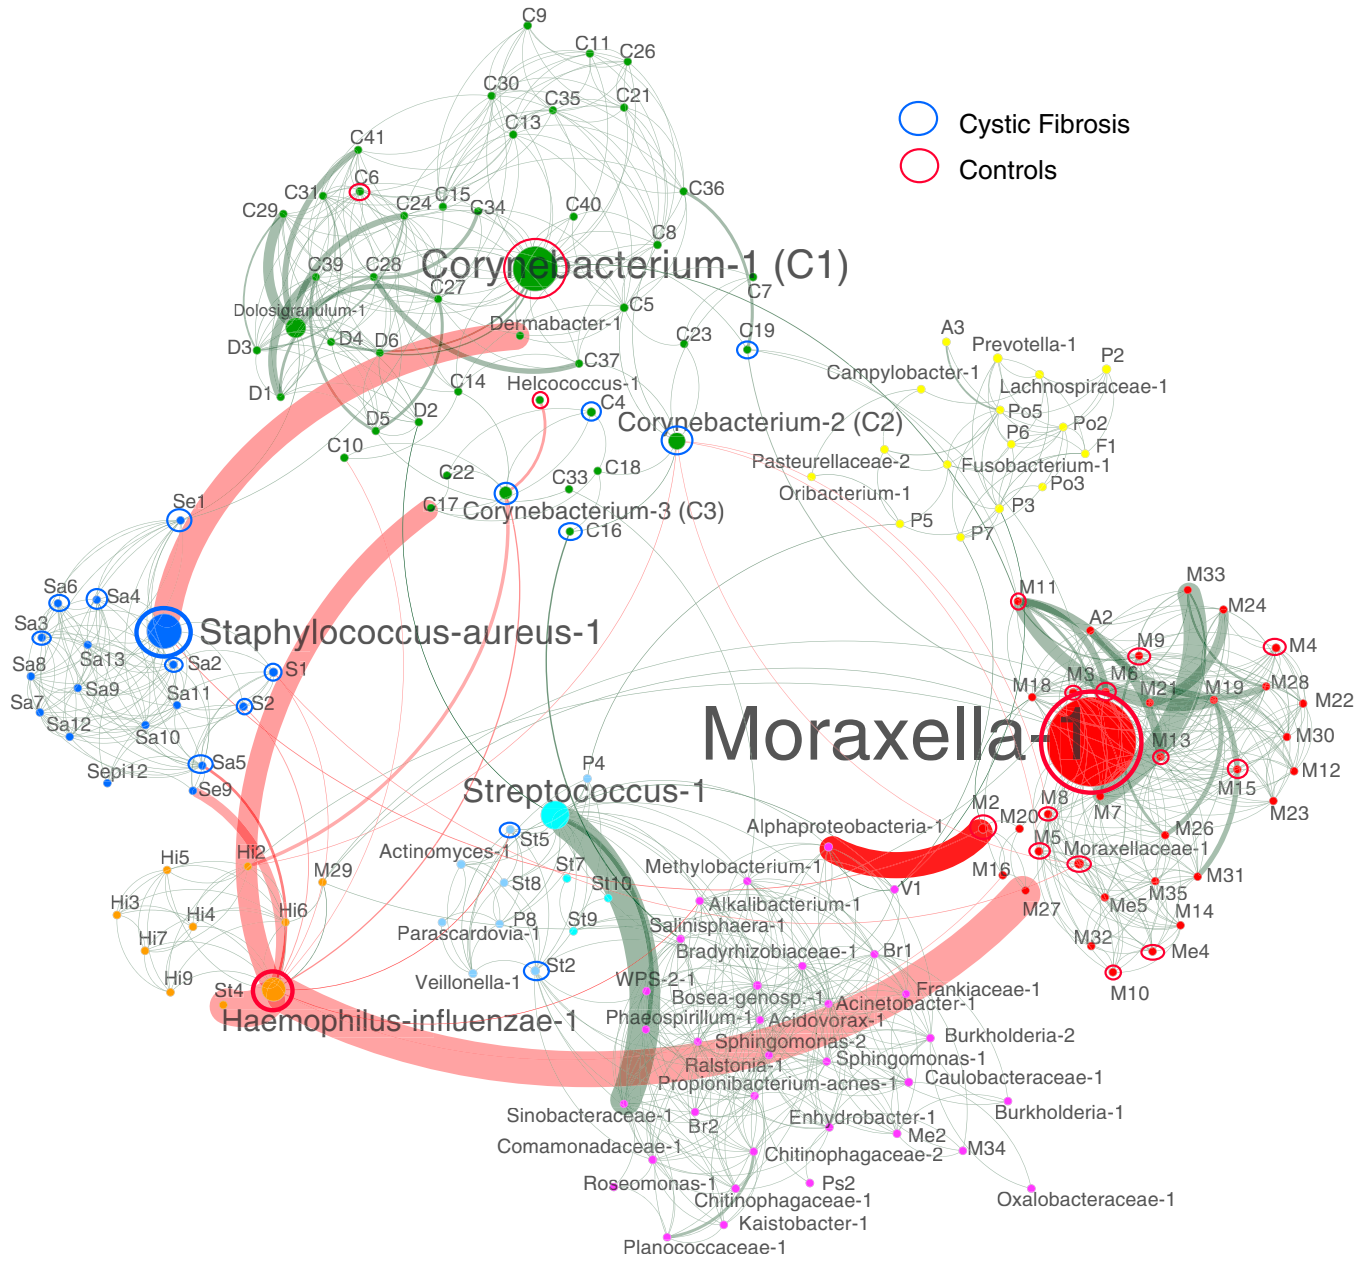

Figure 6. Network analysis of the microbial community structure in infants with cystic fibrosis and control subjects. A network was inferred to study the copresence and mutual exclusion of the top 200 operational taxonomic units (OTUs) observed in our cohort of infants. After bootstrap analysis, 190 OTUs remained as part of the network. Using the Markov clustering algorithm, 16 clusters were identified, of which the largest 8 (representing 169 OTUs in total) are depicted. The OTUs are depicted as nodes; the size of each node represents the relative abundance. Pairwise associations between nodes are depicted by *green* and *red edges*, representing positive and negative correlations, respectively. The thickness of the edges relates to the strength of the association. The OTUs positively correlated with cystic fibrosis (*blue circles*) and control subjects (*red circles*) in multivariate analysis are marked.

low colonization rates in infants with CF during their first 6 months of life.

The increased *H. influenzae*-, *S. pneumoniae*-, and *Moraxella*-dominated profiles in the healthy control subjects compared with infants with CF may also have been a consequence of increased exposure to these bacteria (41) through day care attendance and contact with older siblings, both of which were significantly lower in our CF study group.

Interestingly, on the genus level, *Streptococcus* seems to emerge in both groups from 3 months of age onward, although in contrast to control subjects, infants with CF showed outgrowth of *S. mitis* instead of *S. pneumoniae*. Whereas *S. pneumoniae* is known as a frequent respiratory tract infection (RTI) pathogen, *S. mitis* is regarded as mostly a nonpathogenic commensal of the

oropharyngeal niche. *In vitro* the latter group of streptococci has even been shown to inhibit the growth of potential pathogens such as *S. pneumoniae* (42), *H. influenzae* (43), and even *Pseudomonas* (44) by the production of hydrogen peroxide. Whether the milieu in patients with CF favors the growth of *S. mitis* remains to be shown.

A previous study of children without CF demonstrated that stable microbiota profiles in the first 6 months of life were characterized by either early dominance of *S. aureus*, *Moraxella*, or a combination of *Corynebacterium* and/or *Dolosigranulum* (33). In line with our present study, instability of microbiota dynamics was associated with *Haemophilus*- and *Streptococcus*-dominated profiles. Interestingly, in our study, *H. influenzae* acquisition and expansion over time in our control group seemed to be associated with a reduction in the commensals from the *Corynebacterium* genus, which is supported by a strong negative association between *Corynebacterium* spp. and *H. influenzae* within individuals, as shown by the bacterial interaction network, suggesting a potential negative interaction between both genera (21).

We also conclude that both *Corynebacterium* (often in combination with *Dolosigranulum*) and *Moraxella* might be important symbionts in the nasopharynx, owing to their associations with stable colonization dynamics, with health (present in 96% and 92% of control subjects, respectively), with breastfeeding (21), and with consecutive reduced risk of RTIs (45).

Furthermore, we showed that microbial community composition was highly similar in symptomatic and clinically stable periods, suggesting that respiratory symptoms at this age are still induced mostly by viral infection (46). However, we cannot rule out that symptoms might be a consequence of intrapulmonary infections or of a shift or change in strains within genera or species (47).

It is noteworthy that antibiotics, either as course treatment or as prophylaxis, are often started in cases of respiratory symptoms. Although this is obviously protective against overgrowth and dissemination of targeted species, one should be aware of the potential adverse effects (48). In the present study, we demonstrated that antibiotics prescribed before 6 months of age induced a significant shift in microbial composition, resulting in the emergence of gram-negative bacteria, such as *Burkholderia* and bacteria of the families Comamonadaceae, Bradyrhizobiaceae, and (a trend toward) Enterobacteriaceae. Because these bacteria have a natural tolerance for most antibiotics prescribed in the study population, they have the opportunity to become selectively expanded and to become pathogenic during prolonged treatment, whereas normally they are unable to compete for niche space (11). Furthermore, these gram-negative bacteria are positively associated with a more oral type of microbiota profile, including *Streptococcus mitis*, which might partially explain the emergence of this species in infants with CF from age 3 months onward.

At least as important as the increase in gram-negative bacteria is the observed reduction in the primarily highly abundant symbionts *Corynebacterium* and *Dolosigranulum* following (not preceding) antibiotic treatment; both these genera were recently found to be associated with stability of respiratory microbiota and a decreased risk of consecutive RTIs (21). This topic deserves further study to unravel whether these genera are indeed keystone species (49) of the healthy respiratory microbiota and, if so, whether eliminating these genera by antibiotic treatment should be avoided.

The strength of this study is that it is the first to describe in detail the development of the nasopharyngeal microbiota in infants with CF and birthdate-matched control subjects during the first half-year of life, starting before symptoms occurred and before treatment was initiated. We were thereby able to study the ecological effects of the first antibiotic treatment and initiation of prophylaxis this early in life.

A limitation of our study is the relatively small study population, although we partially counterbalance this by the matching 3 control subjects to 1 CF infant. Furthermore, although URT samples are commonly used as surrogates for the lower respiratory tract in routine clinical practice, we are not 100% certain that the URT samples provided an adequate representation of this niche; therefore, further research is needed to determine the intraindividual concordance of the microbiota present in the upper and lower respiratory tracts in infants with CF.

In conclusion, the development of nasopharyngeal microbial colonization profiles is different in infants with CF than in healthy control subjects from diagnosis onward. Additionally, antibiotic courses and prophylaxis early in life altered the respiratory microbiota significantly, with a reduction in potential beneficial commensals and an increase in potentially pathogenic gram-negative bacteria. This emphasizes the need for improved diagnostic tools to discriminate between viral and bacterial infections in these children and to develop targeted antimicrobial therapy. Follow-up studies are warranted to further understand the relationship between early microbiota development and respiratory disease in children with CF and to study long-term implications of different types of (prophylactic) antibiotic therapy. ■

SUMMARY

Background: Deciphering precise sources and patterns of healthcare-associated *Pseudomonas aeruginosa* colonization/infection is crucial in defining strategies of prevention and control.
Aim: To prospectively investigate the role of hospital environment in *P. aeruginosa* nosocomial bloodstream infections (Pa-BSIs) during one year in a tertiary-care hospital.
Methods: Clinical records of patients presenting Pa-BSIs after >48 h of hospitalization were investigated to confirm the nosocomial character of BSIs and identify the routes of entry and risk factors. Environmental investigations were performed to track *P. aeruginosa* source/reservoir along the care pathway. Clinical and environmental strains were compared by whole-genome sequencing to identify the route of contamination from hospital environment to patients.
Findings: Fifty-three BSIs episodes in 49 patients were considered as nosocomial, mostly involving men (73%), with an average age of 62.4 years, immunosuppressed in >40% of cases, and after previous antibiotic therapy in almost 92% of cases. BSIs occurred after 27 days of hospitalization on average. The main routes of entry were urinary (30%, on indwelling catheters for two-thirds of cases) and cutaneous (17%, catheter-related in almost 80% of cases). *P. aeruginosa* was found in 16 out of 49 investigations, representing 34 positive samples, including 54% of sink traps, 23% of water, and 20% of tap aerators. An epidemiological link was established between environmental and clinical strains only for eight patients, representing 15% of nosocomial BSIs.
Conclusion: The hospital environment usually considered as the main source of *P. aeruginosa* healthcare-associated infections was identified as responsible for nosocomial BSIs in only 15% of patients. Since the implementation of water and hospital environment management, one may hypothesize that *P. aeruginosa* has become a community-acquired pathogen with a nosocomial expression in infection.

Introduction

The most recent European point-prevalence survey reported a prevalence of 5.9% of healthcare-associated infections (HAIs), with bloodstream infections (BSI) ranking fourth and causing the highest mortality [1,2]. Among the causative agents, *Pseudomonas aeruginosa* is increasingly involved in HAIs in intensive care units (ICUs) and in immunocompromised patients [3]. The high level of antibiotic resistance of *P. aeruginosa* is marked by the emergence of multidrug-resistant (MDR) or extremely drug-resistant (XDR) phenotypes [4]. *P. aeruginosa* resistant to carbapenems (CRPa) represents 19.3% of overall clinical isolates and 25.5% of isolates collected in ICU [2,5]. This situation is especially concerning due to the increasing number of systemic *P. aeruginosa* infections in recent years, the 30% mortality attributable to Pa-BSI, and the risk of death in cases of CRPa-BSI increasing by at least 7% [1,6—9].

In hospital, risk factors for *P. aeruginosa* infection are linked to patients, types of care provided, and the presence of *P. aeruginosa* in the hospital environment close to the patient [10]. *P. aeruginosa* acquisition may be endogenous from the patient's intestinal or oropharyngeal microbiota, or exogenous through nursing staff, cross-transmission between patients or from the hospital environment. During *P. aeruginosa* outbreaks, an association between the presence of *P. aeruginosa* in water niches and Pa-HAI onset is suggested, but the contribution of the environment in Pa-HAI outside outbreak circumstances is rarely reported and remains controversial [11—13]. Even if *P. aeruginosa* is an opportunistic premise plumbing pathogen (OPPP) and Pa-HAIs are usually considered as nosocomial, deciphering precise sources and patterns of *P. aeruginosa* colonization/infection is crucial in defining strategies of prevention and control. The aim of this study was to characterize *P. aeruginosa* hospital-acquired (HA-)BSIs and to determine the proportion of them linked to *P. aeruginosa* environmental reservoir.

Methods

Clinical investigation

A prospective single-centre study was conducted at the University Hospital of Montpellier during 2022. Based on daily automated alert from the bacteriology laboratory, all events of Pa-BSI were included in the study, corresponding to *P. aeruginosa*-positive blood cultures at least 48 h after the patient's hospital admission. A case corresponded to a patient presenting at least one event of Pa-BSI. The onset of several Pa-BSIs in the same patient with negative blood cultures in between was considered to be recurrence. Clinical records were analysed to collect risk factors for Pa-BSIs and define the nosocomial character of the BSI (HA-BSI). A case was considered as HA as soon as the reason for hospitalization was not related to a *P. aeruginosa* infection already in progress at patient's admission. Socio-demographic and clinical criteria were collected from patients' clinical records: sex, age, immune status (aged $\geq$85 years was considered as immunosuppression), clinical ward, delay in BSI onset, length of stay, exposure to antibiotics in the previous three months, number and type of invasive devices (including devices removed $<$48 h before BSI onset), mortality at 7 and 30 days, *P. aeruginosa* antibiotic phenotype and suspected route of entry. Descriptive epidemiological data were analysed by multiple correspondence analysis (MCA) using the R packages Rcmdr and RcmdrPlugin.FactoMiner (available at https://cran.r-project.org/web/packages/RcmdrPlugin.FactoMineR/index.html) to identify potential associations between epidemiological criteria and BSI occurrence. Graphs of individuals/variables from the output of the MCA were generated using the Factoextra package (available at https://cran.r-project.org/web/packages/factoextra/index.html). The study was approved by our Ethical Committee (registration number ID RCB: 2016-A00138-43) and declared to ClinicalTrials.gov under the number ID: NCT02751658).

Environmental investigation

Pa-HA-BSIs were prospectively investigated by sampling the patient's immediate environment. After a case of BSI, the water point-of-use representing a risk for patient's exposure to *P. aeruginosa* was sampled, i.e. water point-of-use in the patient's bedroom and bathroom, or in the adjacent room used for nursing care or hand hygiene by healthcare professionals. The systematic sampling plan included shower trap, sink trap in patient's bedroom, faucet aerator of tap water in patient's bedroom, water of tap water and shower in patient's bedroom, damp surfaces around the washbasin, and support ramp near the toilets. Dry and wet surfaces were sampled with sterile cotton swabs (Copan Diagnostics Inc., Murrieta, CA, USA). Swabs were pre-incubated for 12 h at 37 °C in a soybean trypticase broth (Difco, Bordeaux, France) before streaking on to MacConkey agar media (Difco, Bordeaux, France), then incubated for 72 h at 37 °C in aerobic conditions. Volumes of 250 mL water were collected in bottles containing sodium thiosulphate (final concentration of 20 mg/L), filtered on to cellulose nitrate membrane of 0.45 μm porosity (Sartorius Stedim Biotech, Dourdan, France). The membranes were incubated on MacConkey agar plates for 72 h at 30 °C. Each colony morphotype was identified by matrix-assisted laser desorption/ionization time-of-flight mass spectrometry (Brucker, Champs sur Marne, France). If a sample was positive for *P. aeruginosa* and homogeneous, i.e. with the presence of a single morphotype, then a single *P. aeruginosa* colony was sequenced. However, if different *P. aeruginosa* morphotypes could be distinguished, a representative colony of each morphotype was sequenced for comparison with the responsible BSI strain. It should also be noted that we did not select only multidrug-resistant strains from environmental samples as we used MacConkey agar media.

Molecular typing

Clinical strains were genotyped by multi-locus sequence typing (MLST) in order to describe local *P. aeruginosa*

population structure involved in HA-BSI and to identify epidemic high-risk (EHR) genotypes, such as ST111, ST175, ST235 that are global/worldwide EHR, and ST253 and ST395 especially present in French hospitals [14—18]. When an environmental reservoir of *P. aeruginosa* was suspected, clinical and environmental isolates were compared by multiplex repetitive sequence-based polymerase chain reaction (rep-PCR) as a first step to assess their clonal relatedness [19]. Environmental and clinical isolates displaying the same profile in multiplex rep-PCR were then whole-genome sequenced using Illumina NextSeq (Illumina, San Diego, CA, USA) technology (whole-genome sequencing: WGS) and a pairwise single nucleotide polymorphism (SNP) analysis was performed to investigate potential epidemiological link, supported for isolates displaying a core-genome (cg-)SNP distance of $\leq$30 [20]. For this purpose, the 'all-in-one' variant calling tool Snippy (Galaxy Version 4.6.0+galaxy0) was used with the isolate found in the environment as a reference. The environmental acquisition of *P. aeruginosa* was considered as possible when *P. aeruginosa* was absent in water but present in aerator and/or sink traps. The presence of *P. aeruginosa* in water was considered as a strong argument for attributing HA-BSI onset to an environmental exposure and nosocomial acquisition of *P. aeruginosa* was then considered as probable in such case.

The study was registered under the Bioproject number PRJNA1083517.

Results

Clinical characteristics of Pa-HA-BSIs

During our 12-month study, 82 events of Pa-BSIs were observed at the University Hospital of Montpellier, corresponding to 53 HA-BSIs and 29 community-acquired BSIs. No cluster cases nor *P. aeruginosa* outbreaks were detected. The 53 HA-BSIs occurred in 49 patients, including four patients with recurrence. HA-BSI mainly affected men (72.7% of cases), average age 62.4 years, and 43% of patients were immunocompromised (i.e aged $\geq$85 years, or with a malignant disease, or treated with immunosuppressive drugs) (Supplementary Table S1). More than 92% of patients received antibiotic therapy in the three months preceding HA-BSI onset. The average time between admission and positive blood culture was 27.2 days (2—92 days), with an average hospital stay of 57.7 days (range: 7—345 days). There was no evidence of seasonality in Pa-HA-BSIs (Supplementary Figure S1). The prevalence of HA-BSIs by age group showed 25% of BSIs in patients aged 64—85 years, 14% aged 45—64 years, and 8% and 5% aged 15—44 and $>$85 years, respectively. Less than 1% of HA-BSIs occurred in children aged $<$14 years (Supplementary Figure S2). Patients affected by Pa-HA-BSI were mostly hospitalized in medical wards (47.2%) and critical care wards (43.4%). Surgical patients represented 9.4% of cases. When we calculated the ratio of the number of BSIs occurring in critical care wards to those occurring in medical wards, the overall risk of Pa-BSIs was increased by 5.7-fold (RR: 5.7; 95% CI: 3.18—9.42) for patients hospitalized in in critical care wards. Mortality rates were 11.3% at day 7 and 17% at day 30, and exposure to MDR-Pa did not increase the risk of mortality (RR: 1.5; 95% CI: 0.32;7.03). Suspected routes of entry for Pa-HA-BSIs were the urinary tract in 30.2% of cases, skin in 17%, digestive tract in 13.2%, respiratory tract in 9.4%, secondary to surgery in 5.7% of cases, and remained undetermined in 24.5% of cases. Of HA-BSIs originating from the urinary tract, 62.5% were linked to a urinary catheter. Intravenous catheters were involved in 77.8% of skin-originating HA-BSIs. Finally, 100% of respiratory-originating HA-BSIs occurred in intubated or tracheotomized patients.

According to MCA analyses, only 46.2% of the variance was explained by the first four axes, testifying to the complexity of predicting Pa-BSIs due to their multifactorial trait. MCA analysis showed a positive correlation between hospitalization in critical care wards, pulmonary portal of entry, maleness and mortality (day 30) (Supplementary Figure S3).

Prospective investigation of the hospital environment

Of 388 environmental samples collected during 53 investigations, 34 samples in 16 investigations were positive for *P. aeruginosa*. Sink traps accounted for 54.3% of *P. aeruginosa*-positive samples, followed by water (22.9%), tap aerators (20%) and wet surfaces (2.8%). Of *P. aeruginosa*-positive samples, 55.9% were also contaminated by one to four bacteria, mostly belonging to other OPPPs (*Pseudomonas* sp. and *Stenotrophomonas maltophilia* respectively in 38.8% and 16.1% of cases) or Enterobacteria. Eleven samples negative for *P. aeruginosa* were positive for OPPPs and/or Enterobacteria, mainly in sink traps (Supplementary Table S2). One investigation revealed *P. aeruginosa* in water sample, tap aerator, and sink trap of the same water point-of-use, despite the presence of an antimicrobial filter, highlighting a fault in effectiveness of the antimicrobial filter.

Population structure of P. aeruginosa from HA-BSIs and hospital environment

Of the 53 clinical strains typed by MLST, 41 different STs were identified, including eight EHR genotypes, responsible for 13 HA-BSIs, and one ST never yet described (Figure 1). Among the 34 *P. aeruginosa* environmental strains, 16 distinct molecular profiles were identified in multiplex rep-PCR. Subsequently, MLST analyses of 14 *P. aeruginosa* environmental strains involved in suspected epidemiological links (Supplementary Table S1) identified nine different STs, including three EHR accounting for 50% of the environmental strains. All nine environmental STs were common to clinical STs, underlying the higher diversity of clinical than environmental isolates.

Path of contamination of Pa-HA-BSIs

Among the 16 *P. aeruginosa*-positive investigations, multiplex rep-PCR and MLST comparisons of clinical and environmental strains identified nine suspected epidemiological links. Pairwise cg-SNP analysis using the genome of environmental isolate as reference corroborated eight epidemiological links with an average of 16.2 cg-SNPs difference per pair (ranging from four to 25 cg-SNPs depending on the pair considered) (Supplementary Table S3). The refuted epidemiological link identified 3991 cg-SNPs difference among clinical and environmental isolates. The nosocomial acquisition of *P. aeruginosa* was considered as possible in six situations and probable in the last two situations (Table I).

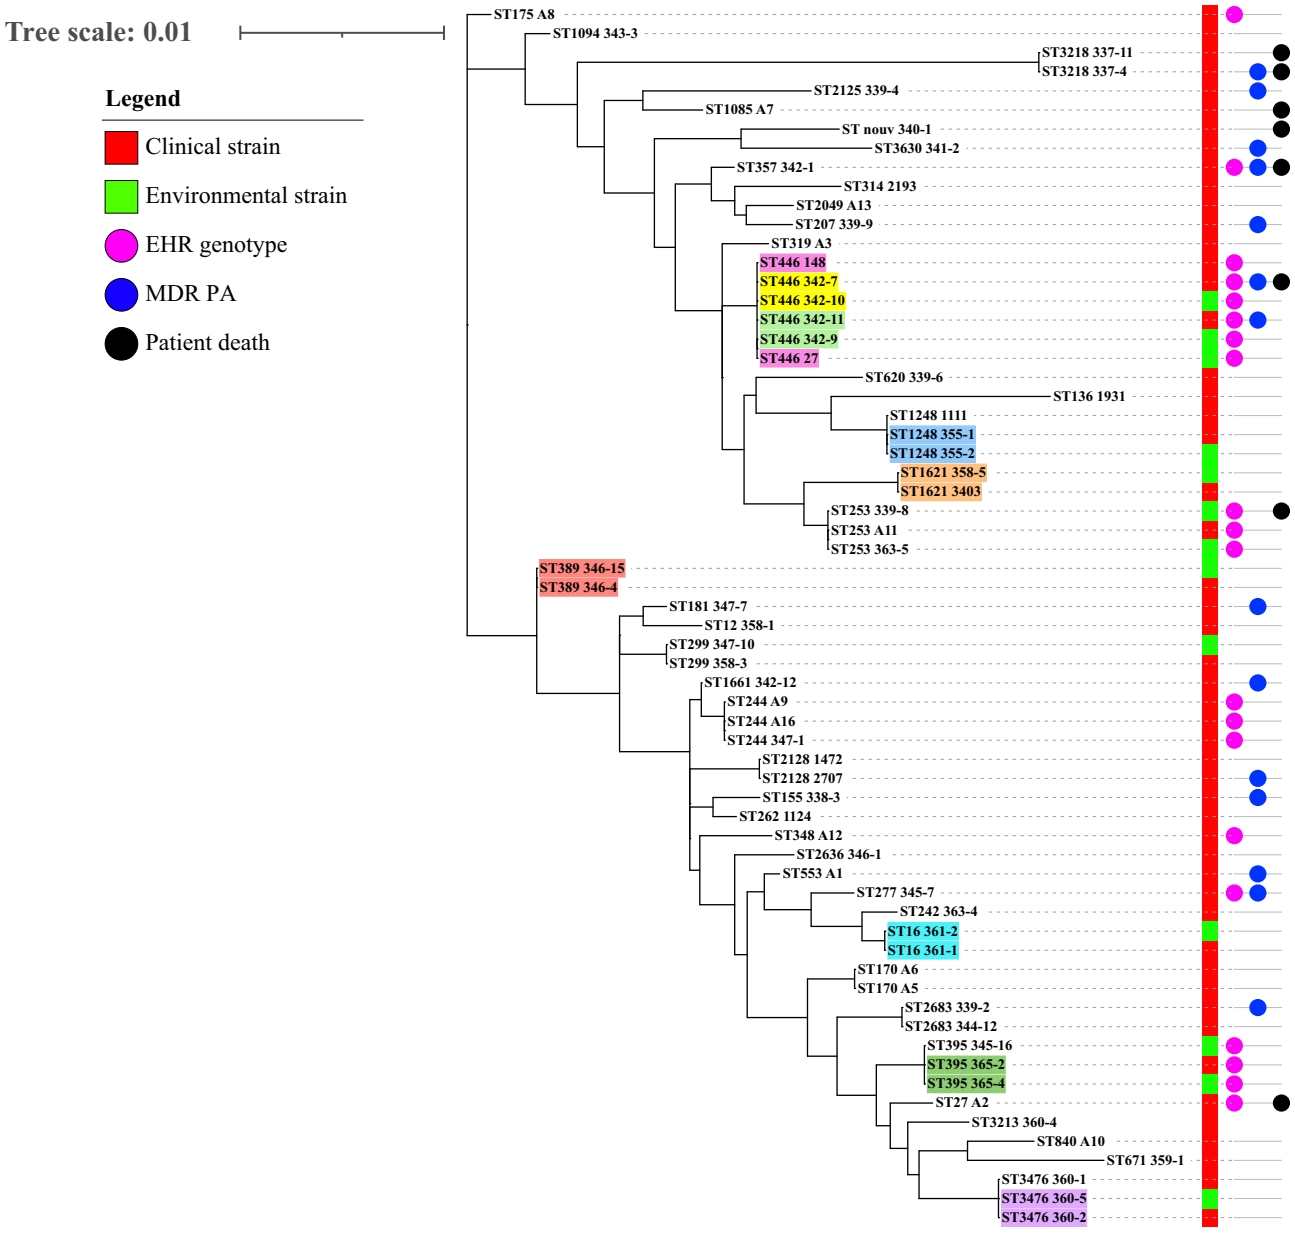

Figure 1. Maximum-likelihood tree estimation using multi-locus sequence typing (MLST) of 53 *P. aeruginosa* causing a bloodstream infection event and 14 *P. aeruginosa* collected in water environment. Epidemiological links are highlighted by coloured labels. Two *P. aeruginosa* reservoirs did not undergo MLST genotype identification, as the molecular fingerprints obtained in multiplex repetitive sequenced-based polymerase chain reaction allowing comparison of the clinical and environmental strains were clearly distinct.

Discussion

During our one-year study, Pa-HA-BSIs occurred predominantly in elderly men with a history of hospitalization, immunosuppression, and urinary tract was the most common route of entry for BSIs, as also described in France the same year [21]. Proper management of invasive devices is essential in preventing HA-BSIs, as ~40% of them were linked to invasive devices. Conversely to previous study, there was no evidence of seasonality in Pa-HA-BSIs occurring in our hospital during the one-year survey [22]. No excess mortality was observed for MDR-Pa-BSIs in contrast to the literature, but this may be explained by the small sample size, as only three MDR-Pa deaths were recorded in our study [1].

Previous studies showed the importance of the environment as a source of Pa-HAIs in outbreaks, estimated to reach 86.3% for VIM-producing *P. aeruginosa* in ICU in a recent study based on a mathematical model [11,23]. However, to date the role of the hydric environment as origin of *P. aeruginosa* sporadic HAIs remains poorly explored. Our prospective single-centre study included all Pa-HA-BSIs and performed real-time investigations of the patient's immediate environment for detecting *P. aeruginosa* environmental reservoirs. In our case, the environmental contamination of water point-of-use close to patients was responsible for 12.5%–50% of HA-BSI. Indeed, eight possible or probable epidemiological links between an environmental exposure to Pa- and HA-BSI were described in a total of 53 HA-BSIs and 16 situations in which *P. aeruginosa* was

[c] Possible epidemiological link (compared with probable epidemiological link for other patients).

retrieved from hospital environment. In our study, the intra-sample diversity of *P. aeruginosa* in environmental samples was not assessed, although when different *P. aeruginosa* morphotypes presented in the same sample, one colony of each morphotype was analysed. Therefore, it is possible that in the eight situations where a *P. aeruginosa* reservoir was identified as unrelated to the bacterium responsible for BSI, the epidemiological link could not be demonstrated due to the selection of a single colony in the case of a single morphotype. However, this bias present in most bacterial genomics studies is difficult to eliminate.

Of the eight environment HA-BSIs, three were involved the worldwide ST446 EHR genotype, described as long-term persistent in the environment and as extensively drug-resistant to antibiotics [24]. EHR genotypes overall were responsible for 24.5% of BSIs. The predominance of EHR genotypes in environmental success has already been reported [13]. However, their predominance in HA-BSIs associated with environmental contamination testifies to the extent of their adaptive capacity, supporting their environmental success and facilitating their change of niche from the environment to the patient [25].

In our study, the origin of a large majority of BSIs characterized as nosocomial on the basis of clinical criteria remained undetermined. The hypothesis of an endogenous origin is supported by the increasing prevalence of *P. aeruginosa* intestinal carriage, estimated according to studies between 10% and 50% in patients hospitalized in ICU, and up to 51% among residents of long-term care facilities [26—28]. To date, the intestinal carriage of *P. aeruginosa* in the hospitalized patients is unknown and probably underestimated since intestinal screening is not performed in hospitals and identification of *P. aeruginosa* is fortuitous, secondary to the search for carbapenemase-producing Enterobacterales. Our results challenge a recent study showing that 50% of Pa-HA infections were linked either to a persistent environmental reservoir or to a cross-transmission [12]. That study focused on all types of Pa-HA infections occurring only in ICU whereas we focused on Pa-BSIs in a whole hospital. Our conclusions were more in agreement with Volling *et al*. reporting on the basis of robust epidemiological and genotypic criteria that 7% of Pa-HAI in ICUs may be attributable to sink drains. One other study reported infrequent contamination of patients by *P. aeruginosa* from sink traps, even if these results seemed undervalued as they did not explore water as a source of *P. aeruginosa* contamination [13]. Such a low rate of environmental acquisition of *P. aeruginosa* could be partly explained by the use of clapper traps and the improved compliance with hand hygiene in ICU, which limits the risk of infection through cross-transmission from an environmental reservoir [13]. Usually, ICU nursing staff are more aware of and trained in the role of the environment in the occurrence of HAI, and the exogenous transmission of *P. aeruginosa* depends especially on compliance with preventive and hygiene measures [29]. In our study, the risk of acquiring *P. aeruginosa* from the environment in critical wards was comparable to that in other care wards, thus highlighting the effectiveness of the prevention and environmental control measures put in place in our hospital. As in Couchoud's study, we compared isolates by both WGS and SNP calling analyses. However, for each group of isolates belonging to the same ST and presenting a difference of $\leq$30 loci in cg-MLST, Couchoud *et al*. performed a cg-SNP search using an external reference [13]. As a result, genomic regions specific to the cluster of isolates but absent in the reference genome will not be studied. As it is essential to choose a reference that is closely related to the genomes analysed, in order to increase the performance and reliability of SNP calling, we selected an internal reference, i.e. the environmental isolate of the pair, in order not to underestimate the genetic distance existing between the isolates of a pair or cluster [30]. Furthermore, the threshold of seven SNPs chosen by Couchoud *et al*. to consider two isolates as clonal was very restrictive [13]. To date, there is no consensus on the threshold of SNPs permissible for epidemiologically linking isolates. The evolutionary speed of *P. aeruginosa* is not clearly defined, although a rate of one SNP every four to five months has been proposed [31]. It would have been interesting to present the results obtained with a threshold of up to 30 SNPs, as widely used in the literature to determine clonally related isolates, even more than the presence of an environmental reservoir increases the genetic distance between isolates belonging to the same cluster [20,32,33].

Our environmental investigations reported sink traps as the most frequent hospital niche colonized by *P. aeruginosa*. Sink traps constitute technological niches at the interface between drains and human activities and offer privileged locations for colonization and persistence [13,34]. The risk of patient contamination from aerosols generated by sink traps is now recognized including during outbreaks [35]. No prospective sampling of the environment (prior to reporting BSI to PA) was performed in our hospital, underlining the difficulty in determining the direction of the environment—patient or patient—environment contamination. However, the aim of our work was to determine the proportion of Pa-HA-BSIs associated with an environmental reservoir but without prejudging the causal link. Previously, it has been reported that contamination of the water environment close to the patient is an independent risk factor for Pa-HAI-BSIs [11]. To consider this difficulty in determining the direction of contamination, we defined two levels of epidemiological association: possible and probable. We can assume that sink or shower trap were easily contaminated by the infected patient due to the proximity of trap and the patient, hence the term 'possible epidemiological link'. However, in our opinion, the presence of *P. aeruginosa* in the water supplied to the patient's room is a strong argument for attributing the Pa-BSI to the existence of the environmental reservoir, since the contamination of the water network from infected patient is unlikely. Thus, despite the complexity of establishing the chronology/direction of *P. aeruginosa* contamination between patients and the hospital environment, the genetic relatedness of two strains must be put into perspective with precise spatial—temporal criteria in order to determine the probability of transmission and to predict the direction of the epidemiological link [36].

Beside *P. aeruginosa*, enterobacteria were retrieved in 25.5% of the environmental samples, especially in sink traps, underlining again their major role as reservoirs of pathogens responsible for HAIs and emphasizing the need for their chronic disinfection. However, continuous exposure of sink traps to low levels of disinfectant may favour adaptive mutations of *P. aeruginosa* to a wide range of disinfectants (beyond those to which the strains were exposed) as well as to antibiotics due to biocide/antibiotic co-selection phenomena [37,38]. Moreover, the perennial adaptation of *P. aeruginosa* and other OPPPs to wet technological niches favours the maturation of biofilms

protecting against disinfection processes and ultimately favouring the establishment and proliferation of other pathogens (meticillin-resistant *Staphylococcus aureus*, CPE) not traditionally associated with water [39]. Biofilms constitute a hot-spot for the spread of antimicrobial resistance [39]. Consequently, improving the management of *P. aeruginosa* environmental reservoirs should limit Pa-HAI, and broadly prevent HAI caused by other pathogens and the dissemination of antibiotic resistance [40].

In conclusion, for 85% of Pa-BSIs defined as HA on the basis of clinical criteria, no environmental reservoir was identified, suggesting that *P. aeruginosa* must no longer be considered as a nosocomial pathogen *sensu stricto*. Since the implementation of management measures of water risk in past decades, one can hypothesize that *P. aeruginosa* has become a community-acquired pathogen of nosocomial expression for which infectious character is revealed as a result of hospital selection pressures.

PAPER

A Decade of Reduced Gram-negative Infections and Mortality Associated With Improved Isolation of Burned Patients

Albert T. McManus, PhD; Arthur D. Mason, Jr, MD; William F. McManus, MD; Basil A. Pruitt, Jr, MD

DISTRIBUTION STATEMENT A
Approved for public release
Distribution Unlimited

Objective: To compare the incidence of gram-negative bacteremia (GNB) and mortality in patients with large burns (≥20% of total body surface) hospitalized in either an open ward (OW) or a single-bed isolation (IW) environment.

Design: Retrospective cohort study.

Setting: The US Army Institute of Surgical Research, Burn Center, Ft Sam Houston, Tex.

Patients: Two thousand five hundred nineteen consecutive patients with large burns divided into two 10-year cohorts. Patients in the first cohort period were treated under OW conditions; patients in the second cohort period, under IW conditions. Infection (bacteremia) data were from a laboratory database. A microbial surveillance system was used to monitor patient isolation. Mortality was compared with predicted mortality derived by logistic regression of outcome, burn size, and age of patients without bacteremia in the study.

Main Outcome Measures: Presence of GNB and survival.

Results: The incidence of GNB was higher in the OW cohort (31.2%) than the IW cohort (12.0%) ($P<.001$). The postinjury time of first GNB was delayed in the IW vs the OW cohort (28.9 days vs 11.8 days, respectively) ($P<.001$). For patients who had GNB in the OW cohort, mortality was higher than predicted (observed-predicted mortality ratio, 1.61) ($P<.001$). Such increased mortality was not present in the IW cohort. Multiple antibiotic-resistant gram-negative pathogens were endemic in the OW cohort. There was no evidence of cross infection or endemic conditions with multiple antibiotic-resistant gram-negative pathogens in the IW cohort.

Conclusion: Improvements in isolation of burned patients were associated with decreased incidence of GNB, delayed postinjury time of GNB, and improved survival. Improved survival is likely related to decreased susceptibility as a result of longer exposure to the benefits of treatment and wound closure. These results suggest that, in patients with severe burn injuries, gram-negative infections and the related mortality can largely be prevented.

(Arch Surg. 1994;129:1306-1309)

19950731 025

INFECTION IS a major cause of morbidity and mortality in hospitalized burned patients. We have previously estimated the added risk for mortality due to infection in a population of more than 5500 admissions for burns and demonstrated that bacteremia was associated with a 21% increase of mortality above that predicted by logistic regression analysis of injury severity and age.[1] When the bacteremic population was subdivided by pathogen, gram-negative opportunists were found to be the principal cause of the observed increase in mortality. Mortality in the group of patients with gram-negative bacteremia (GNB) was more than 50% greater than that predicted for patients without bacteremia.[1]

The clinical significance of gram-negative pathogens in burned patients became obvious after the introduction of newer generations of penicillin and aminoglycosides in the early 1960s.[2,3] *Pseudomonas aeruginosa* and members of the Enterobacteriaceae family became predominant and, during the subsequent 20 years, caused several endemics.[4,5] Distinguishing features of these endemics were multiple antimicrobial resistance and consistent biotypes within causative strains.

In 1983, the intensive care facilities of our burn center were modified so that seriously burned patients could be cared for in individual rooms rather than the previ-

METHODS

In the present study, we have selected a 20-year period that includes the decades prior and subsequent to the opening of the new single-bed intensive care unit. We have arbitrarily used a total burn size of 20% or larger of the body surface as the inclusion criterion in an attempt to compare patients with serious injuries. Burned patients selected by this criterion represent more than 90% of those with bacteremia and 95% of those who died during the 20-year period. A comparison of patient demographics between the open-ward (1974 to 1983) and single-bed-unit (1984 to 1993) cohort periods is presented in **Table 1**.

We have used the same case definition of bacteremia (candidemia) as in our previous report.[1] Isolation of a species once or on multiple subsequent blood cultures was considered a case of infection with that organism (species). For mortality comparisons, a patient was categorized by the presence and types of organisms that caused positive findings on blood cultures.

Mortality predictions were made using logistic regression techniques described by Mason et al[1] for burned patients with no bacteremia. In the present study, a predictor was generated based on 1515 patients (with burns on ≥20% of body surface) admitted between 1974 and 1993 who did not have a positive blood culture during hospitalization. The analysis related patient outcome to burn size and age. The equation derived for this population is:

$$K = -4.985 + 0.1054(\%\ \text{Burn}) - 0.2279(\text{Age}) + 0.006122(\text{Age}^2) - 0.0000351(\text{Age}^3)$$

$$PM = e^K/(1+e^K)$$

where PM is predicted mortality. Predicted mortality for an individual is based on that individual's burn size and age. The estimate of the expected number of deaths within a patient group is the sum of the individual predicted mortalities for that group. Confidence limits for the group mortality estimate were derived by a binomial expansion technique. An example of a group prediction for the 1515 patients with no bacteremia is presented in the following tabulation:

Data	Value
No. of admissions	1515
No. (%) of predicted deaths	351(23.2)
95% confidence interval	328-374
No. of observed deaths	351
Observed-predicted mortality ratio	1.00

Based on our previous observation that gram-negative isolates from blood cultures had the greatest associated added mortality risk, we separated the population with bacteremia into patients with one or more cases of bacteremia (candidemia) and at least one culture positive for GNB and patients with cultures positive for gram-positive bacteremia only. Gram-positive cases were principally due to *Staphylococcus aureus*. Patients with one or more yeast species isolated from blood cultures were examined as an additional group. These patients were included in the gram-negative group as well if they also had GNB. Throughout the duration of this review, blood was cultured only for clinical indications of infection.

Table 1. Patient Demographics*

ously open intensive care ward environment. We have documented that the occupation of this new facility was associated with a break in transmission of two on-going endemics. Well-characterized multiple-antibiotic-resistant strains of *Providencia stuartii* and *P aeruginosa* were eliminated by intentional cohort admission of new patients to the new unit. The break in patient-to-patient transmission is thought to have been facilitated by the move and also associated with changes in nurse staffing that limited cross trafficking between patients in their individual rooms.[6,7] Caregivers wore masks, gowns, and gloves while in contact with patients; these covers were removed and hands were washed when exiting patient rooms. A microbial surveillance system was used to document colonization by *P stuartii* and *Pseudomonas* strains, the presence of new resistant organisms, or any apparent cross contamination of patients with such organisms. This information was made available to caregivers so that possible breaks in isolation techniques could be rapidly identified and corrected. We have continued this microbial surveillance as an element of quality improvement.

RESULTS

The predicted number of deaths in the population of 1004 patients with bacteremia was 405. The 95% confidence limits for this estimate were 381 and 429 deaths. The actual number of deaths among the patients with bacteremia was 535, a number well beyond the upper confidence limit. The ratio of observed mortality to predicted mortality was 1.32, a 32% increase above that expected on the basis of extent of injury and age. A comparison of the incidence of gram-negative, gram-positive, and yeast blood isolates for the two time periods is presented in **Table 2**.

Table 3. Incidence of Gram-negative Blood Pathogens in Patients With Burns*

Organism	Cohort Years, No. (%) of Patients 1974-1983	1984-1993	P†

A comparison of the incidence of the five most common gram-negative species in this 20-year period is presented in **Table 3**. As can be seen, all species were significantly less frequent in the second cohort. The incidence of these organisms over a 35-year period at this institution is presented in the **Figure**. Sporadic outbreaks of these pathogens stopped with the opening of the new single-bed unit. The numbers of blood cultures positive for bacteria, and in particular GNB, have been significantly reduced since that time. The incidence of cultures positive for yeast was similar in both groups.

The actual mortality in each of the organism groups was next compared with the predicted mortality. The results for gram-negative organisms are presented in **Table 4**. The predicted mortality was similar in both groups, with that in the later group slightly greater. As can be seen, the actual number of deaths in the open-ward cohort was 61% above that predicted. This result is essentially the same as that described in our earlier report.[1] The mortality associated with GNB in the later group is within the confidence limit of the prediction for patients without blood cultures positive for GNB. The number of postburn days to the first culture positive for GNB in the single-patient-room cohort was found to be more than twice that found in the earlier cohort (28.9 vs 11.8 days, respectively; $P<.001$). Mortality assessment of patients with candidemia is presented in **Table 5**. The increase in mortality associated with candidemia during the first period is similar to our previous finding. The increase in associated mortality was absent in the later group.

The results for patients with only gram-positive bacteremia during their hospitalization are presented in **Table 6**. These results also agree with those of our previous review. Gram-positive bacteremia, when not preceded or followed by cultures positive for GNB or yeast, was not associated with an increase in mortality above that predicted on the basis of extent of burn and age.

COMMENT

Control of infection has been a goal in burn care since the development of the germ theory. There is, however, no consensus on the most appropriate infection control program for serious burns.[8-10] The purpose of this report is not to make specific claims for the design of this burn center or for our institution's specific methods of patient isolation and infection control, but to demonstrate that reduction in the incidence of blood infections has fulfilled a prediction in our previous review. Improvement in control of GNB has been associated with an improvement in mortality comparable to the previous increment in mortality attributable to such infections.

The improvement in outcome for the fewer patients that still become infected with gram-negative organisms is less easy to explain. Early excision, improved ventilation techniques, nutritional support, and other treatments and support techniques continue to improve patient care. It seems possible that the reduction in GNB has reduced a morbid complication that has traditionally clouded the true benefit of improved techniques of physiological support. We have previously reported on the significance of *P aeruginosa* infections during the history of our burn center and have shown that the incidence of *P aeruginosa* infections was reduced and the associated mortality decreased after the use of single-patient rooms.[4,7,11] These differences were associated with a much later postinjury time of infection, which was thought to explain in part the improved survival. Patients with delayed colonization and infection appear to represent a less susceptible patient population in which response to infection is more effective. The delay in time of infection documented in this study allows patients to have a longer exposure to the benefits of such treatments and reach a stage of recovery in which response to infection is more effective. Isolation from cross contamination closes the window of susceptibility to infection and appears to shift the balance between microbial pathogenicity and host resistance in favor of the patient.

DISCUSSION

David N. Herndon, MD, Galveston, Tex: The authors are to be congratulated on this huge and excellent review of infections and morbidity and mortality in burns over 20% total body surface treated at their institution over the last 20 years. Their results are incontrovertible and will serve as a landmark reference for years to come.

The marked decrease in mortality noted in the current decade vs the previous decade has been reported by other observers, including ourselves, and in a recent collection of mortality data from a variety of burn units performed by Saffle and reported at the American Burn Association [Saffle J, Davis B, Sullivan J, Williams P, The American Burn Association Patient Registry. Improved survival from thermal injury: data from the ABA Burn Patient Registry. *Proc Am Burn Assoc.* 1994;26:105]. The other units reporting improvements in survival, in contrast, had no changes in hospital design or infection control procedures in the year 1983, as described by Dr McManus. Rather, they attribute their observed decreases in mortality, which are remarkably similar to the decreases in mortality described here, to improvements in early excision of the burn wound, early enteral feeding with decreased utilization of parenteral hyperalimentation, improved ventilatory support techniques, utilization of perioperative antibiotics, and more aggressive rehabilitation. These advances have contributed, clearly, to a decrease in length of hospital stay—in these reports—for major burns of 50% in the latter decade vs the former decade. Most burn specialists would predict that the greatest contributor to decreased infections and mortality in this decade has not been change of architecture of a burn unit or infection control techniques, but has been early closure of the burn wound.

Have the authors performed a logistic equation using the rate of wound closure as a factor to determine the degree to which this revolutionary and dramatic change in burn care has affected mortality?

Environmental control or single-bed care may indeed be very important issues. However, randomized prospective studies are required to substantiate independent treatment effects.

Dr McManus: Thank you, Dr Herndon, for your questions and discussion. We certainly agree with you that burn care has improved and mortality has decreased throughout the United States during this past decade. In our own particular instance, we noted this same trend and actually a significant improvement in survival and reported it to this Society in 1986, 1 year after the opening of our new unit. Our early excision practices had not changed when that improvement in survival was reported.

I do not want to argue that the differences that we've shown you in infection are completely unrelated to early excision. I think that early excision is perhaps the greatest improvement that has occurred in the treatment of burns since the development of topical antimicrobial burn creams. But in our case, we noted an improvement in survival with the break in the two endemics that were ongoing when we opened this unit.

And as I stated, I do not propose that this paper is to argue for a specific design of a burn unit. I think it does show you that gram-negative infections, as measured by bacteremia, can be controlled by improved patient care and by isolation.

KEYWORDS
Methicillin-resistant *Staphylococcus aureus*; Environmental contamination; Hydrogen peroxide vapour decontamination

Summary The hospital environment can sometimes harbour methicillin-resistant *Staphylococcus aureus* (MRSA) but is not generally regarded as a major source of MRSA infection. We conducted a prospective study in surgical wards of a London teaching hospital affected by MRSA, and compared the effectiveness of standard cleaning with a new method of hydrogen peroxide vapour decontamination. MRSA contamination, measured by surface swabbing was compared before and after terminal cleaning that complied with UK national standards, or hydrogen peroxide vapour decontamination. All isolation rooms, ward bays and bathrooms tested were contaminated with MRSA and several antibiogram types were identified. MRSA was common in sites that might transfer organisms to the hands of staff and was isolated from areas and bed frames used by non-MRSA patients. Seventy-four percent of 359 swabs taken before cleaning yielded MRSA, 70% by direct plating. After cleaning, all areas remained contaminated, with 66% of 124 swabs yielding MRSA, 74% by direct plating. In contrast, after exposing six rooms to hydrogen peroxide vapour, only one of 85 (1.2%) swabs yielded MRSA, by enrichment culture only. The hospital environment can become extensively contaminated with MRSA that is not eliminated by standard cleaning methods. In contrast, hydrogen peroxide vapour decontamination is a highly effective method of eradicating MRSA from rooms, furniture and equipment. Further work is needed to determine the importance of environmental contamination with MRSA and the effect on hospital infection rates of effective decontamination.

Introduction

Infection with methicillin-resistant *Staphylococcus aureus* (MRSA) has become endemic in hospitals around the world despite concerted efforts by infection control professionals.[1] In the UK, the proportion of blood isolates of *S. aureus* that are resistant to methicillin has risen from just a few percent in the late 1980s to over 30%, with rates of over 40% seen in tertiary referral hospitals.[2–4] Similar prevalence rates are reported from other European countries[4] and the US.[5] *S. aureus* is the commonest cause of surgical-site infection in English hospitals, and more than half the infecting strains are methicillin resistant.[6] Nearly all MRSA infections are acquired in hospital and many of them are potentially preventable.[7]

MRSA is transmitted between patients on the hands of hospital staff, and handwashing is widely recognized as the single most important factor for prevention of colonization and infection.[8,9] Nevertheless, despite the implementation of standard infection control practices, the widespread failure to control MRSA is striking.[10] The hospital environment may be another important, but neglected, factor in hospital cross-infection.[11–13]

Since the 1950s, hospital design and hygienic practices have been largely directed at controlling *S. aureus* contamination of air, hands, instruments and surfaces. By the late 1970s these practices had been so successful that the hospital environment was considered to make little contribution to the spread of hospital infection.[14,15] Nevertheless, *S. aureus* and MRSA can survive on dry surfaces for prolonged periods,[12,16–20] and many investigations since the 1980s have shown that these organisms can contaminate surfaces and equipment touched by hospital staff.[12,21–26] Standards of hospital cleaning have declined[11,13,27] and floors, furniture and medical equipment may now be sources of MRSA transmission.[11–13,22]

The current guidelines for the control of MRSA in UK hospitals recognize the potential importance of the environment and recommend terminal cleaning of isolation rooms after patient discharge.[2] In practice, manual cleaning of complex environments containing beds, furniture, medical equipment and soft furnishings is difficult. This problem may be solved by gaseous decontamination methods.

Hydrogen peroxide vapour is effective against a wide range of organisms, including bacterial endospores,[28] vegetative bacteria[29] and viruses.[30] It is safer than other disinfectant gases such as formaldehyde and ethylene oxide, and decomposes to water and oxygen. It has been used to decontaminate laboratory and medical equipment, pharmaceutical manufacturing facilities and animal houses[31–35] but has not previously been applied in healthcare settings. The present study investigated MRSA environmental contamination in a hospital where MRSA infection is common, and compared the effectiveness of standard hospital environmental cleaning with a commercial hydrogen peroxide vapour decontamination system.

Materials and Methods

Setting

This investigation was conducted in a 1200-bed London teaching hospital where MRSA colonization and infection is common. Environmental sampling was conducted on four different wards dealing with vascular, lower gastrointestinal, orthopaedic/plastic and general surgical patients. Environmental decontamination with hydrogen peroxide vapour was conducted on the vascular surgery ward only.

Surface samples were taken from the following locations: ward single side rooms that had recently been used to isolate patients infected or colonized with MRSA; four-bedded ward bays recently used to cohort MRSA patients; the area around the bed of a patient colonized with MRSA who was being barrier-nursed on the open ward; beds on an open ward that were being used to nurse non-MRSA patients; and bathrooms used for MRSA and non-MRSA patients.

Environmental surface sampling and microbiological methods

Cotton tipped sterile swabs (Bibby Sterilin, Stone, Staffordshire, UK) were moistened in sterile brain–heart infusion (BHI) broth (Oxoid, Basingstoke, Hampshire, UK) and used to sample surface areas of approximately 25 cm^2 by standardized swabbing in two directions at right angles. In intervention studies, two adjacent 25 cm^2 areas were sampled, one before and one after the intervention. Between 10 and 25 different sites, chosen to include surfaces

likely to be touched by patient and/or staff hands, were sampled in each room. These included: floor corners and floor areas beside the bed, over-bed tables, bed frames and bed-raising panels, bedside chairs and lockers, door handles, light switches, sink taps, televisions and remote controls.

Swabs were used to inoculate Baird–Parker (BP) agar plates (Oxoid, Basingstoke, Hampshire, UK) incubated at 37 °C for 36 h. Growth was recorded semi-quantitatively: if growth was only within the section of the plate directly inoculated with the swab, it was classified as '+', and growth outside the direct inoculum after streaking out was classified as '++'. Enrichment cultures were made for each sample by incubating swabs in BHI containing 4 mg/L ciprofloxacin (Bayer, Newbury, Hampshire, UK) at 37 °C for 24 h and then plating on to BP plates incubated at 37 °C for 36 h.

Presumptive *S. aureus* colonies were confirmed by coagulase production and mannitol fermentation. The susceptibility of all confirmed isolates was tested by the British Society for Antimicrobial Chemotherapy disk diffusion method[36] against: penicillin, methicillin, gentamicin, neomycin, vancomycin, erythromycin, fusidic acid, tetracycline, linezolid, rifampicin, mupirocin, trimethoprim and ciprofloxacin.

Conventional terminal cleaning

This is defined as environmental cleaning after discharge of an infectious patient. The hospital has protocols and service level agreements in place for this procedure that accord with NHS standards.[27] These do not specify details of cleaning procedures, but in this hospital a solution of detergent sanitizer (GWP 4L, containing 5–15% non-ionic surfactant and 5–15% cationic surfactant, diluted 1:500) (GWP Group, Elland, W. Yorkshire, UK) is used for surface cleaning; bed curtains and linen are removed for laundering; all horizontal surfaces are damp dusted, specifically including window architraves, high and low surfaces, curtain rails, radiators, pipes, door handles, ventilation and air-conditioning grilles and surrounds; furniture is cleaned, specifically including bed frames and mattresses; all surfaces are dried with a disposable cloth; walls are damp-mopped and left to dry; the floor is swept with a dust control mop, then damp mopped with detergent sanitizer; wash basins and taps are cleaned. The cleaning cloths and mop heads are disposable.

Hydrogen peroxide vapour decontamination equipment

The room bio-decontamination system (BIOQUELL PLC, Andover, Hampshire, UK) consists of four portable modules: the Clarus™ R hydrogen peroxide gas generator, the Clarus™ R2 aeration unit, an instrumentation module and a control computer. The Clarus™ R is placed within the room and evaporates 30% (w/w) liquid hydrogen peroxide (Fisher Chemicals, Loughborough, Leicestershire, UK). The resulting hydrogen peroxide vapour is delivered via a dual axis vapour distribution system that ensures high kinetic energy and even distribution throughout the room. The gas concentration, temperature and relative humidity are measured by the instrumentation module and monitored by a control computer situated outside the room. When decontamination is complete, Clarus™ R2 aeration units inside the room catalytically convert the hydrogen peroxide vapour into water and oxygen.

Room decontamination process

Four single ward side rooms of approximately 35.0 m^3 in volume (two with en-suite toilet cubicles of approximately 4.0 m^3), which had recently housed patients infected or colonized with MRSA, were decontaminated with hydrogen peroxide vapour after the patients had left but before terminal cleaning. The side rooms each contained a bed and other hospital furniture. A shower room dedicated to MRSA patients (13.2 m^3) and a bathroom (45.4 m^3) shared by MRSA and non-MRSA patients, were also decontaminated. The shared bathroom was split into three sections: a communal area leading to two bathrooms, one for MRSA patients and one for other patients. In the communal area there were two shared hoists but one sling was reserved for MRSA patients.

After the decontamination equipment had been set up in the room, the inlet and outlet vents of the air-conditioning system and the door were sealed with adhesive tape. A portable hydrogen peroxide sensor [Portasens II, ATI (UK) Ltd, Ashton-under-Lyne, UK] was used to monitor hydrogen peroxide gas concentrations in adjacent areas outside the room and to verify the absence of hydrogen peroxide in the room at the end of decontamination.

Biological indicators (BIs)

BIs, consisting of $>1 \times 10^6$ *Bacillus stearothermophilus* spores dried on stainless steel disks sealed in Tyvek pouches (Apex Laboratories Inc., Apex, USA), were hung at four points around the room before decontamination. After decontamination, the BI disks were removed and cultured according to the manufacturer's instructions.

Results

MRSA environmental contamination in ward side rooms, bays and bathrooms before terminal cleaning

Three hundred and fifty-nine swabs were taken before cleaning from 18 ward side rooms, two four-bedded ward bays and four bathrooms recently occupied or used by patients infected or colonized with MRSA (15 of the 18 patients in the side rooms were infected with MRSA and three were colonized). MRSA was recovered from every side room, bay and bathroom. Seventy-four percent of swabs yielded MRSA; 70% of positive cultures were by direct plating and 30% by broth enrichment (Table I).

Four (50%) of eight sites in the non-MRSA patient bathroom and six (67%) of nine sites in the communal bathroom area yielded MRSA. The communal area contained two patient hoists, both of which were positive for MRSA.

Single swabs were also taken from the frames of 23 beds on an open ward that were being used to nurse non-MRSA patients. Forty-three percent of the bed frames yielded MRSA; 50% by direct plating. A 24th bed had been removed, but a swab from the floor area of that bed space yielded MRSA on enrichment culture.

MRSA environmental contamination in ward side rooms and bays after terminal cleaning

Two hundred and forty-eight swabs were taken from adjacent sites matched before and immediately after terminal cleaning in eight side rooms and two bays. Ninety percent of swabs from the matched sites yielded MRSA before cleaning; 78% by direct plating. Sixty-six percent of swabs from the matched sites yielded MRSA after cleaning; 74% by direct plating (Table I). In addition, nine of 10 swabs taken after terminal cleaning from the bed area of a patient who had been barrier-nursed on the open ward were positive for MRSA; seven by direct plating.

Hydrogen peroxide vapour decontamination

The complete process of room decontamination took an average of 5 h, with the aeration phase often run overnight for convenience. A typical cycle maintained a concentration of approximately 500 ppm of hydrogen peroxide vapour for 40 min. The ambient temperature and relative humidity ranged from 26–28 °C and 35–50%, respectively. Hydrogen peroxide was not detected in the corridors outside the rooms being decontaminated, nor in the rooms themselves after decontamination. Gas concentrations up to 10 ppm were detected in the ceiling voids in adjacent rooms, but no more than 1 ppm at head height (data not shown). These low levels did not persist because of air circulation and gas decomposition, and are within the UK Health and Safety Executive exposure limits.[37] Exposure to hydrogen peroxide vapour within the rooms killed all *B. stearothermophilus* BIs (data not shown).

MRSA contamination in ward side rooms and bathrooms before and after decontamination with hydrogen peroxide vapour

Before decontamination, 61 (72%) of 85 sites were positive for MRSA; 72% by direct plating. After exposure to hydrogen peroxide vapour, only one (1.2%) of the 85 sites (a floor corner in one of the

[d] Four single isolation rooms, two bathrooms.

rooms) yielded MRSA, by selective broth enrichment (Table I).

Antibiotic sensitivity patterns of MRSA environmental isolates

There were 23 antimicrobial susceptibility patterns amongst the 380 MRSA environmental isolates. The most common pattern (in addition to resistance to penicillin and methicillin) was resistance only to erythromycin, ciprofloxacin and neomycin, which was seen in 159 (42%) of isolates (Table II).

Most of the environmental MRSA isolates had the same antimicrobial susceptibility pattern as the strain isolated from the previous patient occupant. However, in the eight side rooms with matched sampling sites, a mean of 2.3 different susceptibility patterns were found in rooms before conventional cleaning and 1.4 after (Table II). There was greater diversity amongst isolates from sites outside the isolation rooms: four patterns were found amongst the 10 isolates from the bed frames on the open ward, four amongst the 14 isolates from the shared bathroom, and a mean of 3.5 patterns amongst isolates from the two MRSA bays sampled before conventional cleaning and 2.5 after (data not shown).

Discussion

We found extensive surface environmental contamination with MRSA in ward areas previously occupied by colonized or infected patients. The level of contamination was much higher than that reported by Boyce *et al*. (1997)[22] who used similar culture methods and found 27% of 350 environmental surfaces around MRSA patients to be contaminated compared with 74% of 359 in our study. Boyce *et al*. (1997)[22] identified MRSA in 73% of 22 rooms of infected patients and 69% of 16 rooms of colonized patients, whereas we found MRSA in all the rooms sampled, regardless of patient status.

Contamination of isolation rooms is not surprising, and it is usually supposed that the patient contaminates the room rather than the other way around. However, in the present study we found that side rooms were often contaminated with more than one antibiogram-type of MRSA, suggesting survival of MRSA strains from previous room occupants. Similarly, four MRSA types were contaminating 43% of 23 beds in an open ward not currently being used to nurse MRSA patients and four types were found in a shared bathroom facility.

Contaminated environmental surfaces that are commonly touched by patients and/or staff may act as sources for hand transfer. In support of this, Boyce *et al*.[22] demonstrated that five (42%) of 12 nurses contaminated their gloves with MRSA while performing activities that required no direct patient contact but involved touching objects in the rooms of MRSA patients. Oie *et al*.[26] found MRSA on the door handles of 19% of 21 rooms MRSA patients but also on 7% of door handles of 175 non-MRSA rooms. In our study, MRSA was found before

Table II Antibiotic susceptibility patterns of MRSA environmental isolates (number of isolates and percentage in brackets)

Antibiotic sensitivity pattern	Total[a]	Matched before cleaning[b]	Matched after cleaning[b]
MET,E,CIP,N	159 (41.6)	51 (45.9)	28 (34.1)

Total	380	111	82
Mean number of patterns: per room	-	2.3	1.4
per bay	-	3.5	2.5

MET, methicillin (methicillin resistance results in penicillin resistance); E, erythromycin; CIP, ciprofloxacin; N, neomycin; W, trimethoprim; CN, gentamicin; TE, tetracycline; MUP, mupirocin; RD, rifampicin; FD, fusidic acid.

[a] Represents all MRSA environmental isolates throughout the study period.

[b] Represents MRSA isolates from adjacent sites matched before and immediately after terminal cleaning in eight side rooms and two bays.

cleaning on 59% of 27 door handles and 33% of nine sink taps. We also found MRSA on other sites commonly touched by staff, such as bed-raising control panels, light switches and patient hoists.

In the present study, standard methods of terminal cleaning that complied with current NHS guidelines were ineffective in eliminating MRSA: 74% of environmental swabs yielded MRSA before cleaning and 66% after. All the rooms yielded MRSA from some sites. There is other published evidence that terminal cleaning is poorly effective: Blythe *et al*.[23] found that 46% of 41 isolation rooms remained contaminated with MRSA after cleaning, and Byers *et al*.[38] found that 16% of 376 environmental sites in a single room after cleaning remained contaminated with vancomycin-resistant enterococci (another organism that can contaminate the hospital environment).

In contrast, hydrogen peroxide vapour decontamination was highly effective in eradicating environmental MRSA. Before decontamination, 72% of room swabs yielded MRSA; afterwards, only one of 85 samples (1.2%) yielded MRSA, and then only by enrichment culture. Although the present decontamination cycles take 5 h in total, it is likely that this will be reduced with further optimization.

In conclusion, we found heavy and extensive environmental contamination with MRSA in a hospital caring for many infected and colonized patients. The distribution of this contamination and the isolation of multiple strains suggest that the environment may be an important source of hospital cross-infection. Standard terminal cleaning had little impact on this contamination while the hydrogen peroxide vapour decontamination system was very effective. This gaseous method is particularly useful for decontaminating complex furniture and equipment that is difficult to clean manually. The system can be used to decontaminate entire wards if necessary, but as rooms have to be vacated before gassing, it would normally be limited to the decontamination of smaller vacant rooms and bathrooms. However, furniture, bedding and medical equipment could be temporarily removed from the general ward environment and processed in a dedicated decontamination unit. Other nosocomial pathogens can survive in the hospital environment[11,12,39] and are also potential targets for hydrogen peroxide vapour decontamination.

Further investigation of the clinical significance of hospital environmental contamination and of more effective cleaning methods are required. This should include evaluation of the impact on hospital infection rates of chemical disinfectants for surface cleaning and hydrogen peroxide vapour for decontamination of rooms and equipment.

Acknowledgements

We acknowledge the helpful cooperation of the staff and patients on the wards involved in this study. The study was supported financially by BIOQUELL PLC, who were involved in the conception, design and execution of the research project. All aspects of the study were conducted collaboratively.

ABSTRACT

The aim of this study was to investigate the impact of polymicrobial bloodstream infections (pBSIs) on the outcome of sepsis in an area where antimicrobial resistance is of concern. This was a retrospective analysis of data collected prospectively from patients developing BSI outside of an intensive care unit (non-ICU patients) or after ICU admission. Demographics and clinical characteristics were compared for patients with pBSI versus monomicrobial BSI (mBSI) and following stratification by ICU or non-ICU and severity of sepsis status. Possible risk factors for adverse outcome were explored by multivariate analysis, and outcomes were measured by Cox regression analysis. Among 412 patients with BSI, 47 patients (11.4%) with pBSI were recorded; compared with patients with mBSI, they had significantly higher APACHE II scores and presented more frequently with severe sepsis/septic shock. The all-cause 28-day mortality was significantly higher for pBSI versus mBSI (38.3% vs. 24.7%; $P = 0.033$), whereas appropriateness of treatment was comparable (78.7% vs. 86.6%). Primary bacteraemia by combinations of *Enterococcus faecalis*, *Klebsiella pneumoniae* and *Acinetobacter baumannii* was predominant among pBSIs; in mBSIs, urinary tract infections by *Escherichia coli*, *K. pneumoniae* or *Pseudomonas aeruginosa* predominated. Multivariate analysis demonstrated pBSI as a significant contributor to 28-day mortality (HR = 1.86; $P = 0.039$), along with presence of two or more co-morbidities (HR = 2.35; $P = 0.004$). In conclusion, pBSIs differed epidemiologically from mBSIs, with the emergence of enterococcal species, and portended an almost two-fold increased risk of 28-day mortality. Prospective studies are warranted to elucidate possibly modifiable factors.

1. Introduction

Severe sepsis and septic shock are recognised among the leading causes of morbidity, for which the pathophysiology is still poorly understood [1,2]. Polymicrobial infections could reflect single or multiple infectious sites with only scarce data available on their epidemiology or underlying mechanisms. Furthermore, the impact of polymicrobial causality on outcome has not been fully investigated; most of the available data derive from patients with bloodstream infections (BSIs) and particularly from the intensive care unit (ICU) setting. However, no clear-cut answer is provided on whether the prognosis of polymicrobial infections is worse than that of monomicrobial infections [3–7].

Quite often, the golden hour before ICU admission is 'spent' in medical wards [8,9]. Therefore, focusing on the epidemiology of sepsis before ICU admission could have possible implications in improving the ultimate outcome of patients [8]. In the present study, we describe the epidemiology of microbiologically documented septic episodes in a multicentre, mixed cohort of ICU and non-ICU patients. The primary endpoint was to define differences in final outcome between septic bacteraemic episodes of polymicrobial origin compared with those of monomicrobial origin. As a secondary endpoint, we sought to investigate differences in epidemiology between polymicrobial and monomicrobial BSIs in this cohort in view of an established prevalence of multidrug-resistant Gram-negative pathogens in Greek hospitals [10].

2. Patients and methods

Data collected prospectively between January 2007 and May 2011 from 35 centres across Greece were analysed. Data for 2627 patients were available in the database of the Hellenic Sepsis Study Group (HSSG); analysis was restricted to patients with bacteraemic infections. Patients were divided into those developing sepsis after ICU admission (ICU patients) and those either admitted into hospital with sepsis or developing sepsis in the general ward without being transferred to the ICU (non-ICU patients).

Inclusion criteria were: (a) age $\geq$18 years; (b) sepsis, severe sepsis or septic shock due to either acute pyelonephritis, lower respiratory tract infection, intra-abdominal infection (IAI) or primary bacteraemia; and (c) recovery of the offending pathogen from blood cultures. Exclusion criteria were: (a) infection by human immunodeficiency virus (HIV); (b) neutropenia, defined as an absolute neutrophil count $<500/mm^3$; (c) chronic intake of corticosteroids, defined as any daily oral intake of $\geq$1 mg/kg of equivalent prednisone for $>$1 month; and (d) denial to inform consent.

Written informed consent was provided by the patients or by their first-degree relatives for patients unable to consent. The study protocol was submitted to and approved by the Ethics Committees of the hospitals of the participating centres. Every patient was enrolled once in the study.

2.1. Definitions

Sepsis, severe sepsis and septic shock were defined according to established criteria [2,11]. The major infections possibly leading to secondary bacteraemia, namely acute pyelonephritis, community-acquired pneumonia (CAP), hospital-acquired and ventilator-associated pneumonia (HAP/VAP) and acute intra-abdominal infection (IAI), were diagnosed according to established criteria [12–15].

Primary bacteraemia was diagnosed for patients presenting with both of the following: (a) peripheral blood culture positive for Gram-positive or Gram-negative bacteria; and (b) absence of any alternative site of infection consistent with the pathogen cultured in blood. Isolates of coagulase-negative staphylococci or of skin flora isolated from single blood cultures were not considered pathogenic [11]. Polymicrobial BSI refers to an infection in which more than one micro-organism was recovered from the same blood culture.

Patients were followed-up for 28 days and outcome was recorded. For every patient, a complete diagnostic work-up was performed at the discretion of the treating physician comprising history, thorough physical examination, blood cell counts, blood biochemistry, blood gases, blood culturing from peripheral and central lines, urine cultures, chest radiography, and chest and abdominal computed tomography or ultrasound if considered necessary. Co-morbidities captured in the database were type 2 diabetes mellitus, chronic obstructive pulmonary disease, chronic renal disease, chronic heart failure, solid tumour malignancy and chronic intake of corticosteroids; patients with the latter co-morbidity, as defined above, were excluded from the current analysis.

Definite antimicrobial therapy administered to the patient was considered appropriate when at least one of the administered agents was active on the isolated pathogen or pathogens according to the antibiogram.

2.2. Statistical analysis

The database of the HSSG was screened for clinically and microbiologically documented BSIs and the retrieved cases were grouped as either monomicrobial or polymicrobial. Analyses were performed for the basic demographic characteristics of each group, the type and adequacy of the initial empirical antibiotic regimen, and the type of hospitalisation (wards versus ICU).

Survival was estimated by Kaplan–Meier analysis; comparisons were done by the log-rank test. For quantitative variables shown to have a normal distribution by Kolmogorov–Smirnov's statistics, data were reported by mean $\pm$ standard deviation; comparisons between such groups were done by the Student's *t*-test.

Alternatively, the Wilcoxon rank-sum test was used. Comparisons between groups for qualitative data were done by χ^2 test or Fisher's exact test when appropriate. Receive operator characteristic (ROC) curve analysis was performed for numerical variables to define a threshold that significantly affected mortality. Cox regression analysis was done to disclose the impact on survival of the presence of polymicrobial BSI and other independent variables demonstrated in the univariate analysis. Hazard ratios (HRs) and 95% confidence intervals were calculated. A *P*-value of $<$0.05 was considered statistically significant.

2.3. Microbiological studies and resistance breakpoints

Identification of pathogens was performed using standard microbiological methods according to each hospital's procedures. The disk diffusion method or automated systems [VITEK® 2 (bioMérieux Inc., Durham, NC) or Phoenix (BD Diagnostics, Inc., Sparks, MD)] were used for all tested antibiotics according to the most recent recommendations of the Clinical and Laboratory Standards Institute (CLSI) [16]. When an automated system was not available, susceptibilities of pathogens to colistin and tigecycline were also tested by Etest (AB BIODISK, Solna, Sweden). Extended-spectrum β-lactamase production was determined by the double-disk test, metallo-β-lactamase production was confirmed by the ethylene diamine tetra-acetic acid (EDTA) synergy test, and KPC enzyme production was screened by the boronic acid double-disk test. Urine and respiratory cultures were performed quantitatively [17].

3. Results

A total of 2627 patients with sepsis were screened and data for 412 patients with bacteraemic infections were entered into the analysis; in 47 (11.4%) of them the bacteraemic episode was polymicrobial. The studied population was distributed as 132 ICU patients and 280 non-ICU patients. Demographic characteristics of the patients stratified by the presence of monomicrobial or polymicrobial BSIs are presented in Table 1. Patients with polymicrobial bacteraemia significantly more often had severe sepsis/septic shock compared with patients with monomicrobial bacteraemia as well as higher Acute Physiology and Chronic Health Evaluation (APACHE) II scores. Adequacy of administered treatment and co-morbidities did not have statistical differences among patients with polymicrobial versus monomicrobial BSIs. Similarly, ICU or non-ICU admission was not associated with significant differences in either the frequency of polymicrobial BSIs or the appropriateness of administered antibiotics (Table 1).

The most common causative pathogens isolated from polymicrobial BSIs were *Enterococcus faecalis* (20.4%), *Klebsiella pneumoniae* and *Acinetobacter baumannii* (12.2% each), whereas *Escherichia coli* was by far the predominant pathogen in monomicrobial BSIs (32.9%) followed by *K. pneumoniae* (19.7%) and *Pseudomonas aeruginosa* (9.3%) (Table 2). The most common combinations in polymicrobial bacteraemias were as follows: *A. baumannii* + *Enterococcus* spp. (6 cases, equally distributed between *E. faecalis* and *Enterococcus faecium*), *E. faecalis* + Enterobacteriaceae (6 cases, equally distributed between *E. coli*, *Proteus mirabilis* and *Enterobacter cloacae*), combinations of Enterobacteriaceae (4 cases, *P. mirabilis* with either *E. coli* or *K. pneumoniae*), *K. pneumoniae* + *A. baumannii* (4 cases) and *K. pneumoniae* + *P. aeruginosa* (3 cases). The majority of polymicrobial bacteraemias were primary BSIs (38.3%); the urinary tract was the most common source of secondary bacteraemia (27.7%) followed by IAI and VAP. Monomicrobial BSIs where equally distributed as primary bacteraemias (37.5%) and BSI secondary to urinary tract infections (37.5%), followed by IAI (8.2%) (Table 1).

The all-cause 28-day mortality of the cohort was 26.2%; monomicrobial BSIs were associated with a mortality rate of 24.7% and the respective rate for polymicrobial BSIs was 38.3% ($P = 0.033$) (Fig. 1). Mortality varied ($P = 0.071$) according to the type of recovered pathogen (i.e. Gram-negative, Gram-positive, fungal and possible combinations), being highest when a combination of Gram-negative with Gram-positive isolate was recovered (mortality 50.0%) and lowest when a Gram-negative isolate was recovered along with a fungal pathogen (mortality 16%). Gram-negative bacteraemia was associated with lower mortality compared with pooled all other types of bacteraemia (23.8% vs. 36.8%; $P = 0.020$). However, when outcomes were stratified by the presence of polymicrobial infection, polymicrobial BSIs containing at least one Gram-negative isolate had similar mortality to all other types of bacteraemia (38.9% vs. 37.9%; not significant). No differences in adequacy of administered treatment

Table 2
Microbiology of enrolled patients with bacteraemia.

Pathogen	No. (%) of isolates	
	Monomicrobial infections	Polymicrobial infections
Escherichia coli	120 (32.9)	9 (9.2)
Klebsiella pneumoniae	72 (19.7)	12 (12.2)
Pseudomonas aeruginosa	34 (9.3)	9 (9.2)
Acinetobacter baumannii	25 (6.8)	12 (12.2)

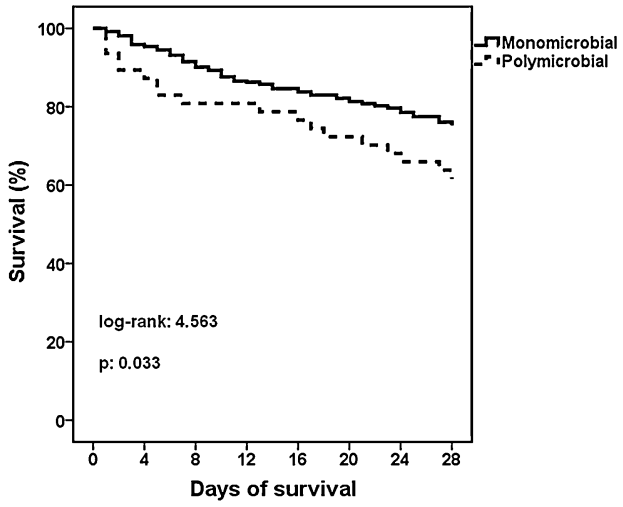

Fig. 1. Survival curves of patients with bacteraemic sepsis enrolled in the study. Patients were divided into those with bacteraemia of monomicrobial and polymicrobial causality.

were demonstrated between bacteraemias containing Gram-negative pathogens compared with all other types of bacteraemia (85.4% vs. 86.5%; not significant).

After ROC curve analysis for age, it was identified that age ≥61 years was related to unfavourable outcome at 80% sensitivity. To this end, a nominal age variable was generated with patients aged <61 years and ≥61 years.

Mortality per infectious source was distributed as follows: acute pyelonephritis, 16.3%; CAP, 35.7%; IAIs, 27.0%; primary bacteraemia, 27.7%; VAP, 48.6%; and HAP, 66.7%. To this end, another nominal variable was generated where patients with CAP, VAP and HAP were grouped together as sufferers from high-mortality infections and patients with acute pyelonephritis, primary bacteraemia and IAIs were grouped together as sufferers from low-mortality infections. In a similar way, it was found that the presence of at least two co-morbidities was linked with unfavourable outcome. Data from the univariate analysis are shown in Table 3.

Finally, all nominal variables representing independent predictors of mortality were entered into one model and Cox regression analysis for unfavourable outcome was selected. As presented in Table 4, only the presence of polymicrobial bacteraemia and the presence of at least two co-morbidities retained statistical significance in the final model and represent the most significant drivers of mortality in the studied population.

4. Discussion

This is one of the first current studies focusing on polymicrobial bacteraemic sepsis in a mixed cohort of ICU and non-ICU patients. According to the results, polymicrobial BSIs were associated with higher APACHE II score and, not unexpectedly, were more likely to express as severe sepsis and/or septic shock. In contrast to the majority of published studies, polymicrobial BSIs were associated with significantly lower 28-day survival compared with the monomicrobial counterparts. The multivariate analysis enabled us to demonstrate only two factors as major contributors to adverse outcome; polymicrobial bacteraemia (HR = 1.86) and the presence of two or more underlying co-morbidities (HR = 2.35). Notably, none of the demonstrated factors is modifiable. In this cohort, 38.3% of polymicrobial BSIs were attributed to primary bacteraemias, with *E. faecalis* being the most prevalent pathogen; these data in the absence of an intra-abdominal focus are indicative of an underlying mechanism of translocation from the gut, which again could represent the epiphenomenon of severe sepsis and not the cause [18].

The least contribution of Gram-negatives in the mortality of the studied population was an unexpected finding. Gram-negatives were predominant in the arm of monomicrobial BSIs and their rank of order was in accordance with other published articles from Greece as well as with the WHONET national registry [10,19]. Multidrug-resistant Gram-negative pathogens have been predominant in nosocomial infections in Greece for almost a decade [10]. Awareness of this particular epidemiology has probably allowed for high rates of appropriate treatment in the current cohort including ICU and no-ICU settings; therefore, it could explain why inappropriate treatment was not demonstrated as a contributor to mortality. The lower mortality of Gram-negative monomicrobial BSIs, originating in the main from urinary infections, might be attributed to an earlier administration of adequate treatment. However, timing of administration of antimicrobials was not recorded in the database, therefore such an explanation remains speculative.

The elucidation of 'other than Gram-negative' pathogens as contributors to mortality in polymicrobial BSIs, along with the high prevalence of *E. faecalis* in this group, was also unexpected. In 2010, according to the national registry WHONET, *Enterococcus* spp. ranked sixth among BSI pathogens both in ICU and medical wards, representing 4.8% and 6.8% of bacteraemic episodes, respectively. These data are in accordance with the monomicrobial BSIs registered in the current study. In this context, the high prevalence of *E. faecalis* observed in polymicrobial BSIs without a demonstrated intra-abdominal source warrants further investigation.

An originality of this study was the addition of information related to the management of septic episodes outside the ICU setting, for which the literature is limited [8,20,21]. ICU studies possess a complexity of definitions and factors affecting outcomes that preclude direct application of conclusions to the non-ICU patient. Therefore, given the expanding population of critically ill patients treated in hospital wards, studies of sepsis outside the ICU have gained importance [8].

Three large publications from the 1980s on nosocomial BSIs did not elucidate worse outcomes associated with polymicrobial infections compared with monomicrobial counterparts. They all pointed out the severity of the underlying disease and various

Table 3

other parameters expressing the severity of the septic episode per se (e.g. respiratory failure, haemolysis, etc.) as predictors of mortality [22,23]. The same applies for a recent study by Aliaga et al. comparing monomicrobial with polymicrobial BSIs implicating *P. aeruginosa* [24]. Interestingly, in the current study the true contribution of polymicrobial infections to 28-day mortality was clearly demonstrated only when sepsis/septic shock were omitted from the multivariate analysis. Publications supporting our observation that polymicrobial infections are associated with worse outcome are limited to two sequential studies by Pittet et al. on nosocomial BSIs in the period 1986–1991 [4,5] as well as a third study among cancer patients where polymicrobial BSIs had a 50% response rate compared with 60–94% for monomicrobial BSIs [25].

A recent study in an ICU population by Sancho et al. reported that polymicrobial BSIs had a similar frequency of species compared with monomicrobial BSIs and did not contribute to mortality, although they were associated with prolonged ICU and hospital stay [26]. The most prevalent pathogens in polymicrobial infections were 'high-risk' micro-organisms, namely non-*E. coli* Enterobacteriaceae, *P. aeruginosa* and *Candida* spp., and were strong predictors of mortality. The authors reported that APACHE II score at the onset of BSI and septic shock were predictors of related mortality, but polymicrobial BSI and inadequate empirical antimicrobial treatment were not [26]. In that study, the respiratory tract was by far the most common source of polymicrobial bacteraemia, whereas in the current study primary bacteraemia was predominant. In both studies the percentage of IAI was very low among polymicrobial bacteraemias, despite the results of other series of patients [20,22,23] (Table 1). It is worth mentioning that both studies have elucidated the increased prevalence of *E. faecalis* among polymicrobial BSIs.

A factor potentially contributing to worse outcomes in the context of polymicrobial sepsis could be the inappropriateness of the antibiotic therapy. Its significance has been clearly demonstrated in ICU studies [27,28]. In contrast, in studies with mixed ICU and non-ICU populations the significance of inappropriate antimicrobial treatment waned, probably because the non-ICU populations were less severely ill [8,29]. Only one study to our knowledge has demonstrated a clear association of inappropriate treatment with polymicrobial infection, among other factors [30]. As mentioned above, high rates of appropriate treatment encountered both in monomicrobial and polymicrobial BSIs (86.6% and 78.7%, respectively) in the current study could explain why appropriateness of treatment was not demonstrated as a contributor to mortality in the multivariate model. According to the majority of published reports, appropriateness was in the range of 30–46% [28].

However, a limitation of this study is that the database did not capture the time elapsed between the advent of sepsis and the onset of antimicrobials. Moreover, adequacy of treatment used in this analysis represents definite treatment, and institution-specific variations may have influenced the speed of distribution of antibiograms and the length of 'empirical' treatment. Another limitation is the lack of data regarding chronic liver failure and cirrhosis, a factor that could potentially be related to polymicrobial bacteraemia and worse outcomes. On the other hand, the multicentre design is probably among the strengths of this study as it allowed an estimation of a wide population of 2627 critically ill patients and a comparison between ICU and non-ICU-admitted counterparts. It also allowed for a representative estimation of the country, as reflected by the epidemiological concordance with the national registry WHONET.

5. Conclusion

The results of this analysis encompassing ICU and non-ICU patients demonstrated that the presence of polymicrobial bacteraemia almost doubled the risk of death in this cohort, whereas the presence of two or more underlying co-morbidities was associated with a more than two-fold risk. An emerging role of enterococci was also demonstrated in this setting. The true significance of these observations, as well as the possible contribution of other factors such as the adequacy and timely administration of antimicrobial treatment, warrant further investigation in prospective purpose-structured studies.

Funding

This study was funded by the Hellenic Institute for the Study of Sepsis.

Competing interests

HG has served as a board member and/or consultant for Pfizer, Novartis, Merck (USA) and Durata-Achaogen, has received grants/grant pending from Pfizer, Novartis, Merck (USA) and Durata-Achaogen, has received payment for lectures including service on speakers bureaus from Pfizer and Novartis, and has received travel/accommodations/meeting expenses from Novartis, Janssen and Pfizer. INFECTION CONTROL AND HOSPITAL EPIDEMIOLOGY SEPTEMBER 2006, VOL. 27, NO. 9

ORIGINAL ARTICLE

Exogenous Sources of *Pseudomonas aeruginosa* in Intensive Care Unit Patients: Implementation of Infection Control Measures and Follow-Up With Molecular Typing

Christiane Petignat, MD; Patrick Francioli, MD; Immaculée Nahimana, MD; Aline Wenger, MSc; Jacques Bille, MD, Marie-Denise Schaller, MD; Jean-Pierre Revelly, MD; Giorgio Zanetti, MD; Dominique S. Blanc, PhD

BACKGROUND. In 1998, a study in the intensive care unit (ICU) of our institution suggested possible transmission of *Pseudomonas aeruginosa* from faucet to patient and from patient to patient. Infection-control measures were implemented to reduce the degree of *P. aeruginosa* colonization in faucets, to reduce the use of faucet water in certain patient care procedures, and to reduce the rate of transmission from patient to patient.

OBJECTIVE. To evaluate the effect of the control measures instituted in 1999 to prevent *P. aeruginosa* infection and colonization in ICU patients.

DESIGN. Prospective, molecular, epidemiological investigation.

SETTING. A 870-bed, university-affiliated, tertiary care teaching hospital.

METHODS. The investigation was performed in a manner identical to the 1998 investigation. ICU patients with a clinical specimen positive for *P. aeruginosa* were identified prospectively. Swab specimens from the inner part of the ICU faucets were obtained for the culture on 9 occasions between September 1997 and December 2000. All patients and environmental isolates were typed by pulsed-field gel electrophoresis (PFGE).

RESULTS. Compared with the 1998 study, in 2000 we found that the annual incidence of ICU patients colonized or infected with *P. aeruginosa* had decreased by half (26.6 patients per 1,000 admissions in 2000 vs 59.0 patients per 1,000 admissions in 1998), although the populations of patients were comparable. This decrease was the result of the decreased incidence of cases in which an isolate had a PFGE pattern identical to that of an isolate from a faucet (7.0 cases per 1,000 admissions in 2000, vs 23.6 per 1,000 admissions in 1998) or from another patient (6.5 cases per 1,000 admissions in 2000 vs 16.5 cases per 1,000 admissions in 1998), whereas the incidence of cases in which the isolate had a unique PFGE pattern remained nearly unchanged (13.1 cases per 1,000 admissions in 2000 vs 15.6 cases per 1,000 admissions in 1998).

CONCLUSIONS These results suggest that infection control measures were effective in decreasing the rate of *P. aeruginosa* colonization and infection in ICU patients, confirming that *P. aeruginosa* strains were of exogenous origin in a substantial proportion of patients during the preintervention period.

Infect Control Hosp Epidemiol 2006; 27:953-957

Pseudomonas aeruginosa is a common cause of infections in intensive care unit (ICU) patients.[1] It is ubiquitous in the environment but can also be part of the endogenous flora of hospitalized patients.[2] Recent studies have shown, using molecular typing methods, that environmental sources, such as sinks, tap water, and medical devices, can play a major role in outbreaks.[3-6] On the other hand, sporadic or endemic infections have generally been considered to originate mainly from the endogenous flora.[3,7-9]

In a previous molecular epidemiological investigation, we reported that acquisition of *P. aeruginosa* from exogenous sources was also an important cause of infection and colonization in ICU patients during a nonepidemic period.[10] The aim of the present study was to evaluate the efficacy of several control measures implemented to decrease the acquisition of *P. aeruginosa* from exogenous sources among ICU patients.

METHODS

This prospective, molecular, epidemiological investigation was performed at the University Hospital of Lausanne (Lausanne, Switzerland), which is an 870-bed tertiary care hospital that opened in 1982. The ICUs of the University Hospital of

From Hospital Preventive Medicine (C.P., P.F., I.N., G.Z., D.S.B.), the Institute of Microbiology (A.W., J.B.), the Medical Intensive Care Unit (M.-D.S.), and the Surgical Intensive Care Unit (J.-P.R.), University Hospital of Lausanne, Lausanne, Switzerland.

Lausanne are located on the same floor but have 2 distinct water distribution networks: the surgical, burn, and pediatric ICUs have one water network, and the medical ICUs have another. Only faucets used for direct patient care were investigated in this study.

Patients were included in the study if they were hospitalized in one of the ICUs and had at least 1 culture of a clinical sample that yielded *P. aeruginosa*. There was no routine bacteriological screening of the patients during the study period. Demographic and epidemiological data (unit and room of hospitalization and dates of admission and discharge) were retrieved from the hospital information system.

Investigation of the water system was performed on 9 occasions (September 1997; January, June, and December 1998; January, May, and December 1999; and July and December 2000). Each faucet was dismantled and the hot-cold water mixing chamber was swabbed. Swab specimens were plated on blood and cetrimide agar plates and incubated at 35°C for 2 days. Growth of *P. aeruginosa* was evaluated semiquantitatively by the streaking method (rare, growth in the first quadrant; few, growth in the second quadrant; moderate, growth in the third quadrant; many, growth in the fourth quadrant).

Molecular typing was performed by means of pulsed-field gel electrophoresis (PFGE) as described elsewhere.[11] In brief, plugs of genomic DNA were digested with the restriction enzyme *Spe*I, and electrophoresis was performed (with the CHEF DR III system; BioRad) at a voltage of 6 V/cm at 12°C for 24 hours with a linear pulse time of 1 to 36 seconds. The PFGE profiles were analyzed with the BioNumerics software, version 3.5 (Applied Maths). On the basis of results of a previous study on the stability of PFGE patterns of *P. aeruginosa* isolates from patients with cystic fibrosis,[11] we considered 2 isolates to be genetically similar if the number of discordant fragments was fewer than 7. In 1998, we found that typing of isolates from the same environmental specimen that had similar colony morphologic features always revealed identical genotypes. On the basis of these results, for each specimen, 1 isolate per colony morphology was typed in 2000. For 10 patients in 1998 and 9 patients in 2000, *P. aeruginosa* isolates were not available for typing.

A case of colonization or infection was defined as isolation of a given genotype of *P. aeruginosa* from a clinical specimen during a patient's stay in an ICU. Thus, recovery of isolates with 2 different genotypes from a single patient was considered to be 2 cases. The cases were categorized into 3 groups according to molecular typing data. Group A comprised cases in which the isolate had a genotype identical to that of an isolate recovered from a faucet. Group B comprised cases in which the isolate had a genotype identical to that of an isolate recovered from at least 1 other patient but not recovered from the faucets. Group C comprised cases in which the isolate had a unique genotype. Patient-to-patient transmission was considered possible if isolates with indistinguishable PFGE patterns were recovered from patients hospitalized during overlapping periods in the same ICU, and an epidemiological cluster was defined as 2 or more such cases.

In 1999, control measures were taken to reduce the reservoir and the rate of transmission of *P. aeruginosa*. These measures were as follows: (1) an attempt to eradicate *P. aeruginosa* in faucets by increasing the water temperature or by copper and silver ionization (these measures were primarily taken to control *Legionella* contamination),[10] (2) replacement of tap water by *P. aeruginosa*–free bottled water for patient use (ie, to drink and as mouthwash), and (3) reinforcement of standard precautions and hand disinfection with an alcohol solution instead of disinfectant soap. Before the intervention, the water temperature was 50°C at the distribution source and 38°C-45°C at the faucets; after the intervention, it was 65°C at the source and 50°C-58°C at the faucets.

The 1998 annual incidences of patients with clinical specimens positive for *P. aeruginosa* for cases in groups A, B, and C were compared with data from 2000 by means of the χ^2 test. Annual incidences of such patients were also recorded in wards (surgery, medicine, ear-nose-throat) supplied by other water distribution networks.

TABLE. Comparison of Epidemiological Data on Patients with *Pseudomonas aeruginosa* Colonization or Infection in the Intensive Care Unit During 3 Years

Variable	1998	1999	2000
No. of admissions	2,367	2,456	2,446
Mean duration of stay, d	4.86	4.37	4.83
Mean no. of specimens per patient	3.1	3.0	3.1
Anatomical site that yielded *P. aeruginosa,* % of specimens			
Respiratory tract	69	ND	76
Wound	14	ND	15
Other	16	ND	9
No. of patients from whom *P. aeruginosa* was isolated	139	99	68
No. of patients per 1,000 admissions	59.0	40.3	26.6
No. (%) of faucet specimens positive for *P. aeruginosa*	12/132 (9.1)	19/114 (16.7)	11/87 (12.6)

NOTE. ND, not done.

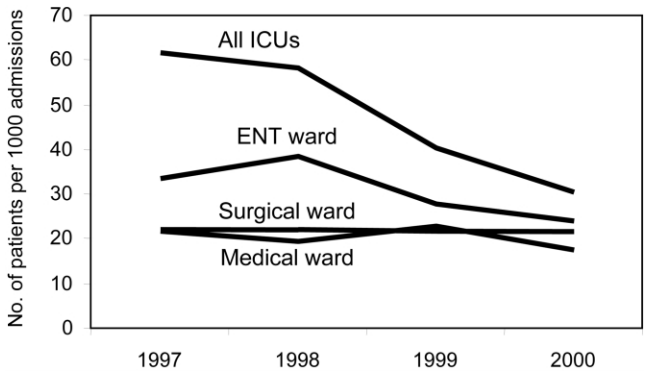

FIGURE 1. Evolution in the annual number of patients per 1,000 admissions in which clinical isolates yielded *Pseudomonas aeruginosa* in all intensive care units (ICUs) compared with medical, surgical, and ear-nose-throat (ENT) wards.

RESULTS

From 1998 to 2000, the annual incidence of ICU patients with clinical specimens positive for *P. aeruginosa* decreased by half (Table, Figure 1). During the same period, the annual incidences of such patients in the medical, surgical, and ear-nose-throat wards were also calculated and showed no significant change (Figure 1). None of these other wards were supplied with water by the same water networks as the ICU. The yearly number of specimens per patient, the distribution of anatomical sites from which *P. aeruginosa* was isolated, and the length of stay in the ICU did not change during the period 1998 to 2000 (Table). Results from the water system investigation showed that, despite the increase in temperature of the hot water, no significant decrease in the rate of faucet colonization was observed (Table) and there was no quantitative diminution of *P. aeruginosa* isolation from faucet swab specimens (data not shown). To understand this decrease in the incidence ICU patients colonized or infected with *P. aeruginosa,* comparison of the molecular epidemiology of *P. aeruginosa* isolates was performed between 1998 and 2000.

The total number of cases identified was 132 in 1998 and 65 in 2000. In 1998, there were 56 cases in group A, 39 cases in group B, and 37 cases in group C; in 2000, there were 17 cases in group A, 16 cases in group B, and 32 cases in group C. The incidence of cases in group A (ie, cases in which the isolate had a genotype identical to that of an isolate recovered from the water system) decreased significantly from 23.6 cases per 1,000 admissions in 1998 to 7.0 cases per 1,000 admissions in 2000 ($P < .01$). The incidence of cases in group B (ie, cases in which the isolate had a genotype identical to that of an isolate recovered from at least 1 other patient but not recovered from the faucets) decreased significantly from 16.5 cases per 1,000 admissions in 1998 to 6.5 cases per 1,000 admissions in 2000 ($P < .01$). However, the incidence of cases in group C (ie, cases in which the isolate had a unique genotype) remained nearly unchanged: 15.6 cases per 1,000 admissions in 1998, compared with 13.1 cases per 1,000 admissions in 2000 ($P = .64$) (Figure 2).

Regarding the cases in group A, the genotypes were first recovered from the faucets in 58 of 73 cases (44 of 56 in 1998 and 14 of 17 in 2000). The most prevalent genotype was isolated from both water distribution networks and was found in 39 cases (30 in 1998 and 9 in 2000). In the medical ICU network, 5 genotypes were isolated only from this network. They were responsible for 17 cases (13 in 1998 and 4 in 2000) in patients hospitalized in this ICU, and for only 3 cases (in 1998) in patients hospitalized in the other ICUs. In the other water network (that for the surgical, burn, and pediatric ICUs), 5 other genotypes were isolated, which were responsible for 12 cases in 1998 (and 0 cases in 2000) in patients hospitalized in these ICUs.

Among the 55 cases in group B, 6 epidemiological clusters (of 6, 3, 2, 2, 2, and 2 cases) were identified in 1998 and only 2 clusters (of 3 and 2 cases) in 2000. The 30 remaining cases (18 in 1998 and 12 in 2000) could not be grouped into clusters, since no overlapping period of hospitalization was recorded for the patients who harbored isolates with identical genotypes.

DISCUSSION

In several recent studies that have used molecular typing, the major reservoir of *P. aeruginosa* in an ICU in which there was not an epidemic was reported to be the endogenous flora

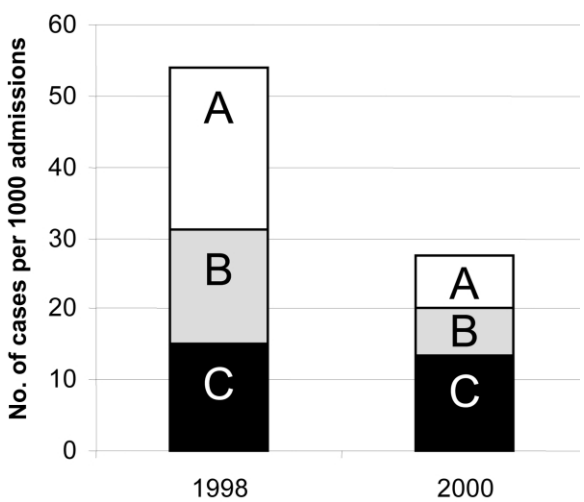

FIGURE 2. Evolution of the annual number of cases per 1,000 admissions in which clinical isolates yielded *Pseudomonas aeruginosa* among patients in the intensive care units. For case definitions, see Methods. Group A comprised cases in which the isolate had a genotype identical to that of an isolate recovered from a faucet. Group B comprised cases in which the isolate had a genotype identical to that of an isolate recovered from at least 1 other patient but not recovered from the faucets. Group C comprised cases in which the isolate had a unique genotype, suggesting that the source was probably endogenous.

of the patients, suggesting that barrier precautions might not have a central role in the prevention of *P. aeruginosa* colonization or infection in a given patient.[3,7,8] The environment was identified as a nonnegligible source of *P. aeruginosa* when the aerator faucets and the sinks were highly contaminated[12,13] or during outbreaks.[4,5,14,15] Faucet water was mostly associated with *P. aeruginosa* infection when it was used for rinsing burned patients or medical devices after disinfection. However, studies have suggested that patients only rarely acquire the pathogen from this environmental source, other than during outbreaks.[16-18] Our results suggest that, before the implementation of infection control measures, an exogenous source (water or cross-infection) was possibly the ultimate source of *P. aeruginosa* in three-quarters of the cases and that the water system was likely to be the primary reservoir in half of the cases. These results are striking, because a relatively low proportion of swab specimens from ICU faucets (12%) revealed colonization, and water samples (not swab samples) failed to reveal the presence of *P. aeruginosa.*[10] The initial contamination of the faucets could have originated from retrograde colonization, but most of the *P. aeruginosa* genotypes (82%) were recovered from the faucets before they were recovered from patients, a finding that strongly suggested that the water system was the primary reservoir. Subsequent transmission of these strains to other patients via healthcare workers or other indirect transmission may also have occurred.

A limitation of the molecular epidemiology of this study is that it was based only on clinical specimens and that no routine bacteriological screening of the patients was performed during the study period. However, it has the advantage that specimen sampling between the 2 periods was comparable. Similarly, we may have underestimated the number of exogenous sources, because we did not perform extensive microbiological sampling of the environment other than in the plumbing system. However, the results observed after the implementation of infection control measures suggest that the decrease in the incidence of cases was the result of a decrease in the number of cases in which the *P. aeruginosa* strain originated from an exogenous source (ie, groups A and B), whereas the incidence of cases in which the strain had a unique genotype and an endogenous source (ie, group C) remained similar. These findings were sustained during the years 2001-2003 (data not shown). Because the infection-control measures that targeted the water supply failed to decrease the rate and degree of faucet colonization, the observed decrease in incidence was likely related to the other measures (mostly use of bottled water and hand disinfection). In addition, the distribution of the anatomical sites from which *P. aeruginosa* was cultivated did not change, supporting the finding that the observed effect was not the result of the introduction of bottled water for mouth care. The importance of compliance with hand disinfection has recently been emphasized.[19-21] It was shown that a sustained improvement in compliance with hand hygiene coincides with a reduction of nosocomial infections and transmission of methicillin-resistant *Staphylococcus* species.[21]

Intrinsic factors (such as virulence, adhesin production, or antibiotic resistance) might contribute to the ability of some strains to infect or colonize.[15] This hypothesis is supported by reports of outbreaks of *P. aeruginosa* infection that involved a single strain.[5,14,15] However, the role of intrinsic factors in our setting is unlikely, because 11 different strains were identified in both faucets and patients, and 6 other strains were recovered from several patients.[10]

Biofilm colonization of faucets with *P. aeruginosa* in the ICU is problematic, especially when a multidrug-resistant strain is involved.[5] In our setting, high water temperature and copper and silver ionization were not able to eradicate this colonization. All colonized faucets were changed, but recolonization occurred after several weeks (data not shown), probably because the biofilm was also present in the pipes. Despite a decrease in the number of cases after implementation of infection control measures, molecular typing of isolates suggests that a substantial proportion of cases (group A; Figure 2) may still ultimately have originated in the water distribution system. Final filtration, with microfilters at each faucet, might be considered to decrease further the number of cases, but studies are needed to assess the cost-effectiveness of this method.

In conclusion, we showed that the implementation of infection control measures can be effective in decreasing the incidence of *P. aeruginosa* colonization and infection in ICU patients when exogenous reservoirs contribute substantially to the rate of colonization and infection. Because *P. aeruginosa* is ubiquitous in the environment and colonizes up to 15% of hospitalized patients, control of the reservoirs is difficult. Therefore, efforts should primarily be focused on the reinforcement of infection control measures to limit the transmission of *P. aeruginosa.*

SUMMARY

Background: *Pseudomonas aeruginosa* is a major nosocomial pathogen in intensive care units (ICUs); however, endogenous versus exogenous origin of contamination remains unclear.

Aim: To identify individual and environmental ICU risk factors for *P. aeruginosa* acquisition.

Methods: A five-month prospective multicentric study was performed in ten French ICUs. Adult patients hospitalized in ICU for ≥24 h were included and screened for *P. aeruginosa* colonization on admission, weekly and before discharge. *P. aeruginosa* acquisition was

Pseudomonas aeruginosa

defined by a subsequent colonization or infection if screening swabs on admission were negative. Water samples were obtained weekly on water taps of the ICUs. Data on patient characteristics, invasive devices exposure, antimicrobial therapy, *P. aeruginosa* water and patient colonization pressures, and ICU characteristics were collected. Hazard ratios (HRs) were estimated using multivariate Cox model.

Findings: Among the 1314 patients without *P. aeruginosa* on admission, 201 (15%) acquired *P. aeruginosa* during their ICU stay. Individual characteristics significantly associated with *P. aeruginosa* acquisition were history of previous *P. aeruginosa* infection or colonization, cumulative duration of mechanical ventilation and cumulative days of antibiotics not active against *P. aeruginosa*. Environmental risk factors for *P. aeruginosa* acquisition were cumulative daily ward 'nine equivalents of nursing manpower use score' (NEMS) [hazard ratio (HR): 1.47 for ≥30 points; 95% confidence interval (CI): 1.06–2.03] and contaminated tap water in patient's room (HR: 1.76; CI: 1.09–2.84).

Conclusion: Individual risk factors and environmental factors for which intervention is possible were identified for *P. aeruginosa* acquisition.

Introduction

Pseudomonas aeruginosa is a ubiquitous micro-organism responsible for severe hospital-acquired infections.[1–3] Length of stay, severity of underlying disease and exposure to invasive procedures but also bacterial adherence and virulence factors, and antimicrobial drug resistance are associated with *P. aeruginosa* acquisition in ICUs.[4–6] Those risk factors were identified in single centre studies which most often focused on antimicrobial-resistant *P. aeruginosa* and rarely took into account the context of care delivery, i.e. colonization pressure or nurse staffing.[7] However, patient case-mix, ecology, organization, and practices vary across ICUs. Endogenous origin was regarded as the most relevant route of *P. aeruginosa* infection, but, during the last ten years, a significant proportion of *P. aeruginosa* isolates have been shown to stem from the ICU environment (moist reservoirs) and from cross-transmission.[8–11] Nseir *et al*. reported that the risk of multidrug-resistant *P. aeruginosa* acquisition was higher when the previous occupant of the room was colonized by such *P. aeruginosa*.[12] The relevance of exogenous reservoirs and the importance of cross-transmission were documented during outbreaks but their importance in non-epidemic situations remains controversial. A pilot study suggested that environmental factors might be associated with *P. aeruginosa* acquisition.[6] Unlike patient and pathogen characteristics, environmental factors such as nursing workload or contamination of water taps could be modified. A prospective cohort study in ten French ICUs, DYNAPYO (Dynamics of Acquisition of *Pseudomonas aeruginosa*), was performed to evaluate the respective contributions of individual and ICU environmental risk factors for *P. aeruginosa* acquisition.

Methods

Study design

A prospective five-month observational survey was performed from February to October 2009 in ten ICUs from eight French healthcare facilities including four medical, two surgical and four mixed (medical and surgical) ICUs. University hospitals of Besançon and Lyon included two ICUs each, university hospitals of Bordeaux, Garches, Montpellier and Paris, and general hospitals of Lens and Tourcoing included one ICU. These ICUs each had between nine and 20 beds and from 10 to 47 water taps. The average length of patient stay was eight to 16 days and ICUs admitted from 27 to 35 patients per month. Specific trained healthcare professionals were identified in each centre for the collection of data, which were entered on to a secured online electronic form. There was no policy to isolate patients with *P. aeruginosa* in each of the study ICUs, and changes such as to infection control initiative or antimicrobial stewardship were not implemented during the course of the study.

Exposure measurements

Every adult patient admitted for >24 h was included and had screening samples (oropharyngeal, rectal swab, and tracheobronchial aspirate) with 48 h of admission and thereafter once a week, and before discharge. The study was approved by the local ethics committees. Cetrimide agar was inoculated and identification of *P. aeruginosa* was performed after 24 and 48 h of aerobic incubation at 42 °C.

Water samples were performed weekly on water taps of the ICUs. Samples were taken on the morning before use, without prior disinfection; taps were opened and the first 250 mL flush of water collected immediately into a sterile flask with 5 mg sodium thiosulphate (pre-flush sample), the aerator was not removed but swabbed and the swab broken into the water sample; samples were processed by membrane filtration: 100 mL were filtered through a 0.45 mm pore size membrane filter; membranes were cultured aerobically on to cetrimide agar plates at 37 °C and examined for growth after 22 ± 4 and 44 ± 4 h; any colonies that grew on cetrimide agar were identified using the API 20NE identification system (bioMérieux, Marcy l'Etoile, France).

Patients found to be positive within the first 48 h of admission were considered to have imported *P. aeruginosa*. Acquisition was defined by a subsequent positive swab culture or *P. aeruginosa* infection during ICU stay if, on admission, screening swabs were negative and the patient was not infected yet by *P. aeruginosa*.

Demographic data were collected on admission, including: age, sex, immunodeficiency, primary diagnosis of infection, simplified acute physiology score within 24 h of admission (SAPS II), Charlson comorbidity index for chronic disease, history of previous hospitalization (<1 year before admission), previous antimicrobial therapy (<30 days), previous surgery (<30 days) and history of previous *P. aeruginosa* infection or colonization (yes/no).[13,14] During ICU stay, data regarding the use and duration of invasive devices and procedures were collected. Antibiotic treatment was recorded daily and classified (no antibiotic treatment; antibiotics normally non-active against *P. aeruginosa*; antibiotics normally active against *P. aeruginosa* including ureido- and carboxypenicillins, antipseudomonal cephalosporins, carbapenems, fluoroquinolones, aminoglycosides, colimycin, fosfomycin).[6] If a patient received simultaneously both active and non-active antibiotics, the patient was considered to have been treated with active antibiotics.

The level of patient care was daily evaluated by the nursing staff using the 'nine equivalents of nursing manpower use score' (NEMS).[15] For each ward, the global daily average nursing workload (daily ward NEMS) was estimated by the sum of all the patients' daily NEMS divided by the number of patients.

The *P. aeruginosa* colonization status of the previous occupant of the bed and colonization of the bedroom water tap before *P. aeruginosa* acquisition (or discharge in case of no *P. aeruginosa* acquisition) was recorded. Daily indices of environmental pressure were calculated. Environmental exposure was assumed to be constant between two screenings. According to the organization of care by ICU staff and the localization of rooms on the ICU floor plan, patients in close proximity (same room or adjacent room) and water taps in close proximity (same room or usually used before entering the room) were defined for each patient. Two variables were then calculated: (i) the patient colonization pressure [cumulative number of positive patients in close proximity (colonized/infected patients, including patients with imported and acquired *P. aeruginosa*) from the admission to the previous day of *P. aeruginosa* acquisition/discharge, in patient-days]; (ii) the tap water colonization pressure (cumulative number of positive water taps in close proximity from the admission to the previous day of *P. aeruginosa* acquisition/discharge, in water tap-days).

Statistical analyses

Patients with imported *P. aeruginosa* were excluded from the risk factor analysis and only used to assess patient colonization pressure ($N = 180$). Only the first *P. aeruginosa* acquisition in the ICU during the study was considered. Hazard ratios for acquisition of *P. aeruginosa* were estimated for individual and environmental ICU factors using Cox regression model stratified on ward and taking into account left truncation. Factors concerning devices and procedures, antimicrobial therapy, patient and water colonization pressures and daily ward NEMS were introduced as time-updated factors. Because variables related to invasive devices and procedures were correlated, mechanical ventilation was included in the model as a surrogate variable for all other invasive procedures. Factors were selected in the final model following an unadjusted analysis ($P < 0.25$) and a backward-manual selection multivariable analysis ($P < 0.05$). Antimicrobial therapy, patient and water colonization pressure were systematically introduced into the model. Interactions between antimicrobial therapy and either patient colonization or water colonization pressures were tested ($P < 0.05$). Linearity of effects was checked; in cases of non-linearity, continuous variables were categorized according to the quantiles of the distribution. All analyses were performed using SAS software (version 9.1.3, SAS Institute, Cary, NC, USA).

Results

Among the 1314 patients without *P. aeruginosa* on admission, 201 (15%) acquired *P. aeruginosa* during their ICU stay. No *P. aeruginosa* outbreak was observed during the study. ICUs included 81–233 patients each (median: 123) and *P. aeruginosa* acquisition ranged from 11% to 21% according to the ICU. Incidence density of *P. aeruginosa* acquisition was 12.7 per 1000 days of hospitalization, ranging from 9.4 to 15.9 in ICUs. Median delay for *P. aeruginosa* acquisition was nine days [interquartile range (IQR): 6–15]. Main characteristics of patients are described according to their *P. aeruginosa* acquisition status in Table I.

Median cumulative patient colonization pressure was five patient-days (IQR: 2–14) for patients with *P. aeruginosa* acquisition and two patient-days (IQR: 0–6) for patients without *P. aeruginosa* acquisition ($P = 0.04$). Patients with *P. aeruginosa* acquisition were in a bed previously occupied by a positive patient in 23% of cases (22% for patients without acquisition; $P = 0.87$).

Water was contaminated in 17% of samples (2–62% according to the ICU; median: 7%). Median cumulative water tap colonization pressure was five positive water tap-days (IQR: 0–26) for patients with *P. aeruginosa* acquisition and zero (IQR: 0–6) for patients without acquisition ($P = 0.01$). In cases of *P. aeruginosa* acquisition, 32% of patients were previously exposed to a positive water tap in their bedroom (19% in case of no acquisition; $P < 0.01$).

Results of multivariate analyses are presented in Table II. Independent risk factors at individual level for *P. aeruginosa* acquisition were: older age, history of previous *P. aeruginosa* infection or colonization, longer cumulative duration of mechanical ventilation, and longer cumulative days of antibiotics non-active against *P. aeruginosa*. Among ICU environmental risk factors, positive tap water in patient's room and cumulative daily ward NEMS were independent risk factors.

Discussion

This prospective multicentre study evaluated the respective contributions of individual and ICU environmental risk factors for *P. aeruginosa* acquisition. In addition to individual risk factors, there were two significant environmental variables: previously contaminated tap water in the room and the cumulative ward level of nursing workload.

Selection biases were limited according to the study setting. The proportion of positive patients on screening swabs could have been underestimated because of an unknown, potentially suboptimal, sensitivity of the swab technique in detecting a small inoculum. However, this lower sensitivity was expected to be the same for all swabs and ICUs.[16] The overall prevalence of acquisition was 15% in our study that is in the range (from 6%

Table I
Characteristics of the patients according to their *Pseudomonas aeruginosa* status, DYNAPYO study (univariate analysis)

Characteristics	*P. aeruginosa* acquisition[a] ($N = 201$)	No *P. aeruginosa* acquisition[a] ($N = 1113$)	*P*-value
General characteristics			
Sex ratio (M/F)	1.91	1.35	0.27
Age (years)[b]	60.4 (18.4)	56.7(18.4)	0.02
Charlson comorbidity index on admission[b]	2.1 (2.3)	1.9 (2.2)	0.29
SAPS II score within the first 24 h[b]	50.9 (17.6)	42.7 (19.3)	0.03

DYNAPYO, Dynamics of Acquisition of *Pseudomonas aeruginosa* study; SAPS, simplified acute physiology score; NEMS, nine equivalents of nursing manpower use score; ICU, intensive care unit.
[a] Acquisition: at least one screening or diagnosis sample positive to *P. aeruginosa* during ICU stay. Characteristics during ICU stay were considered from admission to previous day of acquisition in cases of *P. aeruginosa* acquisition and from admission to previous day of discharge in cases of no acquisition.
[b] Mean (standard error).
[c] No. (%).
[d] Median (interquartile range).

to 32%) of reported estimations in ICU studies using similar screening method.[17–19] Water sampling at weekly intervals was preferred to sampling at times of patients' admission and discharge and to daily intervals as done in previously published studies and because of its feasibility.[6,9,11]

Hazard ratios (HRs) of individual risk factors for *P. aeruginosa* acquisition were stronger than of HRs of environmental factors: history of *P. aeruginosa* was strongest. In this latter case, *P. aeruginosa* acquisition might be a reappearance of an endogenous strain not identified on admission screening (but only strain typing could demonstrate that). However, by assessing the intrinsic endogenous risk and susceptibility for each patient to acquire *P. aeruginosa*, this factor is useful and simple to collect on admission.[16] The effect of the duration of the mechanical ventilation was previously described.[5–7,16,20–22] The third identified individual risk factor can be modified: the cumulative days of antibiotics not active against *P. aeruginosa*. Reducing susceptible intestinal flora

Environmental (ICU) characteristics			
Cumulative daily ward NEMS (for 30 points higher)	1.47	1.06–2.03	0.02
Tap water of the room contaminated by *P. aeruginosa*	1.76	1.09–2.84	0.02

DYNAPYO, Dynamics of Acquisition of *Pseudomonas aeruginosa* study; ICU, intensive care unit; HR, hazard ratio; CI confidence interval; NEMS, nine equivalents of nursing manpower use score.
[a] Acquisition: at least one screening or diagnosis sample positive to *P. aeruginosa* during ICU stay. Characteristics during ICU stay were considered from admission to previous day of acquisition in cases of *P. aeruginosa* acquisition and from admission to previous day of discharge in cases of no acquisition.

would select naturally resistant *P. aeruginosa*. Patients with a history of long-course antimicrobial therapy, especially piperacillin, tazocillin, fluoroquinolones, and aminoglycosides, have been reported to be at greater risk of *P. aeruginosa* acquisition.[5,23–25]

Positive water in the patient's room was a risk factor for *P. aeruginosa* acquisition. Patients' contamination by a *P. aeruginosa* tap water strain has been estimated at 15–50% in the literature.[9,19,26–28] Petignat *et al.* demonstrated that *P. aeruginosa* colonization and infection in ICU patients decreased by eradicating *P. aeruginosa* in faucets and reinforcing standard precautions.[29] The efficacy of regular disinfection to control retrograde contamination has not been proven. However, water taps may be a reservoir of *P. aeruginosa* in ICUs. Water surveillance would assess patients' exposure to contaminated water. A definitive proof of the link between patient and environmental isolates of *P. aeruginosa* would be given by strain typing. Therefore according to our results, in cases of water contamination, decontamination actions and preventive measures would be a feasible preventive action. Although decontamination of a contaminated water tap has been widely studied, no review or guidelines on efficient decontamination strategy are available.[30–32] Promoting compliance with alcohol hand disinfection following hand hygiene in cases of *P. aeruginosa* water contamination should reduce *P. aeruginosa* transmission.

Cumulative daily ward NEMS assessed the cumulative global level of patients' care. A high workload in an ICU can decrease compliance to prevention measures and increase the risk of cross-transmission. To our knowledge, NEMS has never been used to assess risk for *P. aeruginosa* acquisition before; a previous 70-patient study used ICU-PRN (nurse workload system 'Projet de Recherche en Nursing en Réanimation') as explanatory variable for *P. aeruginosa* acquisition in ICU, but results were non-significant.[17] Increased nurse workload could result in underperforming in infection control measures (such as room cleaning or hand hygiene) which could favour both *P. aeruginosa* persistence in the environment and cross-transmission.[33] NEMS is a simple score that deserves to be used in ICU.

The cumulative number of positive patients in close proximity was not an independent risk factor for *P. aeruginosa* acquisition in multivariable analysis. In a previous single-centre study, the presence of positive patients in the ward on the previous day was independently associated with *P. aeruginosa* acquisition.[6] Analysis of the French national database of nosocomial infections surveillance in ICUs (REA-RAISIN) found that hospitalization in an ICU with elevated rate of *P. aeruginosa*-infected patients was significantly and independently linked with a pseudomonal nosocomial pneumonia, though the contamination of water taps and NEMS score were not assessed.[7] Cross-transmission has many variations according to the ward, and our study identified that colonization pressure was not the main environmental risk factor for *P. aeruginosa* acquisition.[4,18,34–40]

To conclude, a patient exposed to prolonged antibiotics inactive against *P. aeruginosa*, exposed to contaminated water in his room, and hospitalized in ICU with a high workload was more at risk for *P. aeruginosa* acquisition during his stay. These results suggest an exogenous, preventable acquisition of *P. aeruginosa* in ICU, which should stimulate research on policies of water decontamination and their impact on *P. aeruginosa* acquisition.

Symposium: Nosocomial Colonization

EDITED BY C. GLEN MAYHALL, MD

The Role of Colonization in the Pathogenesis of Nosocomial Infections

Marc J.M. Bonten, MD, PhD; Robert A. Weinstein, MD

ABSTRACT

The close relationship between colonization and the development of nosocomial infections has been demonstrated. Patient-related factors, such as underlying illness for all major sites of infection and advanced age, and pathogen-related factors, such as the ability of bacteria to adhere to epithelial cells, play the major roles in the pathogenesis of colonization. However, exact mechanisms of colonization have not been elucidated, and modulation of bacterial adherence as a method of infection prevention remains experimental. Current methods of infection prevention, therefore, focus either on preventing growth of colonizing microorganisms or on preventing patient-pathogen contact. Topical antibiotics have been used as a method of colonization prevention. However, their effectiveness may be limited by increases in antibiotic resistance; moreover, the effects on patient outcome are controversial. Maintenance of the physiologic mucosal environment using nonantimicrobial agents seems a promising approach, but only a few studies demonstrating efficacy have been published. Prevention of colonization still must rely heavily on basic infection control measures to prevent contact between patient and pathogen (*Infect Control Hosp Epidemiol* 1996;17:193-200).

INTRODUCTION

Hospital-acquired infections have become increasingly complex over the past 20 years. The availability of sophisticated diagnostic and therapeutic modalities has led to higher survival rates for debilitated patients, creating a population at high risk of hospital-acquired infections. The frequent use of invasive devices in intensive care units (ICUs), especially central venous catheters and mechanical ventilators, is associated with further risk of nosocomial infections. Increasingly, broad-spectrum antimicrobial treatment of these infections has led to major problems with multiply antibiotic-resistant bacteria.

Preventing these infections requires an understanding of their pathogenesis. The occurrence of nosocomial infections most often involves a three-step process: first, colonization of a patient's mucosa or skin with a potential pathogen; second, access of the pathogen to a site where it may invade tissues, often in association with a foreign body such as an intravascular catheter or an endotracheal tube; and third, an imbalance among the pathogen's virulence factors and the host's defense factors, which eventually results in the infection. In essence, what colonizes our patients may infect them.

In this review, we will discuss the evidence for the importance, and the mechanisms, of the first step in the pathogenesis, colonization, and the possible ways to interfere in this process to prevent infection.

COLONIZATION WITH POTENTIAL PATHOGENS

The Respiratory Tract

Epidemiological observations. The development of respiratory tract colonization probably depends on the ability of the bacteria to adhere successfully to epithelial cells or mucus.[1,2] Although the exact mechanisms that facilitate adherence and colonization still

are unclear, a number of epidemiologic observations have been made. For example, the development of ventilator-associated pneumonia (VAP) is related closely to preceding oropharyngeal colonization. More than 20 years ago, Johanson and coworkers demonstrated that 23% of colonized ICU patients developed nosocomial respiratory tract infections as compared to only 3% of noncolonized patients.[3] However, these data must be interpreted in light of the difficulty in differentiating colonization from infection in this patient population.

Recently introduced bronchoscopic specimen collection techniques, such as the use of protected-specimen brush (PSB) and bronchoalveolar lavage (BAL), probably have a higher specificity for differentiating colonization from infection in the lower respiratory tract.[4] Using these techniques, the relationship between colonization and infection of the respiratory tract has been reevaluated in mechanically ventilated ICU patients.[5,6] In one study, 11 of 64 patients developed 14 episodes of VAP; 17 (85%) of 20 bacterial species isolated in significant amounts from respiratory tract samples obtained by PSB or BAL had been isolated from tracheal aspirates prior to, or on the day of, diagnosis of pneumonia, and 10 (50%) had been isolated from the oropharynx.[5] In a second study, the proportion of pathogens colonizing the trachea and oropharynx prior to infection were 96% and 75%, respectively.[6] In that study, VAP was diagnosed in 37% of patients that acquired, and in only 8% of patients that did not acquire, colonization with gram-negative bacteria in the ICU.

Host factors associated with colonization. Many host factors have been associated with increased colonization of the respiratory tract (Table 1). Colonization itself seems to be a marker of underlying illness. For instance, oropharyngeal colonization with enteric gram-negative bacteria seldom occurs in healthy individuals.[3] In one study, introduction of a large inoculum of these bacteria into the mouths of healthy volunteers did not result in colonization.[7] However, with increasing illness or increasing age, oropharyngeal colonization with aerobic gram-negative bacteria occurs more frequently.[3,8] It has been hypothesized that, as the levels of salivary protease increase during illness, fibronectin is digested from the surface of epithelial cells.[9] As a result, the number of available binding sites for gram-negative bacteria increases. However, others failed to confirm this hypothesis.[10]

A change in acidity of salivary secretions also may play a role in bacterial adherence. Bacterial binding to tracheal cells was better under alkaline conditions (pH 7.2) than under more acidic conditions (pH 6.5).[11] Changes in acidity, theoretically, may affect the structure of bacterial and cell surfaces, formation and structure of adhesins and cell receptors, and the activity of protease and glycosidases.

Pathogen-specific factors. Adhesins are the most important pathogen-specific factors facilitating respiratory tract colonization. Pathogenic microorganisms contain hair-like filaments, known as pili or fimbriae, that attach specifically to carbohydrates on surface glycoproteins or glycolipids of epithelial cells.[12] Four groups of adhesins have been identified (Table 2). Adhesins belonging to the same group may be present on different species of bacteria, and, conversely, within a certain species different adhesins may be found.

Because not all bacteria that can adhere to epithelial cells have identifiable adhesins, either detection of fimbriae may not be sensitive enough or other nonfimbrial adhesins must be present.[12] For instance, mucins have been demonstrated to contain receptors for some bacteria and viruses that colonize the respiratory tract.[13] Although binding to mucins may facilitate mucociliary clearance, mucus also may protect microorganisms, such as *Streptococcus pneumoniae* and *Pseudomonas aeruginosa*, from host defense mechanisms.[14,15]

The bacterial source. Several sources of colonizing bacteria have been identified, some within the patient (endogenous) and others outside the patient (exogenous). The most important endogenous source for gram-negative bacteria is the gut. In

healthy individuals, the aerobic colonic flora contains $>10^5$ *Escherichia coli* per gram of feces.[16] Moreover, some patients carry small numbers of *P aeruginosa* and *Enterobacter* species in their gut when admitted to the ICU.[17,18] Antibiotic use in the ICU may provide these bacteria with a selective growth advantage, allowing them to colonize other body sites.

Gastric colonization has been assumed to be important in the pathogenesis of colonization and infection of the respiratory tract.[19] In this hypothesis, bacteria that colonize the stomach subsequently colonize the oropharynx and trachea.[20] Under physiological conditions, gastric acidity (pH $\leq$4.0) prevents bacterial overgrowth of most bacteria. However, in critically ill patients, intragastric acidity may be reduced because of underlying illness, advanced age, or the administration of stress-ulcer prophylactic agents. In addition, administration of enteral feeding, which has a pH of approximately 6.0, has been associated with decreased intragastric acidity. However, the importance of this gastropulmonary route of colonization has been questioned.[5,6,21]

Contaminated medical devices, electric thermometers, or enteral feedings have been shown repeatedly to be exogenous sources for colonization and infection. Although strict hygienic measures should minimize transfer and colonization from these sources, animate exogenous sources, such as other patients in the ward and even healthcare workers, remain a risk for cross-colonization.[22-24] The relative contribution of each of these animate and inanimate sources of colonization has not been elucidated and probably differs among ICUs.

The Urinary Tract

Epidemiologic observations. The general belief that the ascending route of colonization is most important in the pathogenesis of urinary tract infections (UTIs) is based primarily on two epidemiologic observations. In the first place, these infections occur

much more frequently in women, in whom the urethra is short and in direct contact with the moist environment of the vulvar and perirectal areas. Second, it has been shown that the pathogens causing UTI in women colonize the vagina and the periurethral area before infection occurs.[25]

Host factors associated with colonization. Normal urine has some important effects on bacterial growth. For instance, it possesses antibacterial activity for anaerobic and other fastidious bacteria, and high urea and low pH inhibit bacterial growth of *Enterobacteriaceae*.[26]

Hormonal changes probably influence bacterial colonization of the urinary tract. In fertile women, *Lactobacillus* species are the predominant microorganisms of the vaginal flora, and they maintain the normal acidic vaginal pH.[27] Estrogen deficiency is associated with decreased numbers of *Lactobacillus* species in the vagina.[28] As a result, mucosal pH is higher, colonization with enteric gram-negative bacteria occurs more frequently, and the incidence of UTIs is increased in postmenopausal women.[28] Urine of pregnant women also is more suitable for bacterial growth than urine from nonpregnant women.[29]

Pathogen-specific factors. E coli is the most important pathogen causing UTIs, and most infections are caused by only a few serogroups of this species.[30] Among different virulence factors that have been demonstrated, the ability to adhere to vaginal and uroepithelial cells probably is most important. As for pathogens colonizing the respiratory tract, adherence mostly is facilitated by fimbrial adhesins (Table 2). After bacterial entry into the lower urinary tract, type I adhesins probably facilitate colonization of bladder and lower urinary tract.[31] Subsequently, P-adhesins and nonfimbrial adhesins appear to facilitate infection of the pelvis and renal parenchyma.[32] With regard to nosocomial infections, it has been demonstrated that adherence to urinary catheters also is type I adhesin dependent.[33] The significance of bacterial adherence also has been demonstrated for other bacteria that occasionally cause UTI, such as *Proteus mirabilis*, *Staphylococcus saprophyticus*, and *Klebsiella* species.[34,35]

Nasal Colonization With Staphylococcus aureus

Nasal epithelial cells are an important site for colonization, multiplication, and dissemination of both methicillin-susceptible and -resistant *Staphylococcus aureus*. It has been demonstrated that other bacteria (*P aeruginosa*, other staphylococci, *Streptococcus pyogenes*, and diphtheroids) also have an ability to adhere to these cells.[36]

Adherence of *S aureus* to nasal epithelial cells is mediated by teichoic acid, a cell-wall component of staphylococci containing D-alanine and N-acetylglucosamine.[36] From the initial nasal source, the bacteria may disseminate to traumatized or disrupted skin and cause nosocomial wound infections. Attachment at these sites involves the interaction with proteins such as fibrinogen, fibronectin, laminin, thrombospondin, and, possibly, collagen IV.[37]

Intranasal carriage by patients has been associated with the development of staphylococcal infections in patients in hemodialysis and ICUs.[38] Casewell and Hill demonstrated that the incidence of surgical wound sepsis in nasal carriers of *S aureus* ranged from 5.6% to 16.5%, and 47% to 89% of the pathogens were similar to the strains colonizing the nose. The incidence of infection was 1.1% to 7.6% in noncolonized patients.[39]

PREVENTION OF COLONIZATION

Infection Control Measures

The institution of hygienic procedures is a cornerstone in all strategies to prevent colonization in hospitalized patients. Many studies have demonstrated the spread of bacteria from patient to patient via hands of healthcare workers, and the incidence of cross-colonization among patients has been reduced by enforcing handwashing between patient contacts.[40] The question of whether hands should be washed with antimicrobial soap, a general disinfectant, or just be rinsed with alcohol is raised frequently in hospitals. However, compliance with any handwashing guidelines is a problem. In one typical ICU, healthcare workers washed their hands after 41%, and physicians after only 28%, of patient contacts.[41]

In high-risk areas, even more precautions should be taken. High-risk areas are wards where patients are extremely susceptible to infection, such as hematology wards and neonatal ICUs; wards where many patients are heavily colonized with pathogenic bacteria, such as intensive care units; or wards where certain pathogenic microorganisms of epidemiologic concern are isolated frequently, such as outbreak wards. Under these circumstances, additional procedures are needed to prevent the spread of colonization. Specifically, in addition to handwashing, nonsterile examination gloves can be used to protect the healthcare worker from contamination with potentially infectious secretions, excretions, and antibiotic-resistant skin flora from patients. Sterile gloves should be used by healthcare workers to protect the patient against acquiring colonization during invasive procedures, such as suctioning intubated patients or touching open

wounds.[42] Whether the use of cover gowns by personnel provides additional protection against patient colonization and infection remains to be established.[43]

Surveillance Cultures

The performance of surveillance cultures on a regular basis potentially may improve medical care for several reasons. Because there is such a close relationship between colonization and infection, knowledge of antimicrobial susceptibilities of colonizing bacteria may improve empiric antibiotic therapy. Moreover, epidemics or failures in infection control probably are detected earlier when colonization is monitored frequently. However, to the best of our knowledge, the effects of surveillance cultures never have been subjected to a controlled study, and surveillance cultures should not be recommended routinely. The optimal design for such a study would include a cost-benefit analysis, because a large proportion of colonized patients will not develop infection.

Modulation of the Colonizing Bacterial Flora

Modulation of the bacterial flora, as a matter of infection prevention, may be performed at present only by application of antimicrobial agents (applied systemically or topically) or by maintenance of the physiological mucosal environment.

Colonization resistance. In the human gut, the numbers of aerobic bacteria (predominantly *E coli*, streptococci, and enterococci) are far outnumbered by the anaerobic species. In an animal model, it has been demonstrated that an intact anaerobic flora protects the animal against overgrowth with enteric aerobic gram-negative bacteria, a phenomenon that has been called "colonization resistance."[16] This observation has been cited to explain why many patients receiving antimicrobial agents that are active against the anaerobic flora develop intestinal bacterial overgrowth with enteric gram-negative bacteria.

Systemic antibiotics. Systemic antibiotics have been used to prevent infection. They probably work by preventing the progression from colonization to infection more than by modulating colonization. Leukopenic patients often receive absorbable broad-spectrum antibiotics, such as fluoroquinolones, orally for both gut decontamination and systemic prophylaxis. The increasing prevalence of multiresistant microorganisms within hospitals justifies a rationale for restrictive use of these agents, and prophylaxis seems to be justified in leukopenic patients only.

Selective digestive decontamination. Selective decontamination of the digestive tract (SDD) has been studied extensively in ICU patients. SDD combines three potential preventive measures: the intestinal tract is decontaminated, from oropharynx to rectum, using topical, nonabsorbable antimicrobial agents; anaerobic bacteria are spared to maintain "colonization resistance"; and a systemic component (eg, a second- or third-generation cephalosporin) is added to prevent infections already incubating at the time of admission.[44] Despite approximately 50 clinical studies and five meta-analyses, the benefits of SDD in ICU patients remain unproven. Meta-analyses are hampered by lack of uniformity in the patient population, by use of many different antibiotic combinations, and by inadequate methodology to establish the diagnosis of the most important endpoint, VAP. The major concerns with regard to the routine use of SDD in ICUs result from the reported associations between the use of SDD and an increase in gram-positive colonization and infection,[45-47] the relation between SDD and selection of antibiotic-resistant bacteria,[48-50] and the lack of a reduction in mortality or duration of hospital stay.

Topical nasal decontamination. Many attempts have been made to eradicate nasal colonization by *S aureus*. The use of topical and systemic antibiotics either yielded poor results or was accompanied by selection of resistant strains.[38] The most favorable results are reported with the use of mupirocin, which is active against staphylococci, including MRSA, streptococci, and some gram-negative bacteria.[51,52] Mupirocin is not related structurally to other antibiotics and can be used only as a topical agent.

Mupirocin has been demonstrated to eradicate carriage of *S aureus* in healthcare workers[53] and of MRSA during outbreaks in Veterans' Administration nursing homes, ICUs, and neonatal nurseries.[38] Eradication of *S aureus* from the nares reduced the incidence of infections in hemodialysis patients[54] and in patients suffering from familial staphylococcal infections.[55] In thoracic surgery patients, the use of mupirocin nasal ointment was associated with a 0.5% rate of postoperative wound infections caused by *S aureus,* as compared to 3.5% in historical controls.[56]

However, any topical use of antibiotics is associated with concerns about emergence of resistance. Resistance to mupirocin has been reported, for instance, in dermatology wards where patients received prolonged treatment for infected skin lesions.[38] However, cross-resistance of mupirocin to clinically used antibiotics has not been demonstrated yet, probably because of its unique structure and mode of action. Nevertheless, prolonged and inappropriate use of mupirocin should be avoided to maintain its efficacy for eradicating MRSA.

Maintaining the Physiological Mucosal Environment

Gastric acidity. Based on the hypothesis of the gastropulmonary route of colonization, several strategies have been developed to maintain intragastric acidity to prevent gastric colonization and the development of VAP.

Most studies focused on stress ulcer prophylaxis. Sucralfate, a cytoprotective agent that does not influence acidity, has been compared to antacids and H_2 antagonists. Although some trials reported significantly lower incidences of VAP in sucralfate-treated patients,[57-60] the results of the studies are contradictory.[6,61]

In addition, gastric colonization could be modulated by changing the administration of enteral feeding. For instance, enteral feeding could be administered intermittently, allowing a temporary decrease in intragastric pH to prevent bacterial overgrowth. Favorable results of this strategy were demonstrated by Lee and coworkers using a historical control group that had received continuous enteral feeding.[62] However, these benefits were not confirmed in two prospective studies.[63,64] In two other attempts, acidified enteral feedings[65] and intrajejunal administration of nutrition[66] were studied. Although both studies reported favorable effects, the small numbers of patients do not allow conclusions to be drawn.

Estrogen substitution. Recurrent UTIs in postmenopausal women, probably as a result of increased vaginal colonization with *Enterobacteriaceae*, have been prevented successfully by modulation of the vaginal flora with intravaginal estriol.[28] In a randomized, double-blind, placebo-controlled study, the use of topical estriol resulted in reappearance of lactobacilli in 61% of the patients. In addition, the mean vaginal pH declined from 5.5 to 3.8, the rate of vaginal colonization with *Enterobacteriaceae* fell from 67% to 31%, and the incidence of urinary tract infections in the estriol-treated patients was 0.5 episodes per patient-year, as compared to 5.9 episodes per patient-year in the control group ($P<.001$).[28]

Preventing Bacterial Adherence

Given the lack of knowledge about the mechanisms of bacterial adherence, it is clear that methods to prevent bacterial attachment are only in their infancy. The interaction between adhesins and cell receptors could be prevented theoretically either by soluble receptors that bind competitively to adhesins or, conversely, by soluble adhesins that competitively adhere to cell receptors. In another theoretical approach, antiadhesin or antireceptor antibodies may prevent the interaction between adhesin and cell receptor. Passive immunization with purified pili from developing enterotoxigenic strains of *E coli* in female pigs prevented their piglets from developing diarrhea,[67] and rats did not develop pyelonephritis after passive immunization with antisera produced with purified pili.[68]

Finally, adherence could be modified by altering bacterial surface proteins of either adhesins or cell receptors. This may be the mechanism by which aminoglycosides and ceftazidime, when used in subinhibitory concentrations, inhibited adherence of *P aeruginosa* and *E coli* to tracheal and buccal cells in vitro.[69]

CONCLUSIONS

Many data underscore the chronological relationship between colonization and the development of infection. Understanding the mechanisms of, and preventing, colonization—the first of the three steps leading to nosocomial infection—remains an important goal, especially for high-risk patients. However, there still is no ready answer to a seemingly simple question like "Why do hospitalized patients acquire colonization with enteric bacteria in their respiratory tract?" Moreover, in many cases, the exact source of these bacteria remains unknown.

The current knowledge about the initial step in the pathogenesis of colonization, adherence of the microorganism to the epithelial cells, is insufficient to develop adherence-targeted preventive strategies. Prevention of colonization, therefore, relies heavily on very basic infection control measures such as handwashing. Unfortunately, compliance with these measures often is poor. The development of alternative strategies, such as topical antimicrobial prophylaxis, is stymied by antibiotic resistance. Studies aimed at maintenance of the physiologic mucosal environment using nonantimicrobial agents may help avoid this pitfall.

Conference on Reuse of Medical Devices

by Gina Pugliese, RN, MS
Medical News Editor

The Association for the Advancement of Medical Instrumentation is collaborating with a number of organizations to cosponsor a conference on "Designing, Testing, and Labeling Reusable Medical Devices for Reprocessing in Healthcare Facilities" to be held April 9-10, 1996, in Washington DC. Cosponsoring organizations include the Health Industry Manufacturer Association, the Food and Drug Administration, American Medical Association, the Association for Professionals in Infection Control and Epidemiology, and the Association of Operating Room Nurses.

Conference topics will include reprocessing techniques, the perspective of technicians, an overview of standards and regulations, device design considerations, manufacturer responsibilities regarding reusable devices, and the future of reprocessing.

For more information, call (703) 525-4890, ext 260.

Key Words:
Nonsusceptible
Carriage
Infection
Antibiotic
Antimicrobial

Background: Carbapenem-resistant Enterobacteriaceae (CRE) have emerged as important health care-associated pathogens. Colonization precedes infection but the risk of developing infection amongst those colonized with CRE is not clear.

Methods: We searched multiple databases for studies reporting rates of CRE-colonized patients subsequently developing infection.

Results: Ten studies fulfilled our inclusion criteria, including 1,806 patients used in our analysis. All studies were observational and conducted among adult inpatients. The cumulative rate of infection was 16.5% in our study. The most common site of infection was the lung, identified in half of patients, followed in decreasing frequency by urinary tract; primary bloodstream; and skin and soft tissue, including surgical sites. Colonization or infection by CRE prolonged stay and was associated with a 10% overall mortality in our analysis.

Conclusion: Our study results suggest an overall 16.5% risk of infection with CRE amongst patients colonized with CRE. Given the high mortality rate observed with CRE infection and the difficulty in treating these infections, research to investigate and develop strategies to eliminate the colonization state are needed.

Since the early 1980s, carbapenems have been used with success as the last line of defense against multidrug-resistant gram-negative organisms. Widespread carbapenem-resistant Enterobacteriaceae (CRE) were unknown until the early 2000s.[1] During recent years, CRE have emerged as an important family of health care-associated pathogens worldwide, including in the United States.[2-5]

In January 2015, the Centers for Disease Control and Prevention revised the definition of CRE as organisms that are nonsusceptible to imipenem, meropenem, doripenem, or ertapenem or a documented isolate that possesses a carbapenemase.[6] A wide range of species in the Enterobacteriaceae family have been detected with carbapenemases, including *Klebsiella pneumoniae, Citrobacter freundii, Escherichia coli, Acinetobacter baumannii,* and *Enterobacter aerogenes*. *K pneumonia* carbapenemase and metallo-β–lactamase are the main mechanisms underlying resistance to carbapenems.[7]

Infections by CRE are considered a health care challenge because CRE isolates are usually extensively drug resistant and associated with high morbidity and mortality.[8,9] Colonization is considered to be a prerequisite for infection,[10] which suggests that prevention of CRE colonization is important in preventing the morbidity and mortality associated with these infections. However, the extent to which colonized patients develop infection with CRE is unclear. These data are important to guide decision making regarding infection-control interventions such as screening and contact precautions for colonized patients.

Therefore, we undertook a systematic review to understand the relationship between colonization with CRE and subsequent infection.

METHODS

During September 2014 and June 2015 we searched PubMed, Medline, Cochrane Library database, Cumulative Index to Nursing and Allied Health Literature, and Scielo databases from January 1,

1991, the year before the first reported case of CRE, for relevant publications. No language restrictions were used. Key words used in the search, alone or in combination, were: *carbapenem-resistant Enterobacteriaceae*, Klebsiella pneumonia *carbapenemase*, *KPC*, *Verona integron-mediated metallo-beta-lactamase*, *CRE*, *carbapenem resistant*, *carbapenem nonsusceptible*, *carbapenemase*, *carbapenamase-producing*, *colonization*, *infection*, and *carriage*. Reference lists of studies included in this review were also searched for relevant articles.

Inclusion criteria

To be included in our systematic review, studies needed to be clinical trials or observational studies. Data had to be provided to calculate rates of infection in patients initially colonized. Studies that reported data on only colonization or infection or did not allow for determination of infections arising from previous colonization were not included, and studies that reported numbers of cultures or isolates, not patients colonized or infected, were excluded. Review articles, abstracts, and editorials were excluded.

Outcome measures

The primary outcome of interest was rate of CRE infection amongst those colonized with CRE.

Data extraction

Two investigators independently extracted data using a standard data collection form. Data extracted included study sample size, demographic characteristics of the study sample, number of patients colonized, site of colonization, number of subsequent infections, site of infection, length of hospital stay, and mortality rate. The two investigators reviewed studies that met the inclusion criteria. Disagreement amongst investigators was resolved by discussion and arriving at consensus.

Data synthesis

Descriptive statistics were used to determine the percentage of patients initially colonized with CRE who went on to develop clinical infection. The mean age of subjects with infection and length of stay were also calculated for the subset of studies for which these data were available. For the subset of studies for which mortality rates were reported, we calculated cumulative in-hospital mortality, which is reported as the proportion of patients with CRE infection or colonization who died with all patients infected or colonized with CRE as the denominator. Because of the heterogeneity in included studies, we did not perform a meta-analysis.

RESULTS

Study characteristics

Our search strategy yielded 1,709 reports, of which 178 were considered potentially relevant and abstracts were reviewed. Of these, the full text of 42 studies was retrieved and reviewed; 33 were ultimately excluded because data on the numbers of patients initially colonized who subsequently went on to develop infection were not reported. In fact, many were point prevalence reports of those colonized or infected and not consistent with the aim of our review (Fig 1). One additional study[11] was brought to the attention of the authors during the review process and was included in our analysis.

Ten studies fulfilled inclusion criteria; all were observational studies.[11-20] Characteristics of the studies meeting inclusion criteria are reported in Table 1. Among these 10 studies, 1,806 colonized patients were used in our analysis. For 2 studies,[13,14] only data on those patients with nosocomial acquisition of CRE were used for analysis because subsequent rates of infection were reported for only these patients. In a third instance,[15] the authors reported on rates of infection for those patients infected with *K pneumoniae* alone; thus, only this subset of patients was used in our analysis.

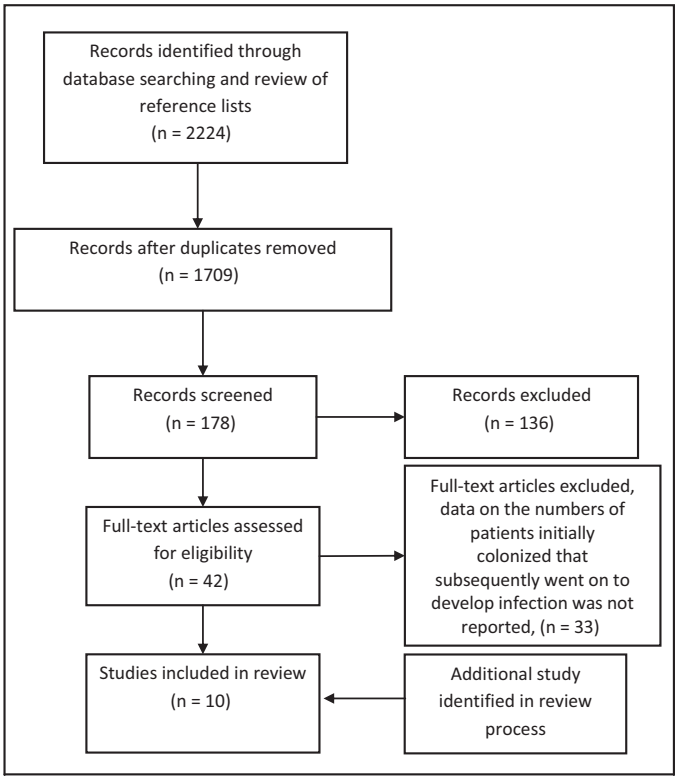

Fig 1. Flowchart depicting the selection process of studies included in the review.

All studies were conducted among adult inpatients, with 4[11,13,14,16] exclusively in an intensive care unit setting. One[17] included liver transplant recipients. One study[15] performed hospitalwide screening, whereas 4[12,18-20] performed screening on patients deemed to be at higher risk based on past acute- or long-term care admission, housing on a high-prevalence ward, or known contact with other patients infected or colonized with CRE. For the remaining studies, screening was performed at specified intervals for those patients admitted to an intensive care unit[11,13,14,16] (Table 1).

Seven studies examined carbapenem-resistant *K pneumoniae* exclusively,[12,14-19] 2 reported prevalence of carbapenem-resistant *A baumannii*,[11,13] and the remaining examined multiple CRE.[20] Seven reported site of infection[11-14,17,19,20] and 6 studies included data on length of stay amongst CRE cases,[12,14-17,20] whereas only 5 included mortality data.[12,14-17]

For those studies that reported data on gender,[11,14,17,18,20] men accounted for 33%-69.6% of patients colonized or infected with CRE. One study[18] found a predominance among women. Patient age ranged from 45-76 years across studies.[11,12,14,15,17,18,20] Four were conducted in the context of an outbreak.[15,17,18,20]

Risk of infection after colonization with CRE

Colonization was defined as gastrointestinal tract carriage determined by rectal swab in the majority of studies.[11,12,14,15,18-20] Five studies cultured specimens on MacConkey agar.[11,14,15,18-20]

Table 1
Characteristics of studies included in the review

Study, year	Patient population	Outbreak setting	Screening frequency	No. of patients colonized by CRE	No. of patients who developed CRE infection	Colonization site	Infection site	Type of CRE	Mortality
Borer et al, 2012[12]	Adults, hospital-wide	No	Rectal cultures performed in patients admitted for nursing or other outside facility and on patients in high-risk units	464	42 (9.1%)	Rectal	Multiple	CRKP	18.75%, colonized 30%, infected
Cho et al, 2014[13]	Adults, ICU	No	On admission, weekly thereafter	530 with nosocomial acquisition included for analysis	111 (20.9%)	Nares	Multiple	CRAB	Not included
Debby et al, 2012[14]	Adults, ICU	No	Within 72 h of ICU admission, then twice weekly	48 with nosocomial acquisition included for analysis	20 (41.7%)	Rectal	Multiple	CRKP	17/48 (35.4%), patients with nosocomial acquisition
Wiener-Well et al, 2010[15]	Adults, hospital-wide	Yes	All hospitalized patients screened during 3 consecutive days	42, 16 with CRKP included for analysis	5 (31.3%)	Rectal, perianal, oral	Not included	CRKP	1/16 (6%) of all CRKP carriers
Papadimitriou-Olivgeris et al, 2013[16]	Adults, ICU	No	Upon ICU admission, days 4 and 7, and weekly thereafter	164	37 (22.6%)	Rectal	Not included	CRKP	41/127 (32%), colonized 22/37 (59.5%), infected
Lübbert et al, 2014[17]	Liver transplant patients	Yes	—	9	8 (89%)	Unclear	Multiple	CRKP	1/1 (100%), colonized 6 out of 8 (75%), infected (2 of these determined "noninfectious causes")
Pisney et al, 2014[18]	Adults, selected high-prevalence units	Yes	7 rounds of point prevalence screening on affected units	15	0 (0.0%)	Rectal	None	CRKP	Not included
Lowe et al, 2013[19]	Adults, hospital-wide	No	Known contact with CRE-infected patients were screened	9	4 (44.4%)	Rectal	Bloodstream, urine	CRKP	Not included
Schechner et al, 2012[20]	Adults, hospital-wide	Yes	All patients hospitalized in the past year and those with CRE-infected contact	502	38 (7.6%)	Rectal	Multiple	CRKP, *Escherichia coli*, *Enterobacter* spp, *Citrobacter freundii*	Not included
Latibeaudire, et al, 2015[11]	Adults, ICU	No	Upon ICU admission and weekly thereafter	49	34 (69%)	Rectal, tracheal	Multiple	CRAB	Not included

CRAB, carbapenemresistant *Acinetobacter baumannii*; *CRE*, carbapenem-resistant Enterobacteriaceae; *CRKP*, carbapenem resistant *Klebsiella pneumoniae; ICU*, intensive care unit.

A53210128

Alternative methods used included inoculation of brain-heart infusion broth[14,15] and use of CHROMagar *K pneumonia* carbapenemase Petri dishes (CHROMagar, Paris, France) for some or all specimens.[12,16,19] The study by Cho et al[13] was unique in using nasal swabs cultured on 5% sheep's blood agar plates. One study did not specify microbiologic techniques sufficiently to allow interpretation.[17]

Amongst the 1,806 initially colonized patients included in our analysis, 299 clinical infections were observed for a cumulative rate of 16.5%. Rates of infection in individual studies varied widely, from 0%[18]-89%,[17] although with the majority falling in the range of 7.6%-44.4% (Table 1).

Quantitative data regarding site of infection was reported for 223 previously colonized patients in the studies.[12-14,17,19,20] The most frequent clinical syndrome was pneumonia, identified in half of patients with CRE infection. Forty-four cases, or approximately 20%, of patients were diagnosed with urinary tract infection caused by CRE. In order of decreasing frequency, primary bloodstream infections, identified in 30 patients, and skin and soft tissue infections, including surgical site infection, identified in 16 patients, accounted for the remaining infections reported.

Risk of adverse outcomes following acquisition of CRE

There was no standardized method for reporting length of stay, so it is difficult to draw a meaningful conclusion regarding mean length of stay from currently available data. However, in studies that reported these data[12,14-17,20] colonization or infection with CRE significantly prolonged hospital stay, with 2 studies reporting hospitalization nearly 2-fold longer in those patients with CRE.[16,17]

The overall mortality rate was 10% for all patients infected or colonized. Amongst the 3 studies that reported mortality in the subset of patients with clinical infection separate from those colonized,[12,16,17] mortality rates ranged from 30%-75%.

DISCUSSION

Our results show that a substantial proportion of patients colonized the CRE go on to develop clinical infection with CRE. We summarized the results of the available literature and found an overall 16.5% risk of infection with CRE amongst patients colonized with CRE. Individual studies that have examined this question have found varying rates of infection, probably due to differences in type of organism, patient population, and clinical setting. Thus, the overall magnitude of risk was unclear. Our study provides an overall assessment of the risk of infection and has implications for infection preventionists and clinicians involved in the prevention and treatment of CRE.

Sites of screening and microbiologic methods varied across studies, contributing to the heterogeneity amongst studies. The most common site of screening for carriage was the gastrointestinal tract, specifically, rectal swabs. Wiener-Well et al[15] examined the sensitivity of 3 screening sites and found rectal swabs to be more sensitive that perianal or oral swabs. MacConkey agar was used most commonly for culturing CRE; however, a limited number of other methods were used in some studies. Future studies should compare the different types of selective media available to determine the best way to recover CRE from surveillance specimens. Studies also varied in the approach to screening for CRE; 9 of the 10 included studies reported screening method. Screening approach varied from hospitalwide point prevalence screening[15] to screening of those only with known contact with a CRE-infected patient.[19]

CRE infections are associated with considerable mortality with rates reported up to 50% in the literature.[9,21] Our review found similar rates, ranging from 30%-75% for those infected amongst the included studies. There are many contributors to this high rate of mortality, including longer length of stay,[12,14-17,20] poorer overall health status, site of infection, comorbid illnesses, and most importantly the limited antimicrobial options for treating these infections. Panresistant Enterobacteriaceae have been reported,[22,23] highlighting the challenges in treating these infections and underscoring the importance of antimicrobial discovery and development targeted to these organisms.

Given the heightened risk of mortality associated with CRE infection, >30% for patients in our review, our results emphasize the importance of identifying and eliminating the carrier state to prevent development of clinical infection with CRE. Studies have examined the role for oral decontamination therapy in decolonizing patients with CRE. In a modestly sized randomized controlled trial of 40 patients colonized the carbapenem-resistant *K pneumoniae*, the utility of treatment with combination of gentamicin and colistin in both oral, nonabsorbable solution and nasal gel delivery method was examined.[24] In the 20 patients randomized to treatment, the rate of rectal colonization at 2 weeks was significantly reduced, with 61.1% of patients decolonized in the treatment group versus 16.1% in the placebo arm. This difference persisted at 6 weeks, with 58.5% of patients remaining decolonized in the treatment arm versus 33.3% in the placebo arm. In a larger study,[25] 50 patients colonized with carbapenem-resistant *K pneumoniae* strains with demonstrated susceptibility to gentamicin and colistin were randomized to treatment with gentamicin, colistin, or combination therapy. Compared with the spontaneous eradication rate of 7% in their study, all 3 treatment arms demonstrated a significantly greater decolonization rate. The rate of decolonization with colistin was 50%, with gentamicin, 42%. Similar to the study by Saidel-Oades,[24] no significant adverse effects were noted. Interestingly, combination therapy yielded the lowest rate of decontamination, only 37.5%, although the differences amongst groups did not reach statistical significance. These promising results should be confirmed in larger studies and tested in both outbreak and endemic situations with close attention to analysis of gut microbiome changes as a result of the antibiotic agents.

Our study has several limitations. First, given the methodology of a systematic review, our results have the limitations of the included studies. Secondly, the studies were quite heterogeneous in their study methods and patient populations. We did develop a priori inclusion and exclusion criteria and did not include studies that did not clearly establish patients as colonized before developing clinical infection. Third, we were not able to study risk factors for development of clinical infection and mortality because of limited available data; this should be an area for future research. Fourth, the included studies used varying approaches to identifying cases of colonization and/or infection, potentially contributing to misclassification of colonization and infection. Similarly, many studies did not include data on those patients developing infection without preceding colonization, which precluded our ability to comment on the relative risk of infection in those patients with colonization. Limited by reported data, we were not able to comment on the time from colonization to the development of infection. Finally, publication bias is a concern.

CONCLUSIONS

We found that colonization with CRE poses a 16.5% risk of subsequent CRE infection. With a high rate of mortality associated with CRE infection, pending further research, eradication of colonization with CRE should be considered in select situations such as outbreaks. Future research should attempt to determine the utility of widespread routine surveillance for CRE amongst hospitalized patients as an infection control strategy as well as determine strategies of eradication of CRE colonization.

Legionella in hospitals: a review

C. A. Hart and T. Makin

Department of Medical Microbiology, University of Liverpool, P.O. Box 147, Liverpool L69 3BX, UK

Summary: Although epidemics of nosocomial Legionnaires' disease attract great attention, up to 30% of sporadic cases of hospital-acquired pneumonia are caused by legionellae. Legionellae are ubiquitous contaminants of potable water and can achieve high numbers in the hot-water systems of large buildings such as hospitals. They are present in the mains water supply in small numbers but are amplified considerably in the hospital's hot-water system. This is encouraged by water temperatures below 50°C, areas of stagnation and sludge formation, the presence of amoebae and other bacteria and the materials used in the piping. Formation of aerosols from contaminated water is a major mode of spread of legionellae, but there is evidence to suggest that aspiration is also a mode of entry.

Safe levels of legionellae in cooling towers have been defined, but not for hot-water systems. A combination of culture and antigen detection by immunofluorescence offer the best method for enumerating legionellae in environmental samples. Control involves a mixture of physical (heat, UV irradiation, sanitation) and chemical (hypochlorite, ozone) methods combined with good plumbing practice (e.g. arrangement of pumps and calorifiers, elimination of dead-legs). Adequate control can be costly and requires considerable attention to detail.

Keywords: Legionellae; nosocomial infection; hospital reservoirs.

Introduction

Since the initial description of an outbreak of pneumonia associated with an American Legion convention in Philadelphia in 1976[1] there has been great interest in legionellae in both the scientific and popular press. Although the initial outbreak was linked to a hotel, it is now clear that hospital-associated Legionnaires' disease, both epidemic[2,3] and sporadic[4,5] is not uncommon.

The infection generally presents as either a severe pneumonia with or without extrapulmonary manifestation or a milder 'flu-like' febrile illness (Pontiac fever),[6] but infection at other sites can occur. Such infections include pericarditis,[7] endocarditis[8] and cutaneous abscesses.[9]

In order for legionellae to produce disease, several factors must be considered. Firstly, because human-to-human transmission does not occur, there must be an environmental reservoir. Secondly there must be a mechanism for getting the bacterium from the reservoir to the site of

infection and thirdly the organism must lodge in a susceptible host. In this review we will discuss the properties of legionellae, their reservoirs and modes of spread in hospitals and methods of detection and control of legionellae in the hospital environment.

The bacterium

There are currently 14 recognized serogroups of *Legionella pneumophila* and at least 29 other *Legionella* species (Table I) although there is still some disagreement over speciation. Not all of these bacteria have been associated with disease in man, and even within *L. pneumophila* serogroup 1 there appear to be subtypes of differing virulence.[10]

Legionellae are not thermophilic but are thermotolerant, i.e. they are able to survive at relatively high temperatures. For example, legionellae will multiply over the temperature range 20–43°C and can survive for varying periods at temperatures 40–60°C. At 50°C, 90% of the organisms are killed within 2 h. Legionellae can survive in water for over a year.[11] Legionellae are able to survive aerosolized in droplets 1–5 μm in diameter and there is evidence to suggest that virulent strains survive longer.[12] Legionellae appear to be able to adhere to substrata such as pipes, rubber, plastics and sediment and can thus persist even when there is constant flushing of a piped-water system. It is possible that they exist in biofilms with release of planktonic organisms. This may explain the discrepancy between the ability of disinfectants to kill legionellae in the test tube and that in piped water systems.

Finally, there is some evidence that legionellae are engulfed by amoebae and are able to survive and multiply inside them.[13] This might also be a mechanism prolonging survival of legionellae in water. It is also noteworthy that amoebae constantly generate superoxide,[14] thus the ability of

legionellae to survive in amoebae might be related to their ability to survive in a patient's alveolar macrophages.

Reservoirs

Legionellae are common contaminants of potable water. *Legionella pneumophila* has been isolated from drinking water from various parts of the world with a frequency ranging from 0 to 8·8% and isolation occurs more frequently in warm summer months.[15] It is probable that the small numbers of legionellae in the incoming water are amplified by the hot water systems in large buildings such as hospitals and hotels. For example, the water systems of over 50% of large establishments have been shown to contain *L. pneumophila*.[16] Large outbreaks of Legionnaires' disease have resulted from contamination of air conditioning and ventilation systems,[3,4,17] and legionellae can be found in large numbers in water in cooling towers. The other major site for colonization and multiplication of legionellae is the hot-water system, or other areas where water temperature is raised into the range 25–40°C. In many hospitals, hot water is produced by taking water through a number of heaters or calorifiers. The water then circulates throughout the hospital and returns to the calorifiers. The factors promoting the expansion and persistence of legionella populations have been described by others.[2,18] They include the arrangement of calorifiers, which should be in series rather than parallel, the presence of a dead space at the bottom of the calorifier which allows sludge and legionellae to persist, and maintenance of the hot-water output below 57°C. The presence of dead-legs in the hot-water system, e.g. associated with showers,[19–21] hosepipes or fire sprinkler systems, the use of spas or jacuzzis, and the addition of hot water to humidifiers or nebulizers[22] can all serve to amplify *Legionella* populations. We have even been able to find legionellae in the melt-water from ward ice-making machines. The pH, ionic composition and conductivity of the water and the nature and age of materials used to make pipes and valves also affect the growth and survival of legionellae. For example, some silicone-based rubbers enhance the growth of *L. pneumophila* by a factor of 10^5, whereas rubbers containing the accelerator thiuram inhibit growth.[23]

There has been considerable debate over the relative importance of the two major reservoirs, namely cooling towers and evaporative condensers and the hot-water system. It is clear that episodes of infection have arisen from contamination of water in cooling towers,[3,24] and the evidence linking such reservoirs and development of infection is strong. Indeed, in one outbreak of Legionnaires' disease in a retirement hotel in which *L. pneumophila* serogroup 1 was found in both the hot-water system and an evaporative condenser, it was demonstrated using air sampling and monoclonal antibody subtyping that the condenser was the source.[25] However, it has also been shown that Legionnaires' disease could occur in

areas where there was no possibility of aerosols from evaporative condensers.[20,26] Similarly outbreaks have been controlled by treatment of the water system alone even though a cooling tower was present.[27] It would appear that the two reservoirs are equally important.

Guidelines on acceptable levels of legionella contamination of cooling towers have been produced[28] but no such guidance is available for hot-water systems. In cooling towers *Legionella* counts of less than $10^3\,l^{-1}$ have been suggested as being acceptable, those above $10^5\,l^{-1}$ indicate that corrective action is required.

It has been demonstrated that there is a link between the extent of colonization of a hospital's hot-water system and the development of nosocomial Legionnaires' disease.[4,29] Thus, in an Ear Nose and Throat hospital where 67% of sites sampled contained legionellae, 30% of the cases of hospital-acquired pneumonia were due to legionellae. After chlorination of the system only 3·5% of sites were contaminated and none of the cases of hospital-acquired pneumonia were caused by legionellae. The patient group studied were resident on head and neck oncology wards and such patients are known to be highly susceptible to legionella infection. Nevertheless, it appears that once contamination of a hospital's hot-water system involves more than 30% of sites sampled, nosocomial Legionnaires' disease occurs.[19] Unfortunately, there is little information on the relationship between numbers of legionellae in the hot-water systems and development of infection. However, we were able to demonstrate that a few days prior to acquisition of pneumonia due to *L. pneumophila* serogroup 12 by a renal transplant recipient, the water from her hand basin hot tap contained 6×10^3 cfu l^{-1} of the same bacterium.[5]

Modes of spread

The most likely mode of spread is by aerosolized particles $< 5\,\mu m$ diameter containing legionellae. It is possible to infect guinea-pigs with aerosols containing as few as $3{\cdot}7 \times 10^4$ cfu *L. pneumophila* serogroup 1[30] and the bacteria can survive for up to 2 h in such aerosols.[31] Aerosols can be produced easily in evaporative condensers, cooling towers, jacuzzis, showers, nebulizers and in large buildings even by normal tap pressure. There has even been an outbreak of Pontiac fever due to *L. anisa* where an aerosol created by an artificial fountain was implicated.[32]

It has also been suggested that aspiration or direct inoculation of legionellae into the tracheo-bronchial tree via respiratory manipulation are important modes of transmission especially in head and neck surgery patients.[2,4]

Detection of legionellae in the environment

Perhaps the most difficult question to answer is should there be environmental testing and if so, how frequently? In general the indication

for environmental testing in hospitals is the presence of a cluster of cases of Legionnaires' disease or an increasing number of sporadic cases. Because legionellae are ubiquitous and because of the high cost, routine surveillance is not recommended.[33] Perhaps in the light of recent developments some re-appraisal of this position is necessary. Guidelines have been produced giving acceptable levels of legionellae in cooling towers, in order to comply with these it is thus necessary to measure levels actually present.

There does appear to be a relationship between the extent of environmental colonization and development of nosocomial Legionnaires' disease.[4] Methods for blanket control of *Legionella* in the hot-water system are expensive and not uniformly effective (see below) and we may now be reaching the point where it is more cost-effective to monitor environmental contamination than implement continuous control.

Finally, with patients increasingly taking recourse to the law, the high cost of hospital-acquired Legionnaires' disease might make regular testing more cost-effective. One author has suggested that hot water tanks and selected distal outlets be tested three to four times a year.[2] We would also suggest that the hot-water systems in areas where patients such as the immunosuppressed, those undergoing head and neck surgery and those with chronic pulmonary disease might warrant regular testing.

Detection of legionellae in the environment is now becoming simpler, cheaper and more accurate. The methods available for detecting legionellae in environmental samples fall into three categories: culture, antigen detection and genome detection.[2,6,15,20,34–36]

Quantitative culture usually involves concentration of water samples by centrifugation followed by incubation of the deposit on suitable selective media (e.g. buffered charcoal yeast extract agar with and without cysteine) at 37°C in a humid atmosphere for 7–10 days.[37] Colonies with the appropriate morphology are then serotyped with specific antisera. Although this is taken as the 'bench-mark' methodology it is rather slow and can be rendered imprecise by the presence of biocides and other bacteria that produce inhibitory compounds.[38] Another problem is the presence of non-culturable *L. pneumophila*.[15] These are bacteria that are visible by indirect or direct immunofluorescence but not recoverable on culture. It is possible that this is a form of 'heat shock' and it has been shown that if appropriate resuscitation procedures are employed the 'non-culturable' legionellae can be grown.[15]

Antigen detection is usually by immunofluorescence, which provides quantification. Although enzyme-linked immunosorbent assay (ELISA) systems have been devised,[36,39] they are not so readily rendered quantitative, since they will detect both bacterium-associated and soluble antigen. Immunofluorescence can be highly sensitive (94%) but is less specific (52%) compared with culture,[35] presumably because of the non-culturable legionellae.[15] Perhaps the use of vital dyes (e.g. that change colour when the bacterial respiratory chain is active) or antisera directed against *Legionella* heat-shock proteins might improve the specificity of such tests.

A53210128

Methods involving genome detection, e.g. DNA hybridization or polymerase chain reaction (PCR) are likely to suffer the same problems of quantification as ELISA, although PCR could determine viability if it were used to detect mRNA.

At present it would appear that a combination of culture and antigen detection offer the best method for quantification of legionellae in environmental waters.[35]

Control of legionellae in the hospital environment

Methods for control of legionellae in cooling towers and evaporative condensers are well-established and involve the use of biocides combined with good engineering practice.[40]

There are many methods, of varying efficacy, for controlling legionellae in hospital hot water systems. They fall into three categories: physical, chemical and good plumbing practice (Table II).

Physical methods

Raising the output temperature in the hot-water system, either intermittently or continually is a well-tried and successful method of elimination[2,27] and is often used in combination with hyperchlorination. Disadvantages of this method include: cost, risk of scalding and incomplete bacterial killing because of the temperature gradient between the calorifier and under-used peripheral outlets. Methods to circumvent this problem

Table II. *Some methods for control of legionellae in hot-water systems*

1. Physical		
(a) Heat	—Raising calorifier temperatures	
	—Instantaneous steam heat systems	
	—Self-regulating trace heat systems	
(b) UV irradiation		
(c) Sonication		
(d) Draining and flushing pipes with compressed air		
2. Chemical		
(a) To prevent scale formation		
(b) To maintain sediment in suspension		
(c) Biocides	—Sodium hypochlorite	
	—Ozone	
(d) Charcoal filters		
3. Good plumbing practice		
(a) Maintenance		
(b) Pumps and calorifiers in series not parallel		
(c) Elimination of dead-space in calorifiers		
(d) Removal of dead-legs		
(e) Regular flushing of outlets.		
(f) Use of Water Research Centre recommended components		

A53210128

include generation of hot-water at outlets via instantaneous steam heat[2] and the use of self-regulating trace heat elements that can maintain water in peripheral outlets at 50°C.[41]

Legionellae are readily killed by UV irradiation.[42] We have been able to demonstrate that fitting a UV irradiation device to a shower was able to maintain it free from legionellae following initial hyperchlorination (unpublished observation). Interestingly although this device did not eliminate other bacteria such as pseudomonads, no amoebae were found. On cessation of UV treatment amoebae and legionellae reappeared concurrently.

Chemical methods

These have been discussed extensively elsewhere.[6] Problems of their use include: inability to kill bacteria in biofilms, corrosion of pipework and generation of organic chlorine compounds. Ozonization of water presents another method of disinfection, and a comparison of various methods for elimination of legionellae has been produced.[2] Finally, charcoal filters have been shown to be of limited benefit in maintaining dental chair water systems free of legionellae.[43]

Good plumbing practice

Design and maintenance of hot-water systems are of prime importance in controlling legionellae in hospitals.[40] For example, elimination of dead spaces by avoiding the use of pumps and calorifiers in parallel, the use of devices to ensure complete water circulation in calorifiers and the elimination of dead legs are all of great importance. We have demonstrated that the fitting of automatic drain valves was ineffective in maintaining a reduction in the number of legionellae in shower water[21] but that regular flushing of the system was highly effective.

In conclusion, our understanding of the ecology, microbiology and pathogenesis of legionella infections has increased tremendously over the last decade. However, legionellae are still an important cause of hospital- and community-acquired pneumonia. For hospital-acquired Legionnaires' disease to develop, a series of events is required. Firstly, there must be a way for legionellae to gain access to the hospital's water system and it is likely that low numbers of legionellae gain access through the mains water supply. Next there must be an amplification step. Legionellae are thermotolerant, being able to survive at relatively high temperatures and they are able to multiply in lukewarm water both in sessile and planktonic forms. There must also be a way for the bacteria to gain access to their host's alveoli. This is usually by the aerosols that are readily produced in hospitals, but may occasionally be due to aspiration. Finally the aerosolized bacteria must lodge in a susceptible host. To prevent nosocomial Legionnaires' disease one or more of these four stages must be prevented. Efforts to decrease or prevent the amplification step are the most likely to be fruitful.

Infect Dis Clin N Am 16 (2002) 363–376

Diagnostic methods Current best practices and guidelines for isolation of bacteria and fungi in infective endocarditis

Michael L. Towns, MD[a,*], L. Barth Reller, MD, DTM&H[b]

[a]*BD Diagnostic Systems, 7 Loveton Circle, Sparks, MD 21152, USA*
[b]*Duke University Medical Center, Box 3938, Durham, NC 27710, USA*

Advances in technology, especially echocardiography, have provided new tools for the better recognition and management of infective endocarditis (IE). Traditional blood cultures remain essential, however, not only for determining the etiological diagnosis of IE but also for antimicrobial susceptibility tests to guide therapy.

Within a decade of Ettlinger's first "hemoculture" using venous blood taken from a patient in Paris [1], use of blood cultures to diagnose bacterial endocarditis had become firmly established [2]. Before then, clinicians relied upon physical examination to detect the presence of "classic findings" such as subungual hemorrhages, Osler's nodes, or Roth spots to make a diagnosis of IE. These findings are not specific for IE, however, and in the absence of positive blood cultures they have limited diagnostic value today. Furthermore, these "classic findings" are seen less frequently in modern clinical practice than formerly, presumably because many cases are now diagnosed before the disease has been present long enough to give rise to these late findings [3]. Moreover, the incidence of IE due to viridans streptococci, one of the principal etiologic agents of subacute disease in which these findings would be more likely, is decreasing, while the incidence of disease due to organisms associated with acute infective endocarditis, especially *Staphylococcus aureus*, is increasing [4].

Pathophysiology

Infective endocarditis is an endovascular infection which typically gives rise to a continuous bacteremia originating from the source of the infection, usually a vegetation on a heart valve. Early studies confirmed that the bacteremia of endocarditis is usually continuous, with ongoing shedding of organisms from the vegetation into the bloodstream and simultaneous clearance of bacteria by the reticuloendothelial system in the liver, spleen, and bone marrow [5]. Detection should therefore be relatively straightforward, and in practice the majority of blood cultures obtained from patients with IE are positive for the etiologic agent [6]. One early study demonstrated that two blood culture sets diagnosed 78% of cases, and that four blood culture sets diagnosed over 90% of patients with IE [7]. In a later series of 206 cases of bacterial endocarditis with positive cultures reported by Werner et al. [8], 95% of 789 blood cultures were positive for the etiologic agent. If all blood culture sets obtained were positive, especially if each set was drawn at least thirty minutes apart, the patient most likely had a source of infection that caused a continuous bacteremia, such as IE, rather than an intermittent bacteremia, such as an occult abscess.

Even in untreated patients with typical bacterial endocarditis the blood culture positivity rate is not 100%, for several reasons. Organisms in vegetations can be located on the surface or just beneath the outer fibrin layers of the vegetation, in close proximity to the bloodstream, or buried deep within the vegetation, therefore sequestered away from circulating blood [9]. Cessation of bacteremia and ''surface sterilization'' of the vegetation when the colonies are deeply buried has been described [10]. The inflammatory damage caused by the organisms continues beneath the surface, however, and valve ring abscesses and ruptured chordae are among the ensuing complications. This phenomenon explains why infected vegetations on valves removed at surgery should be ground up (for bacteria) or minced (for fungi) before culture—to minimize the occurrence of false-negative cultures.

The bacteremia in subacute IE is typically ''low-grade,'' with only 1 to 10 colony-forming units (CFU) per milliliter of venous blood [8]; therefore, an adequate volume of blood is needed for culture in order to maximize the chance of recovering organisms in the culture. Many years ago it was hypothesized that the recovery of microorganisms might be enhanced if arterial blood samples obtained before the blood had passed through the reticuloendothelial system of the liver, spleen, and marrow were cultured. Arterial blood does carry a somewhat higher count of bacteria [5], but it has now been concluded that there is no significant diagnostic benefit gained from using arterial versus venous blood for culture [5,11].

Role of microbiologic findings in diagnostic criteria

Blood culture results provide much useful diagnostic information that has immediate importance for management decisions. A positive result can

A53210128

Page 1207

provide the identity of the presumed etiologic agent, and the identity of the organism may point to the original source of bacteremia. For instance, isolation of viridans streptococci imply an oral or dental source whereas *Streptococcus bovis* points to possible colonic pathology such as a benign polyp or colonic malignancy as the source of bacteremia. This information is valuable because preventive interventions may decrease the risk of recurrent bacteremia and recurrent endocarditis. Endocarditis is itself a risk factor for recurrent endocarditis [12]. In addition, information that suggests a continuous bacteremia (i.e., 3 of 3 positive blood cultures collected at least 1 hour apart) provides clinical value. Earlier criteria for the diagnosis of IE (e.g., the Beth Israel criteria) [13] incorporated the finding of persistently positive blood cultures as a criterion for the diagnosis, but did not give any additional weight to the recovery of organisms that are typically associated with this disease. In 1994, the Duke Endocarditis Service published new diagnostic criteria which increased the sensitivity as well as specificity of clinical diagnosis of endocarditis [14]. These Duke criteria have been validated by many subsequent studies as being more sensitive than other published criteria and have also been shown to maintain a high negative predictive value [15].

The Duke criteria also give diagnostic weight to the recovery of certain species of microorganisms from the blood that are typically associated with IE. Identification of the organism may provide clues as to the origin of the infection. For example, recovery of *Enterococcus faecalis* from the blood of a patient in the community setting without an obvious primary focus of infection (such as a urinary tract infection) indicates a high prior probability of IE. If blood cultures had not been obtained, or were obtained and were negative, this valuable information would not be available to the clinician. More recently, proposed modifications to the Duke criteria have included bacteremia due to *S. aureus* regardless of whether the infection is nosocomially acquired or a removable source of infection is present [16]. A recent study reported that this organism is now the single most common cause of IE seen by the Duke Endocarditis Service [4].

A review of the individual value of each component of the Duke criteria for the diagnosis of IE shows that the major microbiological criteria had the highest relative importance [17]. In a study of the 67 pathologically proven cases, 53% of the ''definite'' cases became ''possible'' or ''rejected'' when the major microbiological criteria were subtracted.

The recovery of microorganisms from the blood in a patient with suspected IE does not, however, prove the diagnosis. The overall positivity rate for clinical blood cultures in the United States is ~10%, but 30% to 40% of these positives represent false-positive isolates. The most common cause of false-positive cultures is contamination arising from skin flora due to faulty skin preparation before venepuncture or from cultures that are obtained through contaminated indwelling vascular catheters. This issue becomes especially important when evaluating patients with suspected prosthetic valve

A53210128

Page 1208

endocarditis; here the leading etiologic species are coagulase-negative staphylococci, which are also the most frequent causes of false-positive blood cultures arising from skin flora. It is imperative, therefore, that skin is adequately prepared prior to obtaining blood cultures in these patients. Furthermore, blood for culture should not be drawn through indwelling vascular catheters, which may be contaminated. If false-positives are to be averted, the importance of meticulous techniques for obtaining peripheral venous blood cultures cannot be overemphasized.

The information obtained from the identification and susceptibility results of organisms isolated from the blood of patients with IE greatly aids the management of these patients. The identification of the organism can provide initial guidance with regard to appropriate antibiotic therapy, duration of therapy, and potential for outpatient therapy. The susceptibility profile of the isolate provides important information that assists the clinician in deciding the optimal therapeutic regimen, including the choice of single-agent versus combination therapy. For example, endocarditis caused by penicillin-susceptible (MIC ≤ 0.1 μg/mL) viridans streptococci may be treated with 2 weeks of combined penicillin and gentamicin while relatively resistant viridans strains (MIC $> 0.1 \leq 0.5$ μg/mL) require an additional 2 weeks of penicillin following the initial 2 weeks of combination therapy [18]. This information might also allow a physician to change a patient from an inappropriate antibiotic (chosen empirically for initial treatment) to an appropriate antibiotic. In a prospective epidemiological study of the clinical significance of positive blood cultures [19] such "corrections" of antibiotic therapy on the basis of susceptibility results were shown to decrease mortality.

Finally, identification of the etiologic species from blood cultures can provide important prognostic information about the potential for curative therapy without the need for adjunctive surgery. Patients infected with certain microorganisms are more likely to require surgical intervention. Prosthetic valve endocarditis due to gram-negative bacilli (other than the HACEK group), *S. aureus*, and yeasts are all associated with a high likelihood that surgery will be required [20]. In addition, native valve disease due to filamentous fungi is also a strong indication for surgical intervention [20].

Best practices for diagnosis of infective endocarditis due to bacteria

Because blood culture results are so critical to the diagnosis and management of patients with IE it is imperative that optimal procedures are utilized. The following guidelines define the authors' opinion of currently accepted "best practices" for evaluating patients with possible IE. The authors believe that use of these recommended practices will yield positive blood cultures in over 90% of cases of bacterial endocarditis and will optimize the yield of yeasts and filamentous fungi. If all cultures remain negative after application of these guidelines, the clinician must either conclude that the patient has blood culture-negative IE or consider an alternative diagnosis.

Optimal antiseptic skin preparation

As mentioned previously, it is vitally important that adequate skin antisepsis be performed prior to venepuncture for drawing blood cultures to minimize contamination of the cultures with skin flora, which may confuse the diagnostic picture. To ensure proper collection of blood for culture it is helpful to have all of the necessary components, including skin preparation materials, venepuncture device, and bottles of culture media pre-packaged in a kit or procedural tray.

The recommended antiseptic skin preparation is liberal swabbing with 70% isopropyl alcohol applied in widening circles over a reasonably wide area of skin around the intended site for venepuncture and allowed to dry, followed by similar application of an iodophor or tincture of iodine over the same area [21]. It is important that adequate contact time with the skin be allowed for both the alcohol and the subsequent iodophor or tincture of iodine preparations, which should be allowed to dry completely by evaporation to maximize their antiseptic effect [21].

Whenever practicable, blood cultures should be obtained by way of fresh venepunctures, not through indwelling intravascular devices, as detailed in the guidelines provided by the American College of Physicians [22]. Blood cultures drawn through catheters are more likely to be contaminated [23].

Optimal timing of blood cultures

It has often been stated that the optimal time to obtain blood cultures on an individual patient is during the hour prior to the onset of chills or fever spikes [24]. Although this makes sense in theory, based on the presumed pathophysiology of bacteremia, it would clearly be difficult or impossible to accomplish from a practical standpoint. Who can predict within one hour when the next fever spike will occur? Clinical data that have been referenced to support this ''recommendation'' are unconvincing [25,26]. The continuous nature of most bacteremias associated with IE renders timing less important. The authors do not therefore recommend attempting to link the timing of blood culture draws to the timing of fever spikes.

In the patients who present with the syndrome of acute endocarditis caused by highly virulent pathogens such as *S. aureus*, any delay in treatment to obtain cultures spaced over more than 1 hour to ascertain whether a continuous bacteremia is present is neither warranted nor necessary. In this critical situation, two to three blood cultures should be obtained from separate venepunctures within 5 minutes of each other, prior to prompt administration of empiric antibiotic therapy.

If, on the other hand, the patient presents with the syndrome of subacute endocarditis, there is usually no need to initiate immediate empiric antibiotic therapy. For these infections it is more important to first attempt to establish a specific microbiological diagnosis. In this instance several blood culture sets should be obtained over a period of several hours to document

A53210128

Page 1210

continuous bacteremia, which may provide additional clinical information, especially if the echocardiogram is negative or equivocal.

Optimal number of blood cultures

What is the optimal number of separate blood cultures? The answer is debatable, but clearly one blood culture is inadequate [22]. A single blood culture, while better than none, suffers from at least three deficiencies: it does not maximize the chance of isolating the etiologic organism, it cannot demonstrate the presence of a continuous bacteremia, and it cannot distinguish between contamination and true bacteremia.

First, multiple cultures provide a higher volume of blood for culture; this is the single most important factor for successful recovery of microorganisms from the bloodstream of patients (Fig. 1).

Second, the rate of positivity increases (up to a point) as more cultures are obtained. For patients with culture-positive bactermia, it has been shown that two blood culture sets using adequate volumes of blood will isolate the etiologic organism in approximately 99% of cases, and that three sets will detect over 99% (Fig. 2). It is important to understand that these figures do not imply that only 1% of all patients with IE will have negative blood cultures. They also do not apply, for example, to patients receiving empirical antibiotics, cases of IE caused by yeasts or molds, or difficult-to-culture organisms such as *Bartonella* or *Coxiella*.

Third, multiple blood cultures are required to indicate that a bacteremia is continuous, as is often the case for intravascular infections such as IE. There is no standardized consensus definition of "continuous bacteremia." The

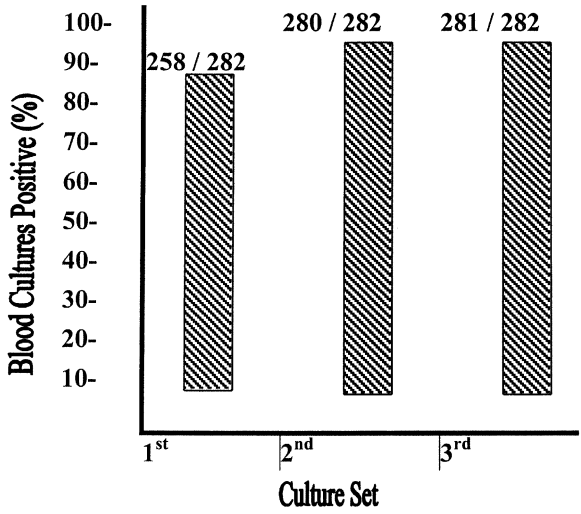

Fig. 2. Cumulative blood culture positivity rate from 282 patients with confirmed bacteremia or fungemia. (*Adapted from* Weinstein MP, Reller LB, Murphy JR, Lichtenstein KA. The clinical significance of positive blood cultures: a comprehensive analysis of 500 episodes of bacteremia and fungemia in adults. I. Laboratory and epidemiologic observations. Rev Infect Dis 1983; 5(1):35–53, with permission.)

Duke criteria [14] suggest the following definition: two positive blood cultures for the same organism drawn 12 or more hours apart, or positive cultures for the same organism from all of three or a majority of four or more separate cultures, with the first and last being drawn at least one hour apart.

Finally, multiple blood cultures are also important to help determine whether a positive blood culture is due to contamination. It has been demonstrated that positives due to skin contaminants usually result in a single-positive blood culture set when multiple sets were obtained (Table 1).

In summary, because IE is associated with high mortality, and given the high value of recovery of the etiologic agent from blood, the authors strongly recommend that multiple separate blood cultures be obtained from all patients presenting with possible IE.

There is one important caveat. If the initial cultures from a patient suspected to have endocarditis are negative, it is intuitively attractive to consider ordering additional cultures. This is appropriate if the prior probability of IE remains high, but may well be inappropriate if the prior probability of IE is low or falling as the clinical evaluation progresses. Consistent with Bayesian theory, the lower the pre-test probability of IE, the higher the probability that any positive blood culture will be a false positive (which is fairly common in any case, due to contamination with skin flora). Clinicians and laboratorians should appreciate that in certain situations obtaining further routine blood cultures may be counter-productive, serving only to increase

rather than to decrease diagnostic uncertainty. In these situations, alternative diagnostic strategies should be undertaken [27].

Optimal volume of blood for culture

The authors recommend that 20 mL of blood be obtained for each two-bottle blood culture set. It is important to state that a ''set'' of blood cultures represents an independent venepuncture; regardless of how many bottles are inoculated from a single venepuncture, blood from a single venepuncture is defined as one set. Obtaining three blood culture sets therefore requires three separate venepunctures with 20 mL of blood obtained per set, for a total of 60 mL. These recommendations apply to adult patients only. In pediatric patients, 1 to 2 mL of blood per culture should be drawn for neonates, 2 to 3 mL for infants aged 1 month to 2 years, 3 to 5 mL for older children, and 10 to 20 mL for adolescents [28].

Optimal choice of blood culture media

There are several commercially available blood culture systems, each providing a choice of various blood culture media. No single blood culture system nor any single culture medium can detect all types of microorganisms that might be present in the bloodstream of patients with suspected IE. It is generally recommended that more than one type of blood culture medium be inoculated to increase the chance of recovery of certain microorganisms. Two-bottle blood culture sets often consist of one aerobic medium and one anaerobic medium. Since the incidence of anaerobic bacteremia is decreasing [29] and IE due to anaerobes is uncommon (<2%), it is not essential to obtain an anaerobic culture as part of every blood culture set that is drawn. Anaerobic cultures do have certain advantages beyond detection of strict anaerobes, however; they may enhance the recovery of certain facultative anaerobes such

A53210128

Page 1213

as streptococci, especially nutritionally variant streptococci (NVS). The authors therefore recommend that an anaerobic culture be included, although not with every blood culture set. If two separate blood cultures are drawn for evaluation of a patient with suspected acute IE, then one anaerobic bottle should be included in the total of four bottles inoculated from the two samples. If three separate blood cultures are obtained in the evaluation of a patient with suspected subacute infective endocarditis, then one or two anaerobic bottles should be included among the total of six bottles inoculated from the three samples. This recommendation places a premium on the recovery of the routine aerobic microorganisms that most commonly cause IE, but also optimizes the chances of recovering streptococci and other facultative anaerobes, and has the capacity to detect those rare cases of IE caused by strict anaerobes.

Frequently, patients who are undergoing investigation for possible IE have already been placed on empirical antibiotic therapy. This is the single most common reason for "culture-negative" IE [30]. To overcome the potential inhibitory activity of those antibiotics on bacterial growth it is desirable to utilize a blood culture medium that has been designed to counteract or neutralize the inhibitory effect of antibiotics. Examples of commercially available products that could be used in these situations are a BACTEC resin containing medium (BD Diagnostic Systems, Sparks, MD), or a BacT/Alert FA medium (bioMerieux, Durham, NC). The BACTEC medium contains resins that have been shown to neutralize many antibiotics that might be present in blood [31]. In addition, the resin granules provide a large solid surface area (like catheters and other foreign bodies), which may enhance the growth of certain species such as staphylococci and yeasts, thus optimizing recovery. The BacT/Alert FA medium contains activated charcoal to counter the potential inhibitory activity of antibiotics. Even these specialized media cannot always recover microorganisms from the blood of patients who have already received antibiotics, however; blood cultures should therefore be obtained from patients prior to the institution of empiric antibiotics whenever possible.

In earlier studies it was reported that another potential cause of blood culture-negative IE was the presence of the so-called nutritionally variant streptococci (NVS). These streptococcal species, since named *Abiotrophia defectiva*, *Abiotrophia adiacens*, and *Abiotrophia elegans*, require supplemental vitamin B6 or cysteine for growth. Today these do not need to be specially added to blood culture media because most commercially available media are already adequately supplemented, and in any case the high volume of human blood added to the culture media may provide these growth factors. If subcultures from blood culture bottles showing chains of gram-positive cocci do not grow on sheep blood agar with a tryptic soy base, presence of NVS should be suspected [32]. Competent clinical microbiology laboratories will perform additional tests to identify these organisms, which account for an estimated 5% to 6% of viridans streptococcal endocarditis cases [33].

A53210128

Page 1214

Optimal length of incubation for blood cultures

Modern commercially available automated blood culture systems demonstrate recovery of most clinically important pathogens from blood within 5 days, which is now the recommended duration of incubation for routine blood cultures. Previously it was argued that at least 2 to 3 weeks of incubation were required [34] for optimal recovery of the more fastidious organisms that may cause IE. The data supporting this recommendation were based on older manual blood culture systems and media and do not reflect the situation today. Even improvements in the media itself, while keeping to a manual system, have shown that the vast majority of fastidious organisms such as the HACEK group, Brucella spp, *Francisella tularensis*, and NVS can usually be recovered within 5 days [35,36]. With automated, instrumented blood culture systems some of these organisms may require longer incubation to reach the growth threshold required to trigger a positive signal. If the organisms were present in the original inoculum of blood, they will still be present in the bottles at 5 days, and therefore should have either multiplied enough by then to trigger a positive result or be detected by appropriate subcultures taken at 5 days. It is probably a better strategy to subculture negative bottles from patients with a significant clinical likelihood of IE onto enriched solid media after 5 days rather than select these bottles for extended incubation for 2 to 3 weeks. This approach, although previously recommended, has not been systematically evaluated using the improved automated blood culture systems available today.

Special considerations for the diagnosis of fungal infective endocarditis

Fungal endocarditis, once a rarity, is now being reported more often [37]. This increase may be attributed to "medical progress," because many of the risk factors for fungal endocarditis are associated with technologic advances such as long-term intravenous catheterization, prolonged use of antibiotics, dialysis, hyperalimentation, immunosuppression, and cardiovascular surgery, including implantation of prosthetic devices such as heart valves and pacemakers [37]. In addition, narcotic addiction is a major risk factor for the development of fungal endocarditis [38]. Fungal IE includes cases caused by yeasts and molds (filamentous fungi), with yeasts being more common.

Diagnosis of fungal IE presents a challenge for clinicians. When IE is suspected, the possibility of fungal etiology is seldom seriously considered until the routine blood culture results have been reported as negative. In a recent worldwide review of 270 cases of fungal endocarditis, this diagnosis was included in the differential diagnosis in only 48 cases (18%) at the time of presentation [38]. It is reasonable to assume that delayed diagnosis may contribute to the higher mortality rate associated with fungal endocarditis compared to subacute IE due to routine bacterial pathogens. The leading isolates causing fungal endocarditis are *Candida albicans*, non-albicans

A53210128

Page 1215

Candida spp, *Torulopsis glabrata*, and *Aspergillus* spp [37,38]. The following comments refer to special considerations for the diagnostic laboratory when this form of IE is suspected.

Blood cultures

Many of the same technical issues for diagnosis of bacterial endocarditis apply to the diagnosis of fungal endocarditis. Most routine manual and automated blood culture system media are able to support the growth of yeasts such as *Candida* spp. If routine blood cultures are negative but the diagnosis of IE remains likely, it may be useful to specifically request a "fungal blood culture" so media that optimally support the growth of yeasts are chosen. Overall, if optimal methods are utilized, the percentage of positive blood cultures from cases of endocarditis caused by *Candida* spp is 83% to 95% [39].

The best system for the recovery of filamentous fungi such as *Aspergillus* is the Isolator (Wampole Laboratories, Cranbury, NJ) lysis centrifugation tube. Even with this technique, the rate of recovery of filamentous fungi from the blood of patients with this form of IE is quite low, <30% of cases. It should be noted that the Isolator is also the best system for the recovery of some uncommon, fastidious organisms such as *Bartonella* that occasionally cause endocarditis.

Additional diagnostic tests

In a recent review of fungal endocarditis, it was shown that the overall sensitivity of pre-operative blood cultures for the diagnosis was only 45% [38]. The remainder of cases confirmed with a mycologic diagnosis were from cultures of the cardiac vegetation or from histologic examination of either the excised valve or embolus from a large artery. Emboli to large vessels are a characteristic feature of fungal endocarditis because the valvular vegetations with this disease are typically large and friable [40]. It is therefore important that any embolus removed surgically be cultured for fungi as well as bacteria, and also examined histologically for the presence of microorganisms. In addition, other sites that should be cultured as part of the work-up of a patient with suspected fungal endocarditis include any suspicious skin or vitreal lesions. A recent case report described the use of a direct DNA probe such as AccuProbe (GenProbe Inc., San Diego, CA) for the rapid diagnosis of *Histoplasma capsulatum* in an excised heart valve [40]. Because the sensitivity of methods using direct probes have not been shown to be equivalent or better than culture, however, they cannot yet replace culture-based methods for the diagnosis of this disease [41–43].

Serological testing for fungi can be useful in the diagnosis of deep-seated histoplasmosis or cryptococcosis [29]. Serology is seldom helpful for other species; to date there are inadequate data to justify the inclusion of serologic testing for the presence of antigens or antibodies to *Candida* or *Aspergillus*

A53210128

as part of the routine diagnostic work-up of a patient with suspected fungal endocarditis.

Summary of best practice guidelines for laboratory diagnosis of bacterial and fungal endocarditis

- Obtain blood cultures before starting antimicrobial therapy whenever possible.
- Always use strict aseptic technique and optimal skin preparation when collecting blood for culture.
- For suspected cases of acute IE obtain at least two, preferably three sets of blood cultures rapidly within 5 to 10 minutes of each other before starting empiric antibiotic therapy.
- For suspected cases of subacute IE draw three separate blood cultures, spaced 30 minutes to 1 hour apart. If these remain negative at 24 hours, draw two further separate cultures.
- The volume of each blood sample drawn should be 20 mL for adults; for infants and other children, draw the amount of blood outlined earlier in the chapter.
- Each separate blood culture should be divided for inoculation into two bottles.
- If all blood cultures remain negative at 5 days but IE remains likely on clinical grounds, subculture bottles onto chocolate agar plates if the bottles are not held beyond 5 days.
- Always culture any embolus or vegetation that has been surgically removed from a patient with suspected IE for both bacteria and fungi.
- If all of the above are negative, consider an alternative, mimicking diagnosis (e.g., antiphospholipid syndrome with systemic lupus erythematosus [Libman-Sacks]).

Conclusion

As the etiological character of IE changes, the microbiological tools used to confirm the diagnosis have also evolved. Here the authors have reviewed the current methods for optimal laboratory diagnosis of bacterial and fungal endocarditis using traditional growth-based technologies and offered good practice guidelines and recommendations. Newer techniques will be required to improve sensitivity of detection for known organisms and to identify emerging or as-yet unknown pathogens (see article by Lepidi et al. in this issue).

SUMMARY

Background: In December 2011 and early 2012 four neonates died from *Pseudomonas aeruginosa* bacteraemia in hospitals in Northern Ireland.
Aim: To assess whether *P. aeruginosa* was associated with the neonatal unit taps and whether waterborne isolates were consistent with patient isolates.
Methods: Thirty taps and eight flow straighteners from the relevant hospitals were categorized and dismantled into 494 components and assessed for aerobic colony and *P. aeruginosa* counts using non-selective and selective agars. *P. aeruginosa* isolates were typed by variable number tandem repeat (VNTR) analysis. Selected tap components were subjected to epifluorescence and scanning electron microscopy to visualize biofilm.
Findings: The highest *P. aeruginosa* counts were from the flow straighteners, metal support collars and the tap bodies surrounding these two components. Complex flow straighteners had a significantly higher *P. aeruginosa* count than other types of flow straighteners ($P < 0.05$). Highest aerobic colony counts were associated with integrated mixers and solenoids ($P < 0.05$), but there was not a strong correlation ($r = 0.33$) between the aerobic colony counts and *P. aeruginosa* counts. Representative *P. aeruginosa* tap isolates from two hospital neonatal units had VNTR profiles consistent with strains from the tap water and infected neonates.
Conclusion: *P. aeruginosa* was predominantly found in biofilms in flow straighteners and associated components in the tap outlets and was a possible source of the infections observed. Healthcare providers should be aware that water outlets can be a source of *P. aeruginosa* contamination and should take steps to reduce such contamination, monitor it and have strategies to minimize risk to susceptible patients.

Introduction

Water supplied via plumbing systems is not sterile and, as a consequence, plumbing materials can become contaminated with biofilm, which provides a niche for opportunistic pathogens.[1,2] Previous studies have demonstrated that pathogens

including *Legionella pneumophila*, *Stenotrophomonas maltophilia* and *Pseudomonas aeruginosa* may be present in biofilms in water systems and result in healthcare-associated infections.[3–10]

P. aeruginosa is commonly found in a wide range of moist, nutrient-limited environments and can colonize hospital and domestic water taps, sinks, drains, toilets and showers.[7,9,10] A number of plumbing materials, such as flexible hoses, have been identified as susceptible to such colonization.[11–13]

A number of colonizations and infections of neonates by *P. aeruginosa* occurred in neonatal critical care units of Northern Ireland hospitals in late 2011 and early 2012 with four patient deaths (http://www.rqia.org.uk/publications/rqia_reviews.cfm). At that time, swabs of the ends of taps and water samples were taken from taps within the units and were positive for *P. aeruginosa*. The water sample isolates were typed using variable number tandem repeat (VNTR) analysis, which indicated some commonality with the strains isolated from the babies (unpublished results). This study set out to determine whether *P. aeruginosa* was associated with particular tap components.

Following infection control measures taken during the incident, all taps and associated pipework were removed (e.g. thermostatic mixer valves, copper tubing, flexible hoses, plastic connectors and flow straighteners) from every neonatal unit in Northern Ireland, and replaced with new taps with reduced complexity (http://www.dhsspsni.gov.uk/hss-md-4-2012.pdf). This study set out to assess a representative number of these tap assemblies using microbiological culture and microscopy analysis for the presence of *P. aeruginosa* in biofilms that may have been present on the plumbing materials associated with the taps.

Methods

Transport and dismantling of taps

Several tap assemblies were chosen to represent the type and style of tap from neonatal units of seven hospitals in Northern Ireland and were removed and transported to Public Health England, Porton Down, Salisbury, where possible within 48 h of removal from the neonatal unit. The containers were held at 4 ± 2 °C prior to the taps being aseptically dismantled and divided into duplicate component parts for microbiology and microscopy, given a unique reference number, photographed and a description recorded. This dismantling process was carried out using manual hand tools to reduce any frictional heat build-up that may have reduced microbial viability. Both sensor (taps with an infra-red sensor that activated water flow) and non-sensor-operated taps shared common component parts in specific locations and for analysis components were categorized as follows: tap body, connectors, isolation valve, integrated thermostatic mixer valve and solenoid, mixer, flow straightener and solenoid; any water found in the transport bags was collected and analysed. Flow straighteners are the terminal component in most taps that produce a uniform flow of water without excessive splashing. The flow straightener components were further categorized into four subcomponents: the centrepiece, collar, filter and washer. Due to the highly varied designs of flow straighteners examined, each was categorized and details of the subjective complexity and material were also included in the analysis (Table I). Pipework used to connect the tap and solenoid valve was subdivided into copper or plastic flexible hose (Table I).

Microbiological analysis

Samples for microbiological assessment were placed in 10 mL of maximum recovery diluent together with 10 sterile glass beads (3 mm diameter, VWR International, Lutterworth, UK). The surface of each component was scraped with a sterile plastic loop (Sterilin, Newport, UK) and the suspension was then vortex-mixed (10 s) to remove biofilm and to suspend the micro-organisms. Each sample was then spiral-plated (Don Whitley, Shipley, UK) on to Plate Count Agar (Oxoid, Basingstoke, UK) and *Pseudomonas* selective agar (PCN, Oxoid, UK) for determination of aerobic colony count (ACC) and *P. aeruginosa* count respectively, and incubated at 30 °C (Plate Count Agar) or 37 °C (PCN) for 48 h.

Microscopy analysis for biofilms

Epifluorescent microscopy was carried out by staining each surface with propidium iodide (1 mg/mL) (VWR) for 1 min, rinsing off excess stain with sterile water and viewing each component part using a Nikon Labphot microscope with epifluorescence (50× water immersion lens).[14,15] The surface of each component was visualized and biofilm images recorded (Imagic Imaging Systems, Germany).

Where tap components were found to be culture-positive for *P. aeruginosa*, a selected number of these biofilm samples were also sent for scanning electron microscopy (SEM) using a Philips XL30 FEG scanning electron microscope.

Strain typing

P. aeruginosa isolates recovered from plumbing materials of two hospitals (up to a maximum of five isolates per tap) were typed using VNTR.[16]

Statistical analysis

Statistical analysis was performed using Stata 12.0 (2011; StataCorp, College Station, TX, USA). Colony counts below the detection limit were assigned an arbitrary value of the midpoint between zero and the detection limit, i.e. 10 colony-forming units (cfu) for *P. aeruginosa* and 100 cfu for aerobic colony count to allow inclusion in the statistical analysis. Tap components were categorized according to location within tap; type of tap (whether sensor or non-sensor); simple or complex flow straighteners; plastic or metal flow straighteners; flow straightener subcomponents; and the type of pipe between the solenoid and tap (copper or flexible hose) (Table I).

Three sets of statistical models were built: a logistic regression to indicate the difference in odds of colonization with *P. aeruginosa* between sensor and non-sensor taps; various single variable mixed-effects regression models to examine the unadjusted association between *P. aeruginosa* count and the various tap component categories; and a multiple linear mixed-effects regression to assess the adjusted significance of the differences in cfu counts between tap type and component categories and to assess any interaction between tap component and tap type. In the mixed-effects framework tap ID and

hospital ID were modelled as random effects, and the tap components were modelled as fixed effects. ACC and *P. aeruginosa* counts follow an approximately log–normal distribution and were transformed to the log scale prior to analysis in the mixed effects regressions. For the logistic regression a tap was considered colonized with *P. aeruginosa* if it had at least one component with a count of *P. aeruginosa* above the detectable limit.

Results

Components for analysis

In all, 30 tap assemblies were received, three of which had a newly replaced flow straightener *in situ* as well as the original flow straightener (packaged separately). Five additional flow straighteners were also received without their associated tap assemblies. A total of 494 individual components or swab samples were generated from the taps and flow straighteners. Sensor taps (all of a single brand) accounted for 23/30 (73%) of taps, and four of the eight additional complex flow straighteners were also from the same brand of sensor taps.

Presence of P. aeruginosa and association with the aerobic colony count

P. aeruginosa was detected on 14% of the components (range of counts from 20 to 2.2×10^7 cfu per component) from different tap assemblies from different neonatal units (Table I). The correlation between the aerobic colony count and the *P. aeruginosa* count (Figure 1) for all 494 components was weak ($r = 0.33$). Many of the components that had a high aerobic colony count did not have detectable *P. aeruginosa*.

Tap type and the presence of P. aeruginosa

Sensor taps (Figure 2) had a significantly higher odds ($P < 0.05$) of having at least one component positive for

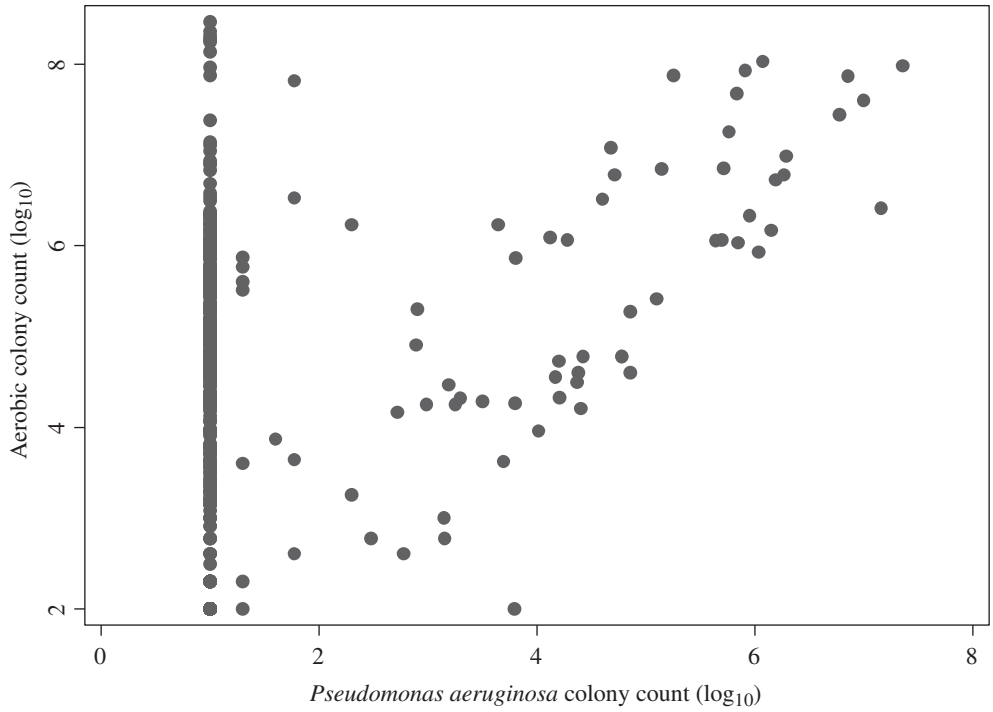

Figure 1. The relationship between *Pseudomonas aeruginosa* count (cfu per component) and aerobic colony count (cfu per component).

P. aeruginosa compared with non-sensor taps (Table II). Furthermore, non-sensor tap components yielded lower median counts of *P. aeruginosa* (1440 cfu) than sensor tap components (23,400 cfu) ($P < 0.05$) (Table I) (for those components with *P. aeruginosa* above the detection limit).

Influence of flow straightener type on P. aeruginosa counts

When both tap type and component type were considered jointly in the multiple regression model of log cfu counts, the flow straightener component in sensor taps was associated with significantly higher *P. aeruginosa* counts than the flow straightener component in non-sensor taps ($P < 0.05$ for interaction term). The expected *P. aeruginosa* count found in the non-sensor tap flow straighteners was 2% of the mean count found in the flow straighteners from sensor taps [95% confidence interval (CI): 0.3–14.1; $P < 0.01$]. Significant differences in cfu counts between tap types were not observed for the other tap components. When comparing *P. aeruginosa* counts within sensor-operated taps, the flow straightener was associated with more than 12 times the mean log cfu of the tap body component (95% CI: 6.07–25.50; adjusted model). This is the highest expected cfu of any component on a sensor tap (other components all have lower expected cfu than the tap body.)

Effect of flow straightener component on P. aeruginosa counts

Although flow straightener components represented 20% of all examined components, they accounted for 60% of components with detectable levels of *P. aeruginosa* (Table I). The single variable regression analyses of the flow straightener complexity, category and material indicated that, on average, complex flow straighteners had a higher expected *P. aeruginosa* count than a simple flow straightener: median of 1549 cfu and 3 cfu ($P < 0.05$), respectively. Complex flow straighteners were only present in sensor taps and so it is unclear whether this effect is related to the flow straightener design *per se*, or to another attribute of a sensor tap. The flow straightener categories C–F (Table I) did not have a significant association with raised *P. aeruginosa* colony counts.

P. aeruginosa colonization of flexible hose and copper pipe

The flexible hoses were associated with approximately three times higher *P. aeruginosa* count than copper pipe (95% CI: 0.91–9.58) but this was not statistically significant ($P = 0.07$), perhaps due to the low numbers of detectable counts and the low component numbers (Table I).

Comparison of component location for the aerobic colony count and P. aeruginosa count

The aerobic colony counts were significantly higher for the integrated mixer and solenoid than other components ($P < 0.05$), and were associated with higher counts than the tap body (95% CI: 18.77–269).

However, the flow straighteners were associated with higher *P. aeruginosa* counts than all other components, i.e. 7.81 times the *P. aeruginosa* count of the tap body (95% CI: 4.11–14.84). Both of these effects are highly statistically significant ($P < 0.01$). There was no significant difference ($P > 0.5$) in the presence of *P. aeruginosa* between the different flow straightener components including washers, filters, collars and centrepieces from sensor taps.

Probability that different tap types will be colonized (above detection limits) with *P. aeruginosa* ($N = 35$)

Characteristic	Odds ratio compared to referent (95% CI)	*P*-value	Probability of *P. aeruginosa* above detection limit (95% CI)
Tap type			
Sensor tap	Referent		0.65 (0.44–0.82)
Non-sensor tap	0.11 (0.02–0.61)	0.012	0.17 (0.04–0.48)

CI, confidence interval.

A53210128

Results from the single variable regression models indicate that the highest aerobic colony counts are found on the integrated mixer and solenoid, which have on average 71 times the mean log cfu count of the reference (tap body) category (95% CI: 18.77–269). This finding contrasts with the results for *P. aeruginosa* from the adjusted model noted above which indicate that the highest *P. aeruginosa* counts are found on the flow straightener. In the unadjusted model the flow straightener is associated with 7.81 times the $\log_{10}$ *P. aeruginosa* cfu count of the tap body (95% CI: 4.11–14.84).

Typing of P. aeruginosa strains

P. aeruginosa isolates recovered from tap biofilm from three taps at one hospital had VNTR profiles that were indistinguishable from the strain found in both patients and tap water from that hospital (VNTR profile 12, 5, 1, 5, 2, 2, 8, 2, 9). Isolates from tap biofilms received from another hospital also had a VNTR profile that was indistinguishable from a patient strain (VNTR profile 8, 2, 5, 3, 4, 2, 7, 2, 10). In addition, strains from the second hospital's tap and water samples (VNTR profile 8, 3, 4, 5, 2, 3, 5, 2, 10) were also indistinguishable. However, these were distinct from the strain isolated from another patient (profile 11, 4, 5, 2, 2, 1, 8, 2, 12), although this strain had also been recovered from tap and tap water samples taken by the hospital at the time and sent to the reference laboratory for typing.

Microscopy analysis

Both epifluorescent microscopy and SEM detected the presence of microbial biofilms on a number of different components. Profuse biofilms were observed on sections of the plastic flow straighteners (internal, external curvatures, flat horizontal areas, mesh grids, and on the prongs) as well as on the internal and external areas of the metallic collars surrounding those flow straighteners (Figure 3).

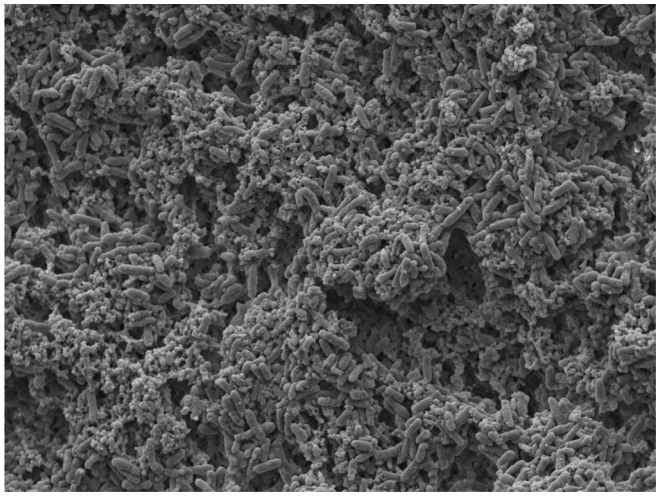

Figure 3. Scanning electron microscope image of biofilm on plastic complex flow straightener.

Discussion

P. aeruginosa can persist in hospital water systems for extended time periods and has resulted in a number of outbreaks.[1,7,9,17] Various medical devices and environmental reservoirs have been implicated in these outbreaks, including water, antiseptic solutions and lotions, endoscopy equipment, ventilators and mouth swabs.[16,18,19]

Following the incidents of *P. aeruginosa* in neonatal units in Northern Ireland hospitals, this study assessed the presence of *P. aeruginosa* and ACC in a range of different tap assemblies. Whereas only 14% of all components were positive for *P. aeruginosa*, some of them were heavily colonized with up to 2.2×10^7 cfu *P. aeruginosa* recovered.

ACC were recovered from 78% of components analysed (range: 200–2.9×10^8 cfu per sample) but there was little correlation between the aerobic colony count and the *P. aeruginosa* counts. ACC does not reliably predict the presence of *P. aeruginosa* and is not recommended in current Health Technical Memorandum addendum 04-01 on *P. aeruginosa* (https://www.gov.uk).

Whereas the highest ACC was associated with the integrated mixer and solenoid, the highest *P. aeruginosa* counts were associated with the flow straighteners, indicating that *P. aeruginosa* is predominantly associated with different tap components in comparison with the other aerobic microorganisms.

Previous studies have demonstrated the association of outbreaks with tap water in intensive care units where all the samples collected from the taps, water outlets and the water supply to the sinks grew >300 cfu/100 mL of a multidrug-resistant *P. aeruginosa* strain and the outbreak was controlled by replacing the sensor taps.[17]

Sensor taps are commonly used in healthcare facilities for staff handwashing and accounted for 79% of the tap assemblies that were received for analysis. These sensor taps had a greater probability of being colonized with *P. aeruginosa* than the non-sensor taps analysed, and our results show that the highest *P. aeruginosa* counts on sensor taps were associated with the flow straightener. However, although flow straighteners represented only 20% of tap components, they comprised 60% of all components with detectable levels of *P. aeruginosa* ($P < 0.05$). Detailed analysis of flow straighteners indicated that it was the complex flow straighteners (plastic ones) that had significantly higher counts of *P. aeruginosa* than more simple designs. In our observational study, complex flow straighteners were only found in sensor taps. This confounding makes it impossible to determine whether it was the design of the flow straightener or another attribute associated with a sensor tap that resulted in the presence of *P. aeruginosa*, e.g. lower water flow rates through the tap or different component materials, and therefore further work in this area is required in due course.

This would indicate that replacing the flow straightener or its component parts could still leave a *P. aeruginosa* biofilm on the adjacent tap surfaces.

There was no significant difference between the *P. aeruginosa* counts from flexible hoses versus copper pipes, although the sample size was small.

The typing data (VNTR) of the strains from two neonatal units linked the *P. aeruginosa* strains recovered from the biofilm on the tap surface and flow straightener, and/or the water from the tap and clinical samples isolated from the patients that died. This was most apparent in one of the hospitals,

where one strain clearly predominated among the patient, water and tap isolates, but not so clear for the samples from another neonatal unit in a different hospital, where a number of distinct strains were found among both patient and environmental isolates; some environmental strains were not represented at all among patient isolates. The strain of profile 8, 3, 4, 5, 2, 3, 5, 2, 10 of serotype 27, recovered from water and sink components, is quite frequently found in the environment globally and was not recovered from any patients from that hospital.[20,21]

Biofilms are an intrinsic way in which bacteria survive in water systems and were extensively observed on a range of flow straighteners and tap components using fluorescence microscopy and SEM. This current study of tap components from neonatal units in Northern Ireland indicated that *P. aeruginosa* heavily colonized specific tap components, i.e. the complex flow straighteners.

The tap outlets were supplied with water via a thermostatic mixer valve (TMV) which mixes the water from the hot and cold supply to deliver water at ~41 °C to prevent scalding during full body immersion. (https://www.gov.uk/government/uploads/system/uploads/attachment_data/file/144148/HTM_04-01_Part_B.pdf). However, TMVs are now frequently fitted to all outlets and as a consequence provide favourable temperature in the tap outlets at which *P. aeruginosa* are able to proliferate. The recently published Department of Health England Health Technical Memorandum 04-01 '*Pseudomonas aeruginosa* – advice for augmented care units' provides advice on what to do if there is *P. aeruginosa* contamination of the water system, including considering removal of flow straighteners, checking for underused outlets and flexible hoses and fitting of non-TMV mixing taps following a risk assessment (https://www.gov.uk/government/publications).

The results indicate that it was the more complex flow straighteners that were heavily contaminated and that these were only found in sensor taps (all of which were a single brand). Flow straighteners are present as the final component in the tap body to produce a non-splashing delivery of water. As the flow straightener and its associated components become colonized, the biofilm will shed micro-organisms into the water phase. With the flow straightener on the water–air interface, the ready supply of oxygen would facilitate *P. aeruginosa* to compete against facultative anaerobes in a biofilm – a factor that is not present in biofilms deeper inside the tap. This could be the reason why there was no link between ACC and *P. aeruginosa* on other tap components. Complex flow straighteners may also be fitted with a flow restrictor and have a large surface area:volume ratio, thus creating a moist, frequently stagnant environment in which the biofilm will grow.

Controlling biofilm could be inherently difficult as removal and replacement of the flow straightener and metal collar may still leave behind a *P. aeruginosa* biofilm on the tap body. Hence, the complete removal and replacement of the tap assembly may be a way in which hospitals can control the presence of *P. aeruginosa* in water samples from such outlets or by replacement of flow straighteners before significant biofilm can form or by physical removal of biofilm from the tap body when flow straighteners are replaced.[17]

Whereas the flow straightener components were contaminated with strains of *P. aeruginosa* indistinguishable from those isolated from patients, it is not possible to determine from the data whether the taps were the source of patient contamination, whether an external factor resulted in the contamination of both patients and taps, patient strains contaminated the taps or whether a mixture of these events occurred. As a consequence, hospitals should determine which patients are at risk in augmented units and undertake a review of not just the water system but also domestic environmental cleaning, infection control practices and related best practice assurances to assess possible tap contamination with patients' bacteria, to evaluate patient contact with water in particular wards and assess other control measures that may be required.

This study indicated that complex flow straighteners were implicated as an important area in the tap where *P. aeruginosa* accumulates. It may be prudent for manufacturers to redesign the tap outlet either to prevent contamination or to enable decontamination. When an increased incidence is identified, hospitals need to be aware that water outlets may be a possible source of *P. aeruginosa* and should take steps to assess the risks from water outlets and minimize risks to patients.

Acknowledgements

The authors would like to acknowledge the contribution of B. Godfrey and R. Sergeant and their many colleagues in Northern Ireland who assisted with this study, including staff in Health and Social Care Trusts; the Public Health Agency in Northern Ireland for comments on drafts of this manuscript; and Professors P. Marsh and N. Woodford for critically reviewing the manuscript. T. Pottage, H. Tolley, S. Macken, F. Jorgensen, S.E. Jones, S. Speight and G. McCracken are thanked for either their technical input or comments on the manuscript.

Running title: Transmission *P. aeruginosa* from water

Summary

Background*: Pseudomonas aeruginosa* is a common opportunistic pathogen and molecular typing in outbreaks has linked patient acquisition to contaminated hospital water systems.

Aim: To elucidate the role of *P. aeruginosa* transmission rates in non-outbreak augmented care setting in the UK.

Methods: Over a 16-week period, all water outlets in augmented care units of four hospitals were sampled for *P. aeruginosa* and clinical isolates were collected. Outlet and clinical *P. aeruginosa* isolates underwent whole genome sequencing (WGS), which with epidemiological data identified acquisition from water as definite (level 1), probable (level 2), possible (level 3), and no evidence (level 4).

Findings**:** Outlets were positive in each hospital on all three occasions, W (16%), X (2.5%), Y (0.9%) and Z (2%), and there were 51 persistently positive outlets in total. WGS identified likely transmission (at levels 1, 2 and 3) from outlets to patients in three hospitals for *P. aeruginosa* positive patients: W (63%), X (54.5%) and Z (26%). According to the criteria (intimate epidemiological link and no phylogenetic distance), approximately 5% of patients in the study 'definitely' acquired their *P. aeruginosa* from their water outlets in ICU. This study found extensive evidence of transmission from the outlet to the patients particularly in the newest hospital (W), which had the highest rate of positive outlets.

Conclusions: The overall findings suggest that water outlets are the most likely source of *P. aeruginosa* nosocomial infections in some settings, and that widespread introduction of control measures would have a substantial impact on infections.

Key Words:

P. aeruginosa, water-outlets, transmission, molecular-ecology, infections, augmented-care

Introduction

Pseudomonas aeruginosa is an important nosocomial pathogen in immunocompromised and critically ill patients and it is the fourth most common health care acquired infection (HCAI) pathogen in the USA [1] and the third most common cause of Gram-negative bacteraemia in hospitals in England, Wales and Northern Ireland [2].

Transmission of *P. aeruginosa* in the healthcare environment has been due to cross-contamination from a variety of environmental reservoirs [3-5]. Contaminated hospital water outlets have been implicated in outbreaks in neonatal and adult critical care units [3-9], including the high profile neonatal unit incident in Northern Ireland [8], where water outlets (last two metres) and associated fittings were identified as the source of infections that led to fatalities. Consequently, UK national guidance was published by the Department of Health for water sampling and control measures [10]. Whilst outbreaks of *P. aeruginosa* cross-infection in critical care units have been attributed to environmental sources, the role of such sources in sporadic (non-outbreak) pseudomonal infection situations has generally been poorly characterised in the UK [3].

Whole genome sequence typing (WGST) delivers a very high level of specificity and resolution compared to previously used typing methods such as pulsed-field gel electrophoresis (PFGE), and variable number tandem repeats (VNTR) which have been applied to *P. aeruginosa* outbreaks in critical care [4, 6, 8, 11]. WGST has been used to investigate transmission in outbreaks of *Staphylococcus aureus* [12] *Acinetobacter baumannii* [13] as well as *P. aeruginosa* [9, 14, 15] and previously used to demonstrate that transmission of waterborne isolates to burns patients most likely occurs during hydrotherapy, which is used in the management of burns patient's wounds [16].

To date there has been no comprehensive longitudinal multi-centre studies of the transmission dynamics of *P. aeruginosa* in UK critical care settings employing WGST. This study undertook a defined snapshot survey using WGST, simultaneously across four large UK hospitals, to investigate the burden

of *P. aeruginosa* infection or colonisation in adults (caused by transmission from water outlets) in the non-outbreak augmented care setting.

Methods

Study design and patients

Four NHS hospitals (anonymised to W, X, Y and Z) with diverse water sources, buildings, and plumbing infrastructures from a wide geographical area in England participated in this study (Table I). A total of 23 augmented care units (ACUs) across the 4 hospitals were studied, from which all 881 water outlets (774 taps and 107 showers) were sampled.

During a 16-week period (30th August - 6th December 2014) water sampling of outlets was undertaken at all sites, on three occasions (designated 'beginning', 'middle' and 'end') within a 10-day window. The ACUs of the hospitals were described as 'non-outbreak' with respect to *P. aeruginosa* as there was no observed increase in incidence of *P. aeruginosa* infections above the average number (from both clinical and environmental observations), and hence these units were not under enhanced surveillance.

All clinical isolates of *P. aeruginosa*, which were retained as part of routine care from patients satisfied the inclusion criteria as follows: an inpatient in one of the included wards for more than 48 hours, with no pre-existing *P. aeruginosa* colonisation/infection, and without an isolate with the same antibiogram and colony morphology having already been saved. The bed, ward number and nearest water outlet (make and model) when sample(s) were retained. No clinical details or patient identifiable data were recorded and we were unable to obtain ethical approval to screen all patients for *P. aeruginosa* carriage upon ICU admission.

Microbiological methods

Pre-flush samples were taken at each hospital as described previously [10]. Water (100 mL) samples were filtered (0.45µM membrane filter) and cultured on cysteine lactose electrolyte deficient agar (CLED) agar (Biomerieux)and on cetyl trimethylammonium bromide and nalidixic acid (CN) agar plate (Biomerieux) (48 hours incubation at 37°C). Oxidase positive colonies were identified using MALDI-TOF (Biomerieux).

Molecular methods and bioinformatics analysis

DNA extraction of *P. aeruginosa* isolates was performed by emulsifying (5µl) each bacterial colony in molecular grade water (100µl) and then heated (10 minutes at 95°C). DNA was isolated and cleaned by adding the supernatant to an equal volume of Ampure XP beads (Beckmann Coulter, High Wycombe, UK).

Whole genome sequencing was performed as described previously [16]. Reads were demultiplexed and then mapped against the *P. aeruginosa* PAO1 reference genome (NC_002516.2). Clusters were identified using a rapid genotyping method described previously [17]. To call variants, representative isolates from each cluster were mapped against *P. aeruginosa* reference genomes from RefSeq [18] and the NCTC 3000 project using bwa-mem (v0.7.15) [19]. The best reference was selected for each cluster based on greatest proportion of mapped reads. Variants were called using FreeBayes Variant calls and filtered for allele frequency and recombination. Phylogenetic trees were constructed for each cluster using RAxML (v8.2.10) [20]. In addition all isolates were MLST typed *in silico* using StringMLST (v0.5.1.1) [21, 22].

Definition of transmission events

The likelihood of transmission was assessed through a multifactorial approach taking into consideration i) the cluster defined dendrograms of environmental water and clinical isolates, ii) a measure of phylogenetic distance, and iii) the metadata relating to geographical locations when samples were taken.

- All clinical isolates within the same cluster as environmental isolates were analysed for potential transmissions by both phylogenetic distance and epidemiological link.
- Pairwise phylogenetic distances between clinical and environmental isolates were measured for each cluster with distances used to identify similarity to an environmental source.
- Metadata for clinical isolates defining ward and bed locations was analysed for potential epidemiological links to the sampling location of environmental isolates.

Four categories of transmission were defined; Level 1 (definite): 'Patient isolate genome indistinguishable from water outlet *P. aeruginosa* genome (phylogenetic distance of 0) with epidemiological link to at least ward level' (patient and outlet linked in time and place), Level 2 (probable): 'Patient isolate genome highly similar to an outlet genome (but with a phylogenetic distance of >0), and with an epidemiological link to outlet', Level 3 (possible) 'Patient isolate genome present in the same phylogenetic cluster as a *P. aeruginosa* water outlet genome but without an epidemiological link to outlet', and Level 4 (no evidence): clearly not a hospital water transmission (no hospital water isolates present in the same cluster as the patient isolates and no epidemiological link). The likely direction of transmission (and temporality) was then inferred based on the dates that the water and clinical isolates were collected.

Results

The overall proportion of outlets positive for *P. aeruginosa* (as a percentage of the total outlets sampled per hospital site) was 26.3%, 10.4%, 6.5% and 8.2% for hospitals W, X, Y & Z respectively. Some outlets (16% in hospital W) remained positive throughout the study (Table 1). The hospital built most recently (2010; with the newest plumbing system (hospital W)) had the highest rate of *P. aeruginosa* positive outlets, and the greatest number of clinical isolates. Hospital Y (the only hospital with a Copper Silver Ionisation (CSI) water treatment system for the prevention of Legionella infections), had the lowest positivity rates from the water outlets, and the fewest number of clinical isolates.

There were 120 clinical *P. aeruginosa* isolates collected from 78 eligible patients during the study (Supplementary Table II). The majority were from respiratory samples (50%), with the remainder from swabs (25.4%), urine (11.2%), blood cultures (6.7%), tissues (4.2%) and fluids (2.5%). Only one patient isolate was not included in the analysis due to inadequate sequencing depth.

Sequence diversity of *P. aeruginosa* isolates

A total of 552 (120 clinical and 432 water) *P. aeruginosa* isolates were analysed. One clinical isolate failed sequencing, and <10% of the water isolates could not be sequenced. We assigned the isolates to 17 clusters which were defined as clades containing at least one patient and one water outlet isolate i.e. a potential transmission. A total of 460 (83%) isolates belonged to a designated cluster, and clusters were consistent with the results of multi-locus sequence typing data reported by StringMLST (Supplementary Table III).

Analysis of the isolates for sequence diversity (Figure 1) demonstrated different clades associated with different hospitals. Hospital W had the largest number of positive water outlet isolates (181 from 231 sampled assets), but also the most defined clusters with the majority of the isolates belonging to one

of three large clusters (ST395, ST17 and ST179). The environmental water outlet isolates from the other hospitals were more diverse, with a smaller proportion of isolates contained in three small clusters (hospital X), one cluster (hospital Z), or with limited clustering (hospital Y).

Detection of linked environmental and clinical isolates

Although all clusters were analysed, further diversity analysis was performed on ST395, as it was present in each hospital (Supplementary Figure 2). Phylogenetic distance was lower within the same hospital when compared to different hospitals, suggesting each hospital was colonised by a local clone or clones. Phylogenetic distance of isolates from the same ward was similar to that of different wards, suggesting that transmission of *P. aeruginosa* to other wards only accounted for a minority of transmissions. Phylogenetic distance of isolates from the same outlet was markedly reduced compared to those from different outlets, suggesting the persistence of a single genotype within an outlet. We have chosen to represent phylogenetic distance data as a violin plot as it allows visualisation of the density distribution for the large number of datapoints from the pairwise comparison of isolates [23].

Clinical isolates (ranging from one to seven per patient) were collected from 78 patients across the four hospitals. The transmission category was determined for every clinical isolate, using the epidemiological information alongside phylogenetic distance. The highest transmission category was then recorded per patient (Supplementary Table IIII) and the positive water and patient sampling results for hospital W are presented (Supplementary Figure 3).

Direction of transmission inference

A summary of the patient acquisition/transmission events for each classification level, and each hospital, is shown in Supplementary Table II. Where multiple clinical isolates existed for a patient, all were investigated (to determine the particular classification levels of all the clinical isolates), and the highest classification level recorded in Supplementary Table III for that patient.

Using this approach, 5.1% of the patients were classified as level 1 ('definitely' acquired their *P. aeruginosa* isolate from hospital water outlets), 18% were level 2 ('probably'…), 24.3% are level 3 ('possibly'...), and 51.3% were level 4 (there is 'no evidence' that they have acquired their *P. aeruginosa* isolate from the hospital water outlets). A single clinical isolate from one of the patients could not be sequenced (1.3%). Consequently, considering the study as a whole, approximately 50% of patient's most likely acquired their *P. aeruginosa* isolate from the hospital water outlets.

Intra-hospital transmission events

The transmission rates varied across the hospitals involved in the study (Supplementary Table II) and were calculated per hospital by dividing those transmission events classified as level 1-3 by the total number of events and multiplying by 100. Hospital W had the highest transmission rate (63.3%), suggesting that nearly two-thirds of patients acquired their *P. aeruginosa* from the hospital water outlets whilst being nursed in augmented care. There were no patient acquisitions at hospital Y, and only a small number of clinical *P. aeruginosa* isolates were collected during the study period, despite a similar rate of sample collection.

Hospital W had four patients with a clinical *P. aeruginosa* isolate classified as level 1 ('definite'). For example, patient 28, was nursed close to an outlet which was positive on all three sampling events (30th August, 23rd October and 6th December 2014). Three clinical *P. aeruginosa* isolates were recovered from this patient (from sputum samples collected in early December) during the course of their treatment, and two of these clinical isolates were indistinguishable from the water isolates recovered from this outlet that was positive on all three sampling events. Interestingly, although classified as level 2 (owing to the phylogenetic distance being 0.002 and therefore greater than 0), this particular outlet had resulted in a previous patient (patient 3) also acquiring infection, with a swab and sputum sample positive on 8th September (water outlet first positive on 30th August). It is therefore assumed that both patients most likely acquired their *P. aeruginosa* from the identified hospital water outlet.

Although we only have evidence of 'definite' transmission from hospital W, there is evidence of probable (level 2), and possible (level 3) transmission for both hospitals X and Z. A probable transmission event in hospital X involved a patient who was nursed in a room with en-suite facilities including a handwash basin, and shower. *P. aeruginosa* was isolated from a blood culture collected from the patient on 21st October 2014 and is closely genetically related (phylogenetic distance of 0.003) to those collected from the handwash basin, and shower on both 3rd September and 27th October.

Hospital Z showed four probable transmission events, the temporality of which fit with the affected patients acquiring their *P. aeruginosa* from their nearest hospital water outlet. There was no evidence of water outlet to patient transmission at hospital Y.

Discussion

The majority of studies focusing on hospital water delivery and disposal have investigated distinct outbreaks of infection caused by *P. aeruginosa* often involving strains with an easily detectable phenotypic marker e.g. antibiotic resistance [9] . Nevertheless, such studies have established clear links between hospital water *P. aeruginosa* strains, and patient strains.

Many previous studies have been hampered by non-molecular typing methods with low discriminatory power, which overestimates transmission rates. Kerr *et al*. [3] concluded that because *P. aeruginosa* occurs in a wide range of hospital environments that investigations restricted to outbreaks are not sufficient to define directionality of transmission. This difficulty of interpretation was confirmed in a systematic review [24] which concluded that although water systems can act as a source of *P. aeruginosa* infection, the route of transmission was unclear, as was the directionality.

Strain typing studies using WGS are relatively uncommon and concentrate on outbreaks and did not examine water outlets as a source [7, 9, 15] with two others showing transmission from water outlets to a total of 5 patients [14, 16].

In order to understand the extent and dynamics of the colonisation of ICU tap water outlets a prospective longitudinal study is required. Only one such study has been published of 10 ICU wards in 8 separate hospitals in France performed in 2010 [25]. Over a 5-month period 233 taps were cultured for *P. aeruginosa* and patient colonisation was determined, as 17 patients were found to be colonised with a PFGE typed strain that matched a water isolate. The authors commented on "discrepancies" between units (e.g. 41/81 positive taps came from just 2 units) but did not investigate the reasons for the variation recommending that further studies on routes of transmission and control were needed.

Our study was a longitudinal, non-outbreak epidemiological study in four large hospitals housing 22 ICU wards with 881 tap outlets which were monitored. We looked for correlation between clinical disease associated isolates and water outlet isolates rather than asymptomatic colonisation, also using WGS in which we were able to assign directionality of transmission in some cases. We have shown 'definite' and 'probable' acquisition of *P. aeruginosa* in three of the four participating hospitals, affecting 19 of 78 (24.3%) patients. These definitions have been based on a measure of phylogenetic distance, epidemiological linkages and are further strengthened owing to the low diversity of water clones encountered (especially in hospital W), making patient contamination of the outlet unlikely. This is a highly conservative estimate, demonstrating that this is a significant potential problem in any ACU.

There is evidence of hospital-specific water associated clones of *P. aeruginosa*. MLST analysis of the WGS data shows that ST179 was found in hospital W only, and ST395 was predominantly associated with hospital W (although was also found in hospitals X, Y and Z) (Figure 1). We hypothesise that the low diversity of *P. aeruginosa* sequences found in hospital W was related to the age of the plumbing infrastructure (newest of the four). The majority (86%) of positive taps in hospital W were of one

model (compared to 38.5%, 64.2%, and 45% in hospitals X, Y and Z, respectively). A possible explanation for the presence of the dominant clone was that they were contaminated during manufacturer's wet integrity testing of the plumbing components prior to distribution[26]. ST395 has been widely reported in water systems and has been noted to carry a copper resistance gene which might aid survival in copper containing water distribution systems [27]. Interestingly the three large clusters from hospital W (ST395, ST17 and ST179) were also found in the other three hospital groups, suggesting that these represent common aquatic clones, despite considerable geographic separation (200 miles between hospital X and Z).

This is the first study to use patristic distances to investigate genetic relatedness of water and patient *P. aeruginosa* in the non-outbreak setting. The question of defining strain relatedness by differences in SNP carriage in WGS data is a vexed one. Attempts have been made to both define isolates as indistinguishable using a range of allowed SNP differences as well as proposing directions of transmission [28]. However, genome rearrangements can lead to overestimation of strain differences if SNP counts are considered in isolation. In the case of *Mycobacterium tuberculosis* (which has no horizontal gene transfer and a relatively slowly evolving genome) such numerical parameters would appear to be ideal and were proposed after sequencing sequential isolates from individuals and family clusters[28]. Their proposed 0-5 SNPs for indistinguishable isolates and >12 SNPs for distinct isolates was applied to a large 14 year outbreak of isoniazid resistant strains in North London [29]. They found that the majority of the 344 isolates differed by only 2 SNPs, but sequencing of 27 individual colonies cultured from a single patient specimen revealed up to 10 SNP differences between colonies. When applying the detailed epidemiological information to the data set it was clear that multiple transmission events had occurred without detectable SNP acquisition. This meant that even identical isolate pairs could not be deduced to have resulted from a direct transmission event without a supporting epidemiological link [29]. This experience has informed our criteria for assigning isolate

relatedness by including epidemiological information and using patristic distance rather than absolute SNP number differences.

There are some limitations of the study. Since the study was a short defined “snapshot” investigation of events over a defined time period, there was no follow up of the patient’s journey during their hospital admission. Consequently, the conservative definitions used to define the transmission events may have underestimated the true transmission rate. Patients were not screened for endogenous (asymptomatic) carriage on admission (owing to ethical considerations) which could be the route for colonisation and/or infection. Additionally, water sampling was performed on three occasions; therefore, it is possible that positives may have been missed in the gaps between samplings. Other wet sources (e.g. sink traps) or patient-to-patient transmissions were not investigated. As hospital Y had a CSI treatment system and copper ions are known to induce a persister state inducing a viable but non-culturable state thus rendering previously culturable bacteria unculturable on the same media [30, 31]. Pre-treatment with a copper chelator may have enabled more accurate viable counts of *P. aeruginosa* in Hospital Y.

The effect of CSI on bacteria other than Legionella in water distribution systems has been reported [32]. The CSI hot water samples showed no increase in species richness (defined by 16S rDNA sequencing) compared to the cold-water samples, whereas the non-CSI showed high diversity. The low rate of recovery of *P. aeruginosa* at hospital Y may be attributable to the CSI treatment, although other factors such as water temperature, plastic pipes and maintenance activity could also have contributed to this significant finding.

This was the largest prospective study that has demonstrated the importance of *P. aeruginosa* in hospital water, and evidence of onward transmission to patients. In hospital W (where outlets were identified as a likely source[33]), positive water samples have been drastically reduced across critical care in hospital W [34]. A series of holistic interventions (fitting new taps, filters on existing taps, improved tap cleaning, and appropriate disposal of patient waste water), resulted in a 50% reduction

in the number of *P. aeruginosa* clinical patient isolates over a year [34], and a 72% decrease in of *P. aeruginosa* acquisition when positive taps were removed and new ones fitted [35].

This study has shown that colonisation of ICU outlets acts as a persistent source of infection with *P. aeruginosa* and this varies in ACU depending on the level of contamination. There is substantial variation between different facilities and an urgent need to introduce control measures to reduce *P. aeruginosa* colonisation in ICU tap water.

Conclusion

In this longitudinal, non-outbreak study of four hospitals, very different levels and patterns of colonisation of water outlets was observed across all three sampling timeframes. Application of WGS to water and clinical isolates demonstrated convincing transmission (level 1) from water to patients for 5% of patients, and probable transmission (level 2) in a further 19% of the studied patients. Strains from water outlets caused a range of clinical infections, including a bacteraemia.

Hospital W had a strikingly high incidence of colonised outlets with a corresponding high incidence of patient isolates, supporting the transmission of *P. aeruginosa* from water outlets causing colonisation/infection in patients. This hospital also had a dominant clone (ST179) which exhibited low intra-isolate diversity, suggesting a common source. Hospital Y had the lowest incidence of colonised outlets which may have been due to the CSI treatment.

There was variability in the frequency of *P. aeruginosa* detected at different hospitals which correlated with the frequency of predicted transmissions. This suggests that in some settings water outlets are the most likely source of *P. aeruginosa* nosocomial infections for the patients in the study with widespread implications for control measures nationally and internationally

Legends

Figure 1. Phylogenetic tree for all isolates generated using the rapid genotyping method. The five predominant clades are coloured according to their MLST clonal complex to aid interpretation (a clonal complex is defined as alleles exactly matching a sequence type or a single-locus variant of that sequence type). The annotation bars below indicate the hospital where that isolate was found and the type either water (blue) or patient (orange).

Supplementary Table II: The transmission events per Trust including the transmission events classified per patient, transmission rate, and clinical specimen types involved

Supplementary Table III: Table showing the multi-locus sequence typing data reported by StringMLST for all isolates for seven highly conserved housekeeping genes.

Where: *acsA* (acetyl-CoA synthetase), aroE (shikimate dehydrogenase), *guaA* (GMP synthase), *mutL* (DNA mismatch repair protein), *nuoD* (NADH-quinone oxidoreductase subunit C/D), *ppsA* (phosphoenolpyruvate synthase), *trpE* (anthranilate synthase component).

Supplementary Table IIII: Showing the categorisation of the transmission events per clinical isolate.

The table shows the clinical isolates, the ward and outlet that relate to each clinical isolate and the closest waters isolates (in terms of phylogenetic distances). This was then used to assign a category to that clinical/water isolate pair according to the definitions used in the paper:

Level 1 (definite): ‘clinical *P. aeruginosa* genome indistinguishable from water *P. aeruginosa* genome (phylogenetic distance of 0) with epidemiological link to at least ward level’, Level 2 (probable): ‘Patient genome most closely similar to an outlet genome (but with a phylogenetic distance of >0), and with an epidemiological link to outlet’, Level 3 (possible) ‘Patient genome present in the same phylogenetic cluster as a *P. aeruginosa* water genome but without an epidemiological link to outlet’, and Level 4 (no evidence): not clearly a hospital water transmission (no hospital waters present in the same cluster and no epidemiological link). ‘none’ refers to clinical isolates for which there were no related water isolates present in our sampling set.

Supplementary Figure 2. Violin plots showing phylogenetic distance between all pairs of isolates from the same hospital (left), the same ward (middle) and same outlet (right) for the ST395 cluster. Phylogenetic distance was calculated by the R package ‘ape’ [36] which are derived from the RAxML branch length themselves based on mutations per site.

Supplementary Figure 3. Map of four wards in hospital W, demonstrating association between water outlets and *P. aeruginosa* genetic clusters. The three water sampling periods (beginning, middle and end) are shown separately from top to bottom. *P. aeruginosa* isolates from water isolates (diamonds) and patients (circles) are coloured by their cluster type.

Pseudomonas aeruginosa
Intensive care unit

SUMMARY

Background: *Pseudomonas aeruginosa* remains one of the most common nosocomial pathogens in intensive care units (ICUs). Although exogenous acquisition has been widely documented in outbreaks, its importance is unclear in non-epidemic situations.
Aim: To elucidate the role of exogenous origin of *P. aeruginosa* in ICU patients.
Methods: A chronological analysis of the acquisition of *P. aeruginosa* was performed using samples collected in 2009 in the DYNAPYO cohort study, during which patients and tap water were screened weekly. Molecular relatedness of *P. aeruginosa* isolates was investigated by pulsed-field gel electrophoresis. Exogenous acquisition was defined as

Water taps
Pulsed-field gel electrophoresis

identification of a *P. aeruginosa* pulsotype previously isolated from another patient or tap water in the ICU.

Findings: The DYNAPYO cohort included 1808 patients (10,402 samples) and 233 water taps (4946 samples). Typing of 1515 isolates from 373 patients and 375 isolates from 81 tap water samples identified 296 pulsotypes. Analysis showed exogenous acquisition in 170 (45.6%) of 373 patients. The pulsotype identified had previously been isolated from another patient and from a tap water sample for 86 and 29 patients, respectively. The results differed according to the ICU.

Conclusion: Exogenous acquisition of *P. aeruginosa* could be prevented in half of patients. The overall findings of this survey support the need for studies on routes of transmission and risk assessment approach to better define how to control exogenous acquisition in ICUs.

Introduction

Pseudomonas aeruginosa remains one of the most common hospital-acquired pathogens, and is endemic in many intensive care units (ICUs) [1,2]. Infections caused by *P. aeruginosa*, especially ventilator-associated pneumonia or bloodstream infections, are often severe and associated with considerable mortality in ICU patients; morbidity and mortality rates are even higher in cases of multi-drug resistance [3—6]. In ICUs, these infections are usually considered to be endogenous, arising from pre-existing colonization of patients. In addition, the roles of exogenous reservoirs and patient-to-patient transmission during outbreaks have been documented convincingly. However, the importance of exogenously acquired *P. aeruginosa* in non-epidemic situations remains uncertain [7,8]. Several epidemiological studies have indicated that colonization pressure seems to be a more relevant risk factor than exposure to antibiotics for the acquisition of *P. aeruginosa* [9—12].

A previous monocentric study showed a clear genetic temporal and spatial relationship between *P. aeruginosa* strains isolated from tap water samples and ICU inpatients [13]. Moreover, the first part of the multi-centre DYNAPYO (Dynamics of *Pseudomonas aeruginosa* Acquisition in ICU) study showed that exposure to contaminated tap water was a risk factor for *P. aeruginosa* colonization in ICU patients [14,15]. It is essential to better understand the true contribution of the exogenous acquisition of *P. aeruginosa* in ICUs to inform infection prevention and control strategies. As such, a chronological analysis was performed within DYNAPYO-participating ICUs to assess the respective contributions of *P. aeruginosa* exogenous acquisition by patient-to-patient transmission and from contaminated taps.

Methods

Study design and study population

The DYNAPYO study was a prospective 5-month observational survey performed in 2009 in 10 ICUs (four medical, two surgical, and four mixed medical and surgical ICUs) from eight French healthcare facilities: the university hospitals of Besançon and Lyon which included two ICUs; the university hospitals of Bordeaux, Garches, Montpellier and Paris; and the general hospitals of Lens and Tourcoing which included one ICU. These ICUs had nine to 20 beds with an average length of stay of 8—16 days (Table I).

The ICUs did not implement changes during the course of the study, such as infection control or antimicrobial stewardship initiatives. The ICUs had to follow French recommendations in terms of water use for care, and measures to prevent patient-to-patient transmission. Outlet taps were equipped with antibacterial filters in one ICU (ICU 1).

The DYNAPYO cohort included all adult patients admitted for more than 24 h during the study inclusion period. Demographic and epidemiological data (admission dates and discharge, room number) were collected prospectively. The type of tap (electronic or conventional) was recorded, and patients and tap water were monitored weekly for contamination with *P. aeruginosa* over the study period. Specific trained healthcare workers were identified in each centre for water sampling and for data collection on a secured online case report form. This study was approved by the local ethics committee, and the data underlying this study were restricted by the French data protection commission (Commission Nationale Informatique et Liberté, France).

Surveillance culture and microbiological analysis

During the data collection period, patients were screened on admission (within the first 48 h of ICU stay), then once per week, and finally on discharge or death. Screening samples were oropharyngeal swabs, rectal swabs and tracheobronchial aspirate (or sputum). Other clinical specimens were performed as clinically indicated (as appropriate).

Table I
Description of the intensive care units (ICUs)

	Type	Rooms (*N*)	Mean length of stay (days)
ICU 1[a]	Mixed	20	14
ICU 2	Mixed	16	12
ICU 3	Medical	12	10
ICU 4	Surgical	14	14
ICU 5	Medical	18	8

ICU 7	Mixed	18	11
ICU 8	Medical	15	11
ICU 9	Surgical	15	11
ICU 10	Mixed	15	16

[a] ICU with filtered taps.

Cold water samples were taken weekly from the 233 taps in the 10 ICUs (patients' rooms and other sites) for testing for *P. aeruginosa* (without colony count). Taps were turned on and the first 250 mL of water was collected immediately in a sterile flask with sodium thiosulphate. The aerator was swabbed and the swab broken into the water sample. Tap water samples were processed by membrane filtration. A volume of 100 mL was filtered through a 0.45-μm pore size membrane filter (Millipore Microfil, Molsheim, France). Swabs and filters were cultured on cetrimide-agar plates (Bio-Rad, Marnes-la-Coquette, France) at 37°C and examined for growth of colonies after 24 and 48 h. Any colony that grew on a cetrimide-agar plate was identified using the API20 NE identification system (bioMérieux, Marcy l'Etoile, France). All *P. aeruginosa* isolates were sent to the coordinating centre (Bordeaux) on semi-solid agar.

Genotyping

Molecular relatedness of *P. aeruginosa* isolates was investigated by pulsed-field gel electrophoresis (PFGE). Clonality of strains was investigated by PFGE with DraI digestion as described previously [16]. The banding patterns were analysed by scanning photographic negatives. GelCompar software was used for analysis of PFGE patterns (Applied Maths, Kortrijk, Belgium). Pulsotypes were defined according to international recommendations [17]. All patients' first isolates from each anatomic site were analysed. For each newly identified patient, we selected for comparison the isolates identified in tap water, the previous week and the following week.

Definitions

Exogenous acquisition was defined as colonization or infection by a strain of *P. aeruginosa* with a pulsotype previously isolated from another patient (i.e. patient-to-patient transmission) or from a tap water sample in the ICU. Patient-to-patient transmission was considered possible when a similar pulsotype was isolated in more than two patients hospitalized during an overlapping period without a similar pulsotype isolated from tap water. Exogenous origin from tap water was considered possible when a similar pulsotype was isolated in a patient and at least one ICU tap water sample prior to *P. aeruginosa* identification in the patient.

Results

Study population

Of the 1808 patients included in the DYNAPYO cohort, 206 were excluded because screening was not performed at admission. In total, 10,402 screening samples were taken and 427 patients were positive for *P. aeruginosa*; of these, 41 were found on entering the study. The average incidence of *P. aeruginosa* in the 10 ICUs was 12.7 per 1000 days of hospitalization (Table II).

Water samples

In total, 4946 water samples were obtained. Among the 233 taps screened, 81 (35%) were positive for *P. aeruginosa* at least once during the study, including 51 at the beginning of the study. The median duration of contamination was 5 weeks (range 1–13 weeks). The median duration of contamination differed between electronic and conventional taps (12.6 vs 8 weeks, respectively; $P=0.003$).

Genotyping and chronological epidemiological analysis

Typing of 1880 non-replicate isolates (1515 from 373 patients and 375 from 81 water samples) identified 296 pulsotypes. A total of 270 different pulsotypes were found in patients: 201 (74%) were sporadic, 52 were shared by patients, and 17 were shared by water and patient. Variations according to the ICU are shown in Table II.

The chronological epidemiological analysis showed exogenous acquisition in 170 (45.6%) patients out of the 373 patients for whom at least one isolate was available for typing, with variation according to the ICU (from 16.3% in ICU 7–85.7% in ICU 5; Table II). There was patient-to-patient transmission for 86 of the 170 patients (50.6%) and an exogenous origin from tap water for 29 other patients (17.1%). Moreover, it was not possible to draw conclusions for 55 patients from the two ICUs with the highest rates of positive tap water (ICU 5 and ICU 10) because pulsotypes were shared by many patients and tap water samples.

Discussion

To the authors' knowledge, the DYNAPYO study is the largest cohort study to assess the relative contribution of exogenous acquisition of *P. aeruginosa* in ICUs [14]. The present study showed an exogenous origin of *P. aeruginosa* in nearly half of the patients. Patient-to-patient transmission was more frequent than acquisition from tap water. At least half of the cases of colonization or infection by *P. aeruginosa* could be preventable. Furthermore, this study showed discrepancies in the rates of exogenous origin of *P. aeruginosa* according to the ICU, which could explain the differences in results in previous monocentric studies.

Patient-to-patient transmission occurs by carriage on the hands of healthcare workers or through contaminated medical equipment [18–20]. There is a considerable body of published literature for patient-to-patient transmission of multi-drug-resistant *P. aeruginosa* from outbreak reports [12,21,22]. The strict maintenance of infection control measures is essential to limit the spread of this bacteria. Infection control strategies to decrease the incidence of infection due to *P. aeruginosa* in ICUs mainly include bundle approaches involving general measures, disinfection and replacing reservoirs [23–25].

Previous studies found that clinical strains of *P. aeruginosa* were genetically related to the strains found in the patient's environment, such as in tap water, P-traps, sinks, handwashing stations, tap aerators or washbasin drains, but a causal link was controversial [25]. In a systematic review, seven monocentric studies were considered to provide plausible evidence of a link between tap water as a reservoir for *P. aeruginosa* and colonization/infection in patients in an endemic setting. In these studies, rates of exogenous acquisition of *P. aeruginosa* varied from 29% to 81% of patients, as in the different ICUs in the present study [13,19,26–30].

ICU, intensive care unit.
[a] ICU with filtered taps.

In this study, there was wide heterogeneity in tap water contamination by *P. aeruginosa* among the ICUs. In common with other studies, the present study showed that *P. aeruginosa* may persist in tap water over prolonged periods, and that electronic taps are potential reservoirs of *P. aeruginosa* in ICUs [31–33]. Tap water could become positive for *P. aeruginosa* through contamination of the water supply or retrograde contamination (e.g. from splashing on to the tap when water is drawn, especially if the water flow impacts directly on the drain outlet, or if fluids are discarded inappropriately in handwash basins) [34,35].

Discrepancies observed between ICUs may be explained by various factors, including compliance with infection control measures, contamination load of the environment, and biological features of the pathogen (intrinsic fitness factors) [36]. Based on the study findings, the authors suggest monitoring tap water in ICUs with high rates of colonization or infection with *P. aeruginosa*, although there are no recommendations for systematic screening in search of *P. aeruginosa* in ICUs. Furthermore, these ICUs should consider eliminating work processes involving sinks in close proximity to patients, and favour the use of alcoholic hand disinfection in order to limit the spread of *P. aeruginosa* among patients. Some guidelines recommend sampling outlets in ICUs on a six-monthly basis and taking remedial action for outlets that are positive for *P. aeruginosa* [37].

This study had several strengths: the prospective multicentre design with a study population in accordance with most previous studies analysing *P. aeruginosa* colonization/infection in ICUs; the use of methods enabling a temporal relationship to be identified between water taps and identification of colonization/infection in patients; repeated sampling during the 5 months of the study; and the huge number of isolates typed by PFGE. However, some limitations should also be noted. First, isolates were selected for genotyping and this was performed from one colony of each positive culture; however, isolates were not available for some patients. So, the results may not accurately represent the whole epidemiology. A robust methodology would involve typing four to 10 different colonies from each culture. In a study of more than 1600 isolates of *P. aeruginosa*, the authors found that over 60% of the tap water samples were contaminated by *P. aeruginosa*, and 83% of the patient strains were classified as exogenous. They typed at least four colonies that were representative of the different morphological types of *P. aeruginosa* present on each culture plate [29]. Second, the limitation of water samples may have underestimated the number of exogenous sources, as extensive microbiological samples of the environment were not taken other than water taps and patients. The range of reservoirs in healthcare environments from which *P. aeruginosa* has been isolated is wide, including respiratory therapy equipment, ice makers, endoscopes and cleaning equipment [38,39].

In conclusion, this multi-centre study conducted in ICUs suggests that an exogenous origin of *P. aeruginosa* could be prevented in a substantial proportion of patients. Given the possible consequences of *P. aeruginosa* infection in ICUs, it is clear that strategies to prevent *P. aeruginosa* acquisition should become a key priority. There is a need for studies on routes of transmission and risk assessment approach to better define how to control exogenous acquisition in ICUs.

SCOTTISH HOSPITALS INQUIRY

Review of the Expert Report for the Scottish Hospitals Inquiry on the evidence of risk of infection from the water and ventilation systems at the Queen Elizabeth University Hospital and Royal Hospital for Children, Glasgow

written by Professor PM Hawkey, Dr SG Agrawal and Dr LN Drumright

regarding Chapter 7

Expert Report prepared for the Scottish Hospitals Inquiry

Date: 10 June 2025

Mr. Sid Mookerjee, BSc, MSc, MPH, FRSPH

This document may contain Protected Material within the terms of Restriction Order 1 made by the Chair of the Scottish Hospitals Inquiry and dated 26 August 2021. Anyone in receipt of this document should familiarise themselves with the terms of that Restriction Order as regards the use that may be made of this material. The terms of that restriction order are published on the Inquiry website.

1. Summary

1.1. This report has been prepared at the request of the Scottish Hospitals Inquiry and reviews Chapter 7 of the report of Professor Hawkey and colleagues, hereon referred to as the HAD report, on its methodology and conclusions from an epidemiological perspective.

1.2. This report does not address the *aspergillus* infections seen at QEUH and RHC. This subject is dealt with through a joint report by Dr. Sara Mumford and me, Sid Mookerjee.

1.3. The Inquiry has asked a series of questions in order to assist in this review.

2. Review of the HAD report

2.1. I am asked for my opinion on the validity of the principal proposition advanced that appears to be advanced at section 5.4.3 and section 6.1.2-6.1.3 that it would be possible to determine whether there was 'widespread contamination' of the hospital water system or 'inadequate or insufficient ventilation system' by considering whether there was an increased rate of infection in the patient population as a whole or in part'.

2.2. Dr Walker's expert report [1] and the Storrar and Rankin[2] HPS report , both evidence widespread contamination of the hospital water system. This contamination is noted to be owing to a wide range of gram-negative waterborne pathogens.

2.3. Dr Mumford's HAD review report [3] , sections 6.12 – 6.27 outline numerous points of evidence pointing to the widespread contamination of the hospital water system, with sections 5.13, 7.3, and 8.17 pertaining to the inadequacy of the ventilation system.

[1] Bundle 21, Volume 1, Document 5, page 180.
[2] Bundle 19, Document 21, page 174.
[3] Bundle 44, Volume 2 - Dr Mumford's Review of HAD Report 2025.

2.4. My 2024 supplementary report[4] noted the magnitude of the difference between the infection rate in wards 2A and post decant to 6A and the overall comparator units' rate over the period 2015-2022, specifically "*The IRR statistic shows that the year the Schiehallion opened – 2015, the magnitude of the difference between the 2A rate versus the comparator units' rate was 3 times. This rose to 18 times in 2018, at the point when patient admissions (among other actions) were restricted and the decant of patients to 6A (primarily) took place. At the time of the decant, the 6A rate was approx. 9 times that of comparator units', dipping to approx. 5, 7 and 8 times over 2019 – 2021, rising to 13 times in 2022 versus comparator units*".

2.5. Furthermore, the report evidences the association between the rate of water contamination and infection rate at the Schiehallion – "*the Pearson's correlation coefficient statistic compares two time series data points over a period of time and provides a figure indicative of how 'associated' these two time series are to each other. Recall that the Pearson's correlation coefficient in section 7.3 was 0.7, indicating a 'moderate – very strong' positive correlation between the trend in Schiehallion infection rates and the trend in water positivity, i.e. contamination. I recalculated the statistic, this time comparing the aggregated 2A and 6A rate against the water positivity figure for the period 2015 – 2019 (see paragraph 2.41 for an explanation of why I excluded the 2020 water positivity figure), with the resulting statistic = 0.6, interpreted as indicating a 'moderation – strong' association between infection rates and water positivity".*

2.6. There is clear evidence, borne out of analysing NHS GGC's own data on infections and activity, specifically that the rate of infections owing to environmental organisms was higher (for certain years) than that of comparator units across the UK, and correlates strongly with the trend in water contamination over 2015 – 2019, from which I surmise that long-term environmental contamination led to the increased rates of infections.

2.7. I am asked for my opinion on whether Paragraph [29] of the Executive Summary

[4] Bundle 21, Volume 1, page 71.

advances the proposition that amongst the paediatric haematology and oncology patients at the RHC and before that at Yorkhill the incidence of BSI Bacteraemia caused by 'environmentally relevant' microorganisms in a particular hospital or patient population is largely the same as the incidence of BSI Bacteraemia caused by microorganisms that are 'not environmentally relevant'.

2.8. In my 2024 Quantitative infection link report [5] as noted in paragraph 2.5 and 2.6 above, I evidenced the 'moderate-very strong' association based on the Pearson's correlation coefficient statistic, between rates of infections in the Schiehallion cohort and concurrent rates of water contamination. Furthermore, section 10.10 of the Quantitative report notes that the evidence presented satisfies all eight of the relevant Bradford Hill postulates, cementing the association between rates of infection caused by environmental organisms and rates of water contamination.

2.9. In my view as a clinical epidemiologist, trends in infections owing to environmental and non-environmentally relevant organisms are not mutually exclusive, that is the two can occur simultaneously, and the existence of one does not limit the other from being possible. In a clinical context, evidence of concurrent infections owing to non-environmentally relevant infections would necessitate a corresponding investigation to uncover the factors driving the cases. If infections from any source – environmental or otherwise – are high, it indicates a problem which ought to be dealt with to mitigate risk to patients. Furthermore, the differences in terms of habitat, pathogenic roles, and biochemical characteristics between environmental and non-environmental gram-negative bacteria make them unsuitable for comparison.

2.10. I am asked for my opinion on the relative merits of occupied bed days versus admission data and to set out my understanding of the consensus amongst medical epidemiologist about the challenges of comparing rates or incidence of bacterial blood stream infections in different groups of hospital patients in

[5] Bundle 21, Volume 1, page 3.

different hospitals and comment on the approach of the HAD Report to this issue.

2.11. The HAD report's use of rate of infections per 1000 bed days is in line with accepted scientific usage when adjusting incidence for activity over time.

2.12. The report makes comparisons between QEUH and other GCC hospitals, and Yorkhill – which is understandable as the first step in contextualising rates of infection, with the expectation, from an epidemiological viewpoint, to then extend the net wider and compare to other large tertiary hospital Trusts, which the HAD report does not do.

2.13. Benchmarking rates with other large hospitals across the UK allows for a) building a relevant frame of reference, i.e. where does the hospital rate in question sit within the context of other similar institutions in the country, b) peer comparisons, reducing biases which can creep into internal comparisons, i.e. structural issues which impact all local sites, c) allows for fair performance evaluation when comparing like patient cohorts across the country, and d) it is the internationally accepted gold standard utilised by UKHSA, ECDC, CDC and the WHO.

2.14. In my expert opinion, internal comparisons between RHC and Yorkhill does not adequately adjust for internal biases within an institution – QEUH, with and does not allow for a fair performance contextualisation of the rates of infection at the RHC. As noted in section 2.53 of my supplementary report [6] the comparator dataset used to contextualise the rates of infection in the Schiehallion cohort comprised of 140,689 admissions, 1232 gram-negative and fungal infections over a period of 8 years, providing a very high level of confidence in the statistic it delivers.

2.15. I've been asked for a formal comparison in tabular form of the categorisation of microorganisms into two classes within Table 1 and Table 2 (pages 60 to 61) with the categorisation of microorganisms in his report at 8.1.16[7], in the various

[6] Bundle 21, Volume 1, Pg 71.
[7] Bundle 21, Document 1, Page 25.

HPS reports from 2019[8] and the list of microorganisms used by Dr Kennedy in his reports based, according to his evidence, on the case definition for the 2018 Water Incident IMT[9].

2.16. Table 1 provides a comparison in tabular form of organisms included in each report noted in section 2.15.

2.17. Caveats – Quantitative report and CNR are environmental pathogen specific, with the HAD and Dr. Kennedy's reports including additional enteric pathogens, and the HPS reports including a much wider set of organisms such as gram-positive and non-environmental bacteria. Only pathogen names explicitly named in the HPS reports have been included in Table 1.

[8] The HPS Situational Assessment, Wards 2A/B, Royal Hospital for Children, NHS Greater Glasgow and Clyde, Appendix 4 (Bundle 7, Document 5, Page 205; The HPS SBAR: To support NHS GGC IMT Mycobacterium chelonae cases and the Incidence of gram-negative bacteraemia in the paediatric haemato-oncology, September 2019 (Bundle 3, Document 16, Page 127); the Draft HPS Review of NHS GG&C Infection Outbreaks in the Paediatric Haemato-oncology Data October 2019 (Bundle 7, Document 6, Page 219) and the final redacted HPS Review of NHS GG&C Infection Outbreaks in the Paediatric Haemato-oncology Data October 2019 - 29 November 2019 (Bundle 7, Document 7, Page 255).

Mycobacterium chelonae			Yes		
Rhodotorula mucilaginosa		Yes			
Veillonella species					Yes

2.18. I am asked for my assessment of the methodology set out in section 7.2.2 to 7.2.6 and to compare the approach to that taken by me in my reports for the Inquiry. I am also asked for my views on approach taken to considering the potential for clusters and the factors considered in doing so, identify the source of the bed day data in Table 4 (page 66), and on the adjustment made by the HAD authors owing to "an uncharacteristically low number of bed days" at certain points.

2.19. On scrutiny, the following potential issues points can be noted.

1. There are inconsistencies in the dataset [10] used by the HAD authors. Dr Christine Peters' First Supplementary statement[11] details key inconsistencies, which for the sake of brevity I note in brief alongside additional points.

2. Adult patients designated by consultant are analysed corresponding to areas flagged as BMT, North and South, but data in the 'IPE admission hospital' does not always correspond to data in the 'IPE Admission ward'.

[10] IP Haem onc selected consultants from 2013 by sector. NHS GCC - This document contains patient-identifiable data, therefore it has not been included in a Hearing Bundle.
[11] Dr. Christine Peters, First supplementary Witness Statement, 2025.

E.g. in the BMT tab, selecting 'QEUH' under column 'IPE admission hospital', line 2742 notes the 'IPE admission ward' as 'BOC Ward B8 - Haemopoietic Unit', which is a Beatson ward. Another example of this inconsistency is on line 548. Additional examples are provided in Dr. Peters' First Supplementary Statement.

3. Clustering based on presence/absence of whole genome sequencing is problematic considering the evidence regarding the lack of consistency in the range, volume and organisms tested pertaining to water sampling across the QEUH/RHC campus[12]. Furthermore, there is questionable levels of contemporaneous WGS testing to rule clusters in or out [13],[14],[15], calling into question the robustness of the clustering methodology adopted by the HAD authors.

4. The analysis underpinning Figures 1 – 4 includes environmental and non-environmental pathogens, including *Escherichia coli, Staphylococcus epidermidis, Coagulase negative staphylococcus* included alongside *Pseudomonas aeruginosa* (environmental bacteria). Owing to significant differences in habitat, pathogenic roles, and biochemical characteristics between environmental and non-environmental gram-negative bacteria, it is not epidemiological nor clinically sound to combine bacterial incidence in such a manner.

5. Highly specialised area such as BMT should have fewer bed days than non-BMT haemato-oncology, but here South sector has fewer bed days than BMT and the North [16] - 60930 adjusted bed days for BMT, 25417 bed days for the South and 48453 for the North. It would be useful to ask the authors their view on this.

[12] Bundle 21, Volume 1, Document 1, page 3.
[13] Bundle 8, Document 44, page 223.
[14] Bundle 8, Document 45, page 230.
[15] Bundle 8, document 46, page 239.
[16] Adult_Beddays spreadsheet, NHS GGC - This document contains patient-identifiable data, therefore it has not been included in a Hearing Bundle.

6. As Dr. Mumford notes in her review [17] – "*The descriptors of the adult patients are confusing, so for instance the BMT group. In the supporting documentation[18] some of the patients included on the list are not patients who would require bone marrow transplantation according to the clinical details provided. For example, disorders of iron metabolism, hereditary spherocytosis and solid tumours. These patients do not have the same risk factors as those with haematological malignancies and are therefore not comparable*".

7. In relation the authors' point "an uncharacteristically low number of bed days" the South sector at the QUEH in September 2016, November 2019 and January 2023", they note adjusting some denominator data which appeared to them lower than the month-on-month average, which is in line with scientific methodology, albeit no reason is provided for the unusually low bed days figures at key points and further calls into question the robustness of the activity datasets used.

8. There are inconsistencies of note in the 'Adult Haem Onc 2013 – 31Aug23 – Matched GMC' spreadsheet [19]. Selecting 'QEUH' under 'Unit location group', there are 1483 rows under column 'Location' relates to SGH – Southern General Hospital. Dr. Peters' first supplementary statement details further examples.

9. On page 67, the authors note that the bacteraemia rate is higher than the Beatson and SGH GGC hospitals and write this off to increase to '*greater immune compromised status… indication of greater testing for bloodstream infection or other policy differences'*. It would be useful to ask the authors why they did not investigate this point further, by comparing the rate of infections over time to other large acute tertiary hospitals, a like to like

[17] Bundle 44, Volume 2, Document 15 – Dr Mumford's Review of HAD Report 2025.
[18] IP Haem onc selected consultants from 2013 by sector, NHS GCC - This document contains patient-identifiable data, therefore it has not been included in a Hearing Bundle.
[19] Adult Haem Onc 2013 – 31Aug23 – Matched GMC.xlsx, NHS GGC - This document contains patient-identifiable data, therefore it has not been included in a Hearing Bundle.

comparison, akin to undertaken in my Quantitative report [20].

10. Page 68 – 86 relates to adults. Adult and paediatric haemato-oncology patients differ significantly on points such as cancer aggressiveness, with paediatric cancers tending to be more aggressive, paediatric chemotherapy regimens being more intensive, often involving higher doses of certain chemotherapy agents, and differences in prognosis [21], [22], to note a few, I do not see how the adult focused analysis on these pages has any bearing on understanding the question as laid out in 'Direction 5' of the inquiry, which is concerned with rates of infections in the Schiehallion patient population and the role of environment.

2.20. I am asked for my assessment of the methodology set out in section 7.2.7 to 7.2.9. On scrutiny, the following additional potential issues points can be noted.

1. Figure 17, compares Yorkhill and QEUH rates of all bacteraemias, including gram-positive, gram-negative, environmental, non-environmental pathogens. In addition, scrutinising the paediatric data set provided 'RHC Haem onc adms from 2008 with monthly figures 2024-01-09' 23 the analysis combining patient groups who have haematological malignancies, the focus of this inquiry, alongside those with iron metabolism disorders, hereditary spherocytosis, sepsis, general vomiting and diarrhoea, and solid tumours, which is a very heterogenous mix of patients, therefore making the outcomes of the analysis unapplicable to understanding trends of environmentally relevant infections in the Schiehallion cohort.

2. Diluting the Schiehallion patient cohort which moved from Yorkhill to QEUH with additional patient groups, goes onto dilute the outcomes, which are not in keeping with the extensive reporting of infection rates in the Schiehallion

[23] RHC Haem onc adms from 2008 with monthly figures 2024-01-09, NHS GGC - This document contains patient-identifiable data, therefore it has not been included in a Hearing Bundle.

unit at the RHC, with all reports [24] [25] [26] [27] [28] showing that the rates of bacteraemia with gram negative environmental organisms increased following the move of the Schiehallion Unit to RHC, peaking in 2017-18.

3. Internal comparisons within an institution of rates of infection over time are useful as an initial step to understand peaks in infection, but necessitates utilising the 'temporal mean', which is the arithmetic mean of the values and flag changes in infection trends by measuring the variance from the mean value at the minimum. The authors do not provide any statistical output to defend their view purported in paragraph one of section 7.2.8 - ' Incidence starts off at QEUH similar to that observed for the prior 10 years at Yorkhill, but then steadily declines from ~2018 onward'.

4. Analysing the bed days data used by the HAD report [29], hereby referred to as 'RHC BD 2025' specific to ward areas of 2A, 2B, 4B and 6A, and comparing it to the NHS GGC bed days dataset[30], hereby referred to as 'RHC BD 2024' relied on in my 2024 reports, I note stark differences in bed days assigned to wards 2A, 2B and 4B, with 6A bed days remaining fairly consistent, and a 10% decrease in the combined 2A, 2B, 4B and 6A bed days, 41206 in RHC BD 2024 versus 37720 in RHC BD 2025. These differences are set out in Table 2.

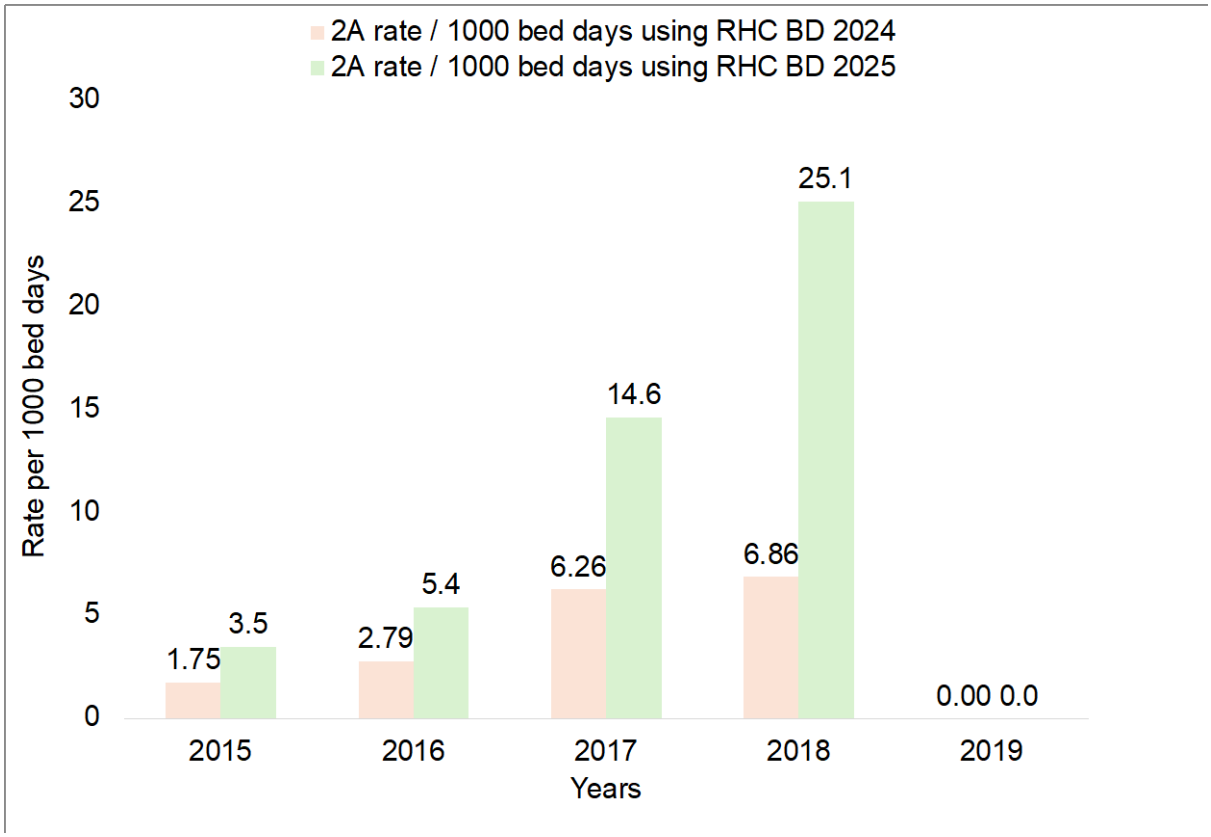
2021	0	0		NA	NA
2022	0	4299	2241	0.00	0.0

Figure 1: Comparison of rate of infections in 2A, RHC BD 2024 versus RHC BD 2025



5. If we are to recalculate the rates of infections in 2A using RHC BD 2025, for the period 2015 – 2022, as noted in Table 3 and illustrated in Figure 1, we see a doubling of the rate of infection for ward 2A over the period 2016 – 2017 and thereafter a tripling for the year 2018, as compared to the rates reported in my supplementary report [31] using RHC BD 2024. It would be valuable to understand why the two bed days datasets differ, and if the HAD authors were aware of the differences.

6. There are inconsistencies when comparing Dr. Drumright's [32] bacteraemia spreadsheet to the original bacteraemia spreadsheet provided by NHS GGC [33]. Table 4 provides a tabular comparison of ward areas which have

[31] Bundle 21, Volume 1, page 71.

environmental bacteria and fungal specimens linked to them. Note that Dr. Drumright's spreadsheet is missing environmental organisms from five RHC wards, equalling approximately 18 deduplicated environmental organisms. Would be useful to understand what the HAD authors think of this inconsistency and why it is so.

2.21. I am asked for my assessment of the methodology underpinning Figure 22 on page 113.

1. We understand as per Dr. Mumford's report [34] - "it would be expected that moving to a brand-new facility from a much older facility there would be a reduction in infections with environmental organisms. From Sid Mookerjee's work it is clear that this was the case for the Schiehallion Unit patients but the numbers of environmental infections rapidly increased to a peak in 2017 and a decline from 2018 due to multiple interventions including, but not limited to, point of use filters on taps, bottled water for washing and teeth cleaning, enhanced cleaning including silver hydrogen peroxide vapour (HPV) decontamination, mobile HEPA filters in patient's rooms and decant away from ward 2A/2B." The year-on-year fluctuations in the rate of infection per 1000 bed day at the RHC reflects this (blue line, Figure 22). Furthermore, it concurs with the Schiehallion overall rate trend graph, Figure 2, in my 2024 supplementary report [35]. Both figures chart an increase in the rate of infections from 2016, less than a year into the opening of the RHC, with the first peak in 2017, succeeded by a trough owing to the key mitigation interventions, particularly the decanting patients from 2A and 2B, to 4B and 6A. Both trends then chart a steep increase in the infection rate before a decline towards 2022. Lastly, the HPS Situational Assessment report [36], page 210 reiterates the rise in infections – "In the 2A/2B Group, the SPC chart shows a shift below the centreline for 17 months from January 2015 to May 2016, then a shift above the centreline from April 2017 to December 2017. The rate was also above the UCL, and therefore higher than expected". This is not in keeping with the authors' assertion that 'BSIs with environmentally relevant organisms are following the same pattern' as noted on page 112.

2. Using the data table underpinning Figure 22, provided by Dr. Drumright [37],

[34] Dr. Mumford HAD report review. 2025
[35] Bundle 21, Volume 1, document 3, page 86.
[36] Bundle 7, Document 5, page 210.
[37] Paeds_bsi_count_beddays_rates. NHS GGC - This document contains patient-identifiable data, therefore it has not been included in a Hearing Bundle.

Table 6 below details the cumulative sum of bed days, environmental bacteraemias, and a rate per 1000 bed days for three periods –

- Yorkhill 2005 to May 2015,
- RHC pre-decant June-2015 to September-2018
- RHC post-decant October-2018 to December-2022

Table 6: Yorkhill and RHC, pre and post decant figures

Indicator	Time period	Cumulative bed days	Cumulative environmental BSIs	BSI rate per 1000 bed days
Yorkhill	Jan 2005 to May 2015	68520	317	4.62
RHC pre-decant	June 2015 to Sept 2018	24363	122	5.00
RHC post-decant	Oct 2018 to Dec 2022	22555	60	2.66

3. Comparing the three periods' rates of infections, we note that the rate of infection at Yorkhill for the period 2005 up-until to move to RHC, rate of 4.62, and the pre-decant RHC rate, 5.00 are very similar, with a incidence rate ratio (IRR) of 0.92, evidence of their similarity. In contrast, the rate post-decant at the RHC, 2.66, and the pre-decant RHC rate, 5.00, are statistically significantly different, with an IRR of 1.88 (95% CI 1.38 – 2.56), evidence of the effect the specific infection mitigation, the decant from 2A, 2B to 4B and then 6A, had on the rate of infection at the RHC.

4. Both the above statistics – the lack of difference between the rate at Yorkhill to the pre-decant RHC rate, and the difference between the pre-and-post decant RHC rate is not in line with the assertions of the HAD authors that the rates follow the same pattern at Yorkhill and the RHC.

2.22. I am asked to consider section 7.1 and whether I can confirm the accuracy of

the reportage of *Pseudomonas aeruginosa* testing results on pages 57 to 58 and to produce a table from the water testing results for the QUEH already analysed setting the number of tests carried out at the QUEH for *Pseudomonas aeruginosa* and the number of positive results for *Pseudomonas aeruginosa* during the whole period of that data set with the results reported on a quarterly basis.

2.23. Table 7 details the *Pseudomonas. spp* positivity rate (%) by quarter for the period Aug-2015 to Jan-2021, taking into account water samples taken in the Schiehallion wards, utilising Dr. Chaput's water sampling data as described in my Quantitative Infection link report [38],alongside the number of positive *Pseudomonas. spp* samples.

2.24. Note as per Dr. Chaput's report [39], specifically Table 1, which states that any count of *Pseudomonas* bacterium found in water sampling from specialist high risk areas, such as the Schiehallion wards, is considered as per national guidance, to be out of spec.

2.25. Table 7 details the rate of *Pseudomonas. spp* results by quarter, for the Schiehallion wards, all of which are high risk areas, with rates of positivity of 2.6% in Q3 of 2015-16, 2.3% in Q1 of 2018-19, 1.6% in Q1 of 2019-20, all of which stand higher than those quoted in section 7.1 of the HAD report, i.e. 1.1% in high-risk areas.

2.26. Dr. Chaput's report, Table 3[40], notes the corrected *Pseudomonas* out of spec % for 2015 and 2016 as 7.95% and 4.87% respectively, albeit I understand this to be representative of the entire QEUH, some of which would have been in high-risk areas.

2.27. In keeping with the clinical opinion that any count in high risk areas, like the haematology-oncology units, is above the accepted threshold, the rates noted

[38] Bundle 21, Volume 1, page 3.
[39] Bundle 18, Volume 1, Document 2, Table 1.
[40] Bundle 18, Volume 1, Document 2, Table 3.

in 2.26 and 2.27 is clear evidence of high levels of contamination.

Table 7: *Pseudomonas. spp* results by quarter, for the Schiehallion wards.

Acute Lymphoblastic Leukemia in Adults and Children

Session Chair: Charles Linker, MD

Speakers: Stephen E. Sallan, MD; Nicola Gökbuget, MD; and Ching-Hon Pui, MD

Myths and Lessons from the Adult/Pediatric Interface in Acute Lymphoblastic Leukemia

Stephen E. Sallan

The development of effective therapy for children with acute lymphoblastic leukemia (ALL) is one of the great successes of clinical oncology, with long-term survival achieved in over 80% of patients. However, cure rates for adults with ALL remain relatively low, with only 40% of patients cured. With an age-unrestricted, biology-based approach, we anticipate a better understanding about why these outcome differences exist, and think that by extending successful pediatric clinical programs to include adult patients with ALL, we can directly compare uniformly treated adults and children in terms of response to therapy, toxicity and underlying biology.

"The child is the father of the man"…
William Wordsworth

Background

Within childhood acute lymphoblastic leukemia (ALL) populations, older children have had inferior outcomes[1] and within adult ALL populations, younger adults have had superior outcomes.[2,3] In recent reports, "overlapping" populations of older children and young adults have been compared for the likelihood of inducing a complete remission and long-term event-free survival (**Table 1**).[4-8]

None of the clinical trials listed in **Table 1** was designed to be compared to its age-overlapping pediatric or adult counterpart; thus, the comparisons were all retrospective. Although well-recognized age-related dissimilarities in the biology of ALL and event-free survival exist (**Tables 2** and **3**), the more favorable outcomes for older adolescents treated on pediatric regimens in **Table 1** cannot be explained by differences in patient characteristics. Nor would one expect other potential "adult vs. pediatric"

Table 1. Older child/young adult acute lymphoblastic leukemia (ALL) outcomes.

differences (for example, co-morbidities associated with smoking, or host pharmacokinetic differences based on age) to play a substantial role in the findings summarized in **Table 1**.

There are clear differences between current adult and pediatric therapeutic approaches. For example, bone marrow transplantation in first remission is more common for adults (in part, because of the higher incidence of Philadelphia chromosome–positive ALL), and pediatric regimens generally include greater dose density of many chemotherapeutic agents (such as asparaginase, vincristine, corticosteroids and methotrexate).

What are some plausible explanations for these differences between pediatric and adult outcomes? In a thoughtful, provocative and prescient editorial, Dr. Charles Schiffer reflected on biological differences among the hosts and diseases, and also raised issues pertaining to clinical practice, such as the frequency of and familiarity with ALL protocols and care of such patients.[9] In addition to recognizing that ALL is the most common malignancy in children and relatively rare in adult oncology populations, he also noted that most children, but not most adults, with ALL were treated in the context of clinical trials, by experienced support teams, and that many adults were not treated at academic medical centers. The cultural differences between care of pediatric and adult ALL patients, described as "disparities in treating attitudes" by Boissel and co-workers,[5] was highlighted by Schiffer's colorful and accurate description of pediatricians' tight adherence to complex treatment protocols "…with a military precision on the basis of near-religious conviction about the necessity of maintaining prescribed dose and schedule come hell, high water, birthdays, Bastille Day, or Christmas." Although the necessity of such vigor has not been formally tested, the proof of the pudding is in the tasting.

Obstacles to Age-Unrestricted, Biology-based Treatment

Why have adults with ALL not received the same chemotherapeutic regimens as children?

There are two principal hurdles: 1) systems of care, and 2) regulatory impediments.

"Systems of care" and related differences

Referral patterns

Commonly held views suggest that pediatricians refer 15- to 20-year-old patients to pediatric academic medical centers where (a) > 90% of patients are < 15 years old, and b) > 90% of patients with ALL are enrolled on clinical trials.

Similarly, internists frequently refer 15- to 20-year-old patients to adult hospitals, mostly not academic medical centers, where a) > 90% of the patients are > 40 years old and b) most patients with ALL are not entered on clinical trials.[10]

Table 2. Acute lymphoblastic leukemia (ALL): incidence & biological differences.

	Children	Adults
Peak incidence	5 years	50 years
% of Leukemias	80-85%	15%
Chromosomes		
Ph+	3%	30%
MLL	1-2%	7%
TEL/AML1	20%	2%
Hyperdiploid	25%	5%
T-cell	10-15%	20-25%
Mature B	1-2%	3-5%

Table 3. Five-year event-free survival.

	Children	Adults
Pre-B	> 80%	30-40%
T-cell	75-80%	45-55%
Ph+	20-25%	< 10%
MLL	40-50%	20%
TEL/AML1	90%	N/A

Frequency of and familiarity with ALL

Although there might be as many adults with ALL as there are children with the disease[11] (**Figure 1**), the relative frequency of the disease is markedly higher in young children. ALL represents about 15% of all malignancies in 1-15 year olds, 5% in 15-19 year olds, and < 10% of malignancy in > 20 year olds.

Adherence to protocol and mitigating psychosocial factors

Although most of the drugs used for ALL today have existed for over four decades, little is known about their ideal antileukemia dose or the role of individual patient differ-

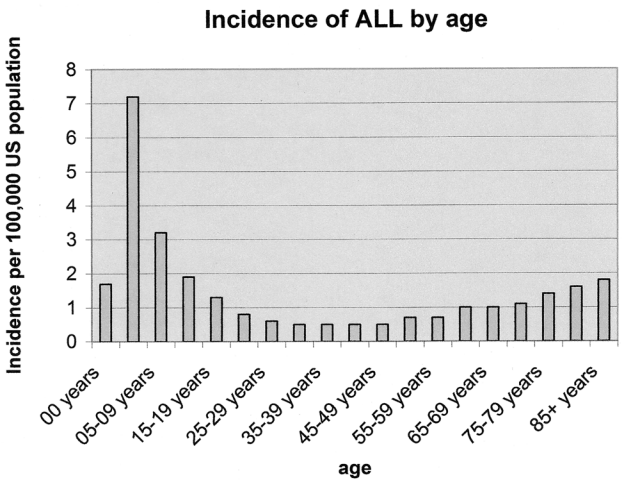

Figure 1. Incidence of acute lymphoblastic leukemia (ALL) by age, SEER 1992-1999.

Downloaded from http://ashpublications.org/hematology/article-pdf/2006/1/128/1091607/128_132ash.pdf by guest on 11 June 2025

ences in drug metabolism. In pediatric practice, "pushing the dose" by using myelosuppression as the endpoint, assures delivery of the maximum dose for each child with each course of chemotherapy. Although it is difficult to assess whether such rigid adherence to protocols is necessary, Boissel and co-workers reported on one "therapeutic practice" measure. They determined the median number of days from the time of initial complete remission until the time of the first postremission chemotherapy: 2 days in the pediatric study and 7 days in the adult study; $P = 0.002$.[5]

Is this time-to-next-treatment measure a medical or psychological problem? Have the older patients fully recovered physiologically, or are there other mitigating features (e.g., "I need some time with my family") resulting in delays in therapy?

In the pediatric setting, in addition to the meticulous attention to detail by the pediatricians, a primary driver of subsequent therapy is the caretaker, usually the mother. ("What are we waiting for? The leukemia is growing back. Let's get going!")

Difficulties in comparisons

"Simple" apples-to-apples comparisons in a heterogenous disease such as ALL can be difficult, and occult differences in practices among internists and pediatricians might not be appreciated.

For example, **Table 1** demonstrates comparisons in the percentage of complete remissions between older children and adults. Not shown is the time to enter complete remission. All pediatric trials report complete remission at the end of approximately 1 month of multiagent chemotherapy. However, many adult trials report on the complete remission rates after 2 months of treatment (**Table 4**). Although the time to attain a complete remission was not of prognostic importance in at least one adult trial,[12] we found that in childhood ALL, the time to enter a complete remission had significant implications, and the difference between a complete remission in 1 month or 2 months was a matter of life or death for the majority of slow responders.[15]

Regulatory obstacles

No diseases begin or end at age 18 years. But current review systems of clinical trials (e.g., Institutional Review Boards) and funding sources (e.g., cooperative groups and pharmaceutical company-sponsored trials) frequently establish "biologically arbitrary" age limits for protocol eligibility and evaluation. Thus, diseases such as ALL, whose biology extends across a broad age spectrum, are usually approached as two diseases: childhood ALL (patients < 18 years old), and adult ALL (patients ≥ 18 years old). Such "age-restricted" criteria have played an integral role in our current understanding of the disease and its treatment. However, this approach, based on the single differentiating measure—patient age—has until recently hampered clinical research across a broader spectrum of the disease. Although likely a meaningful host variable, age, *per se*, is highly unlikely to trump leukemia biology or the impact of an individual treatment regimen. Overcoming such well-institutionalized barriers to research remains a formidable challenge.

Recently, the Dana-Farber Pediatric ALL Consortium, a group of nine collaborating pediatric centers with a successful record of ALL research and treatment,[16] joined together with nine adult institutions to form a Dana-Farber Combined Adult/Pediatric ALL Consortium.

In anticipation of a common approach to the over 18-year-old patients, we evaluated our oldest pediatric ALL population—those aged 15-18 years old.[17] Among 844 patients treated on two consecutive protocols (Dana-Farber 91-01 and 95-01) between 1991-2000, we found 51 (6%) were in the 15- to 18-year-old population. Statistically significant biological characteristics at the time of diagnosis included a higher proportion with T-cell ALL and a lower proportion with hyperdiploidy or the TEL/AML1 translocation compared to younger patients. Except for a lower incidence of complete remissions (1-14 year olds, 98% vs. 15-18 year olds, 94%; $P = 0.01$), there were no other statistically significant differences with regard to 5-year event-free survival (> 1-10 years old, 85%; > 10-15 years old, 77%; and >15-18 years old, 78%; $P = 0.10$). Patients 10 years old and older had more asparaginase-related pancreatitis and thrombosis, but there were no differences between the 10- to 14-year-old and 15- to 18-year-old populations. An updated analysis of the efficacy of our pediatric regimen for adult patients, 18-50 years old, appears as a 2006 American Society of Hematology abstract (DeAngelo et al).

We are now poised to investigate the biology of ALL and its treatment across a broad age spectrum, and to have common treatment regimens for common disease among patients ages 1-50 years old.

From our DFCI Combined Adult/Pediatric ALL Consortium, many myths have surfaced, and many lessons have been (and are being) learned.

Table 4. Time to complete remission in adult acute lymphoblastic leukemia (ALL) trials.

Study	% CR after One Cycle of Chemo	% CR after Two Cycles of Chemo
UKALLXII/ECOG[12]	51%	91%
CALGB 8811[3]	62%	86%
LALA-94[13]	72%	84%
Hyper-CVAD[2]	81%	92%
DFCI pilot[14]	82%	N/A

Myths and Lessons

Myth #1. It cannot be done!

You cannot have a common approach to therapy for children and adults. The disease biology, medical practices, regulations and cultures are incompatible with a uniform approach to clinical research.

Downloaded from http://ashpublications.org/hematology/article-pdf/2006/1/128/1091607/128_132ash.pdf by guest on 11 June 2025

Lesson #1. It can be done!
(But it isn't easy.) Finding common ground requires time, communication and compromise. We are confident that our work within the DFCI Combined Adult/Pediatric ALL Consortium, as well as similar efforts by others who are striving toward the same goals—improved outcome for all, diminished toxicity and a better understanding of leukemia biology—will be rewarding and result in lives saved and quality years of life added.

Myth #2. Adults do not tolerate asparaginase.
It is generally assumed that adults are less tolerant to the acute and cumulative side effects of antileukemia drugs, and asparaginase, a drug used in all pediatric ALL regimens, is often cited as a prime example.

Lesson #2. Our initial adult protocol, a feasibility trial using one arm of our pediatric ALL regimen, includes 30 weeks of high-dose asparaginase therapy. Adults ages 18-50 years old and children ages 10-18 years old tolerate multiple weekly asparaginase doses (≥ 12,500 IU/m^2) with similar incidences of allergic reactions, pancreatitis and thrombosis.

Myth #3. Adults have a high rate of therapy-related deaths.
Some would argue against initiating combined adult/pediatric clinical trials because the remission mortality in children (now in the 1-2% range) is far less than in adults.

Lesson #3. In fact, the experience of Dutch[6] and British[7] investigators suggests that it is the practice of bone marrow transplantation in first remission for non-Philadelphia chromosome–positive ALL that accounts for the increased incidence of therapy-related deaths. Given the paucity of data supporting the superiority of bone marrow transplantation in first remission, many now agree that use of chemotherapy alone would result in both improved outcomes and in a lower incidence of therapy-related deaths. Our DFCI adult pilot protocol and mature pediatric protocols have ~1% incidence of therapy-related deaths.

Myth #4. Adults don't have asymptomatic central nervous system (CNS) leukemia at diagnosis.
And because they don't, the practice of routine sampling of CSF at the time of diagnosis in asymptomatic patients is variable among adult treatment regimens.

Lesson #4. ALL is always a systemic disease. About 2-3% of children and adults have symptomatic CNS disease at diagnosis and an additional 5-10% of asymptomatic children and 5% of adults have lymphoblasts in their CSF disease at time of diagnosis. Routine lumbar puncture at the time of diagnosis and prior to initiating systemic chemotherapy, as well as routine CNS treatment, should be part of ALL management for all patients. An argument against this practice, that one might inadvertently introduce blasts into the CSF, can be readily mitigated by the routine use of intrathecal chemotherapy at the time of the initial diagnostic lumbar puncture.

Myth #5. Who needs a parent or caregiver?
The patient and his or her physician are sufficient for optimal care and outcomes.

Lesson #5. Never underestimate the value of a caregiver! The best motivated patient and physician can have their well-intended treatments and outcomes enhanced by surrounding themselves with "a mother figure"; in fact, parental surrogates, committed family members and loved ones, as well as an extended supportive team of professionals (especially nurses), are likely to assure optimal adherence to protocol, emotional support, and (hopefully) better outcomes.

Conclusion

Retrospective analyses clearly demonstrate that current pediatric therapeutic regimens are more effective than adult regimens for 16- to 21-year-old patients. Current and future clinical trials will focus on "the ages of uncertainty": the 21- to 50-year-old population. Age-unrestricted, biology-based therapy should be the standard of all patients with ALL. Pediatricians and internists treating patients with ALL have much to learn from one another. Such efforts are likely to result in more cures and a higher quality of life among the survivors.

SCOTTISH HOSPITALS INQUIRY

Review of the Expert Report for the Scottish Hospitals Inquiry on the evidence of risk of infection from the water and ventilation systems at the Queen Elizabeth University Hospital and Royal Hospital for Children, Glasgow

written by Professor PM Hawkey, Dr SG Agrawal and Dr LN Drumright

regarding *Aspergillus* infection

Expert Report prepared for the Scottish Hospitals Inquiry

Date: 4 June 2025

Dr Sara Mumford, MB. BS., MSc., FRCPath., SFFMLM.

Mr. Sid Mookerjee, BSc, MSc, MPH, FRSPH

This document may contain Protected Material within the terms of Restriction Order1 made by the Chair of the Scottish Hospitals Inquiry and dated 26 August 2021. Anyone in receipt of this document should familiarise themselves with the terms of that Restriction Order as regards the use that may be made of this material. The terms of that Restriction Order are published on the Inquiry website.

1. Introduction

1.1. This report has been prepared at the request of the Scottish Hospitals Inquiry and reviews the report of Professor Hawkey and colleagues, hereon referred to as the HAD report, with respect to Chapters 6 and 8 from the different perspectives of a Microbiologist and Director of IPC, and a medical epidemiologist.

1.2. The Inquiry has asked a series of questions in order to assist in this review.

2. Review of the HAD report

2.1. The purpose of enhanced ventilation in hospital settings is to control the patient environment and to minimise the risk of hospital acquired infection. Ventilation with the correct number of air changes per hour helps to dilute and remove airborne contaminants such as viruses, bacteria and pollutants creating a healthier environment for patients and staff. The removal of airborne micro-organisms reduces the risk of cross infection between patients and healthcare workers. A filtered air supply will also mitigate the risk of infection owing to recognised airborne pathogens such as *Aspergillus*, *Cryptococcus* and tuberculosis. A constant supply of fresh air provides a more comfortable environment for the patient. Overall providing ventilation which addresses these factors can lead to better patient outcomes by reducing the risk of healthcare associated infections.

2.2. At point 6.1, the authors of the HAD report conclude that the *"risk of infection arising from an "inadequate or insufficient" ventilation system would not be equal across all patient populations" and "would be most visible in these patients and one of the highest-risk populations is the group of patients with haematological, and other, cancers undergoing intensive chemotherapy and/or haematopoietic stem cell transplants (HSCT)".* Paragraph 6.1 of the HAD report relates to airborne diseases which the authors state are Aspergillosis, tuberculosis and viral infections. In principle we agree with this statement in that the most vulnerable patients; those with immunosuppression whether due to disease or treatment with corticosteroids, those in intensive care, cystic fibrosis patients, etc, would be most likely to acquire infection as a result of inadequate ventilation. However, as described in Dr Mumford and Ms

Dempster's earlier expert report[1] to the inquiry, the insufficient ventilation in ward 2A/2B contributed to the high levels of infection with environmental organisms, due to the failure to dilute and remove these, resulting in environmental contamination, and when looking at increases in infections this cannot be assumed to be restricted to typical airborne pathogens. As a conclusion to the preceding paragraphs in 6.1, this statement is, in our expert opinion, incomplete and fails to take into account the wider context of infection prevention mitigation which ventilation provides.

2.3. Aspergillosis is undoubtedly one of the potential consequences of inadequate ventilation in a healthcare facility. However, as described above it is not the only indicator. The epidemiology of Aspergillosis is multifactorial.

2.4. *Aspergillus spp* are ubiquitous in the environment and cause disease which often goes undiagnosed[2]. It is one of the most underdiagnosed infections in intensive care units[3]. An estimate of the burden of adult invasive aspergillosis[4] (IA) in the UK identified high risk populations as BMT patients, solid organ transplants, patients living with HIV, haematological malignancies, chronic obstructive pulmonary disease with emergency hospital admission, critical care patients, and patients with lung cancer. Critical care patients were identified as the largest at-risk group. Allergic bronchopulmonary aspergillosis complicates asthma and cystic fibrosis.

2.5. The estimated incidence of invasive aspergillosis is highest (8.1%) in allogenic bone marrow transplant patients, with AML patients (7.1%) and heart transplant patients (4.8%) also seeing high rates. Overall the numbers of infections annually in the UK range from 2901-2912 (excluding ITU patients), an overall rate of 4.59-4.61 per 100,000 population. The numbers of invasive aspergillosis cases in critical care patients is estimated to range from 387-1345, a rate of 0.61-2.13 per 100 000 population[5].

[4] Pegorie M et al. Estimating the burden of invasive and serious fungal disease in the United Kingdom. Journal of Infection (2017) 74, 60-71.
[5] Pegorie M et al. Estimating the burden of invasive and serious fungal disease in the United Kingdom. Journal of Infection (2017) 74, 60-71.

2.6. In a study of invasive fungal infections in patients with haematological malignancy[6], 69% of invasive fungal infections occurred in patients with AML. Over half of all infections (346/538) were caused by moulds and 90% of mould infections were caused by *Aspergillus spp,* indicating that *Aspergillus spp* is the commonest invasive fungal pathogen in patients with haematological malignancies.

2.7. The function of enhanced ventilation is not only to filter the incoming air, but also to dilute any contaminants in the air, provide fresh air and environmental comfort. The failure to dilute contaminants in the air is, in our expert opinion, more likely to result in increased infection rates generally in immunocompromised patients than an observable increase in invasive aspergillus, only detected retrospectively with statistical analysis due to the small numbers of aspergillus infections seen in this group of patients. This is confounded further by the use of prophylactic anti-fungal drugs in patients perceived to be at risk of IA where ventilation is deemed to be inadequate. As a result, the observed incidence of invasive aspergillosis can be assumed to be an underestimate of the true risk of infection due to inadequate ventilation.

2.8. Aspergillus spores are ubiquitous in the environment. It is well recognised that some patients become colonised prior to their diagnosis and treatment for haematological malignancy. Stringent infection prevention and control and ventilation measures are put in place to prevent nosocomial (as opposed to endogenous) aspergillus infection in these patients. High quality enhanced ventilation with HEPA filtration of incoming air, high air changes of 12 air changes per hour (ach), and 6 Pa of positive pressure to the corridor are collectively required to minimise the risk of infection. In addition, prophylactic anti-fungal antimicrobials are used to minimise the risk of endogenous and nosocomial infection.

2.9. The upgraded ventilation on 4B provided HEPA filtration to the rooms only, 5.8-8.9 ach, and 6.6-13.9 Pa of positive pressure to the corridor. The changes provided an improved level of protection for the patients on 4B. 4C continued to have the same provision of ventilation as was standard across other wards, 2.8-3.3 ach, no HEPA filtration (mobile HEPA units in use), chilled beams and neutral to +1 Pa positive pressure[7] [8]. Although mobile HEPA units were used both in 4C for adult haematology

[8] Bundle 21, Volume 1, document 7, page 468.

oncology patients and in 2A / 6A for the paediatric haematology oncology patients, these have been found to have an insignificant effect on the incidence of IA in neutropenic haematology oncology patients[9]. Concentrations of airborne aspergillus spores even below 1 colony forming unit per cubic metre (cfu/m^3) have been shown to be sufficient to cause outbreaks in immunocompromised patients[10].

2.10. The risk of acquiring invasive aspergillosis in both adult and paediatric patients depends on their underlying disease and treatment (BMT, solid organ transplant, chemotherapy). In children, the highest risk is for those who undergo bone marrow transplant (BMT), with the greatest risk in those where the underlying disease is acute myeloblastic anaemia[11]. In adults, the highest risk is in those undergoing BMT. However, determining the comparative risk is complex. Children are thought to be more at risk, however the incidence of IA in both adults and children is increasing over time[12].

2.11. The methodology applied to case selection adopted in Chapter 8 of the HAD Report seems reasonable in the absence of clinical notes to confirm the working diagnosis and response to treatment which would normally be used by clinicians caring for a patient in making their judgement as to likelihood of infection.

2.12. Section 8.1.3 of the HAD report, Figure 24 provides details the incidence, i.e. case numbers only of *Aspergillus. spp* in the paediatric haemato-oncology population. A rate per 100,000 bed days or similarly appropriate denominator should have been calculated by the authors to account for any changes in activity over the period 2005 – 2022 and highlight peaks in incidence rate.

2.13. The definitions cited at 8.1 of the HAD report are consensus definitions agreed by the European Organisation for Research and Treatment of Cancer (EORTC) and the Mycoses Study Group Education and Research Consortium (MSGERC)[13].

2.14. The definition of 'Proven' for *Aspergillus spp* involves recovery of the organism from a normally sterile site. In the guidance this specifically excludes broncho-alveolar lavage (BAL), paranasal or mastoid sinus cavity aspirate and urine. It could include a blood culture, however fungaemia due to *Aspergillus spp* is very rare and this is an unlikely source of a positive culture. Other sites where the organism might be recovered from include the cerebro-spinal fluid (CSF), heart, bones, soft tissues, kidney etc depending on the extent of the infection.

2.15. 'Probable' infection relies on host factors being present which confirm that he patient is immunocompromised, for example recent history of neutropenia, BMT at any time, haematological malignancy, corticosteroid use etc, combined with clinical features such as imaging evidence, plus mycological evidence, either culture for sites such as BAL or sinus aspiration OR antigen detection in plasma, serum, BAL or CSF. Beta D-glucan is not considered as mycological evidence here and the paediatric patients who had this as their only laboratory result on the data sheet provided did not have radiological evidence of fungal infection according to the imaging reports seen by us.

2.16. No blood cultures on the data set provided by NHS GGC grew *Aspergillus spp*. None of the cases identified in the Qualitative Report[14] were identified by blood cultures. PCR and aspergillus serology are done on blood samples and other clinical samples such as broncho-alveolar lavage.

2.17. The cases discussed in the earlier report from Dr Mumford and Ms Dempster[15] are identifiable from the data set provided. Incident Management Team (IMT) meetings were held for four cases of invasive aspergillosis.

2.17.1. IMT 05 August 2016[16] was held for two cases, one confirmed negative on admission screening and subsequently culture positive and PCR positive. The second case was positive on PCR one month later but was also known to have *candida tropicalis* infection. Both cases were identified as hospital acquired at the IMT. Issues with the pressure gradient, a torn ventilation duct, lack of HEPA filtration and ongoing construction on the QEUH campus were identified as risk factors. Actions from the IMT included environmental sampling, the introduction

[14] Bundle 21, volume 1, paper 3, page 96.
[15] Bundle 21, volume 1, document 3.
[16] Bundle 1, document 6, page 22.

of portable HEPA filters, anti-fungal prophylaxis to be given to at risk patients and enhanced cleaning.

2.17.2. IMT 07 March 2017[17] was held for an additional two cases and included an update on the patients from the previous IMT. The second case from the previous IMT was no longer classed as a case under EORTC classification. The other three patients are all classified as probable cases. The first of the two new cases was diagnosed on 23 Feb 2017 by PCR and the second diagnosed on 9 Feb 2017 by imaging only. No laboratory tests were done for the second case which is an additional case for 2017 not noted in the HAD report. At this IMT it was noted that the air quality conditions in the now closed Yorkhill Schiehallion unit were the same as those on 2A. The level of construction on the QEUH site was also noted. Actions from this meeting included giving antifungal prophylaxis to all patients, the wearing of masks when leaving the ward, air sampling and to undertake targeted water sampling. Concern was voiced that a new chemotherapy regime may be increasing the vulnerability of patients. A similar effect was being experienced in Lothian.

2.17.3. IMT 04/02/2019[18] was held for the ongoing cryptococcus cases. A patient was reported as *Aspergillus* PCR positive on CDU. Other investigations were normal (CT and ultrasound) and it was agreed that this patient was unlikely to be a case of aspergillosis. This patient was moved from 6A to CDU due to the mould issues identified.

2.17.4. IMT 01/08/2019[19] was held for the ongoing cryptococcus investigation. It was noted that air samples from patient's bathrooms on 6A taken on 15 July 2019 grew *Aspergillus spp*.

2.17.5. IMT 06/09/2019[20] was held for the ongoing gram-negative bacteraemia cases. It was noted that aspergillus had been isolated from air samples taken from the bathrooms on 6A. Mobile HEPA filtration was installed as a result.

[17] Bundle 1, document 9, page 35.
[18] Bundle 1, document 68, page 303.
[19] Bundle 1, document 75, page 334.
[20] Bundle 1, document 79, page 354.

2.18. In addition, Problem Assessment Group (PAG) meetings were held for further cases of aspergillus.

2.18.1. PAG 27/10/17[21] was held for a patient on 2A with *A. fumigatus* isolated from a broncho-alveolar lavage.

2.18.2. PAG 20/07/2018[22] was held for a case of aspergillosis on ward 2A classified as a probable infection.

2.19. It is unlikely that the decant of the ward from 2A/B to 6A and 4B would be an added risk factor for increased rates of invasive aspergillus infection. Patients would routinely leave the ward for investigations such as imaging so a move through the hospital would not be an unusual occurrence. For the BMT patients, they were moving to what was considered a safer environment on 4B so their risk would be expected to decrease as a result of the move. If surgical face masks were worn during the transfer, this would provide additional protection.

2.20. The paediatric cases from 2005 to 2015 and their location in Yorkhill by date and method of diagnosis are shown in the table below. One case on the data sheet was excluded as aged 19 on the date of diagnosis in 2014. The numbers of cases for 2010 differ from those in the HAD report in that the patient diagnosed on 30/12/2009 was tested again on 9/02/2010 during the same admission[23] having moved to ITU and therefore the second tests were classed as the same infection episode. This reduces the cases shown in Table 24 of the HAD report by one case in 2010 and one case in 2014.

[21] Bundle 2, document 25, page 66.
[22] Bundle 2, document 40, page 105.
[23] The HAD report case definition de-duplicated on the basis that 'where the same patient had multiple positive tests for the same admission episode, this was classified as one case'.

Table 4: Yorkhill *Aspergillus. spp* cases, 2005 – 2015

Location	Specimen type	Date collected	Investigation

2.21. Consultant names are shown in the data set for *Aspergillus spp*.[24] All shown are consultants in paediatric haematology or paediatric oncology except Dr Claudio Giacomozzi (consultant in paediatric endocrinology).

2.22. The data set for *Aspergillus spp*. cases in the paediatric population does not contain any admission data. However, it does contain CHI numbers which allow cross referencing to the data set provided for paediatric haemato-oncology admissions[25]. The following details are noted:

[24] Complete Aspergillus Positives, Adults 2013-2023 & Paeds 2005 – 2022 provided by NHS GGC - This document contains datasets relied upon by the HAD Expert group, and was provided to the Inquiry by NHS Greater Glasgow & Clyde on 18 February 2025. As it contains patient-identifiable data, it has not been included in a Hearing Bundle.
[25] RHC Haem onc adms by episode Subtype.xlsx provided by NHS GGC - This document contains datasets relied upon by the HAD Expert group, and was provided to the Inquiry by NHS Greater Glasgow & Clyde on 18 February 2025. As it contains patient-identifiable data, it has not been included in a Hearing Bundle.

- The 2015 case was not admitted to Yorkhill at any time
- None of the 2018 cases were inpatients at the time of the move to 6A and subsequently diagnosed.
- One patient had been an inpatient during the decant from 2A to 6A in September 2018 but was not diagnosed until November 2019
- One 2019 case diagnosed on 1 Feb 2019 was moved to the CDU for part of their admission and was on the CDU at the time of diagnosis.
- One 2019 case was initially admitted to CDU on 21 Feb 2019 prior to being moved to 6A, however this was after the ward had moved back on 11 Feb 2019. The patient was on ward 6A when diagnosed on 27 Feb 2019.
- No other cases were involved in any of the ward moves.

2.23. From the data provided [26] [27] it can be derived that from 2008 to June 2015 at Yorkhill and June 2015 to 2022 at RHC, there were 53 paediatric haemato-oncology patients with positive tests for Aspergillus infection. A number of cases were excluded from further analysis, 2 excluded by their age (over 18 at the point of diagnosis), 4 excluded as they only appeared on the aspergillus positive spreadsheet and could not be cross referenced by CHI number on the admissions spreadsheet, and 5 excluded as they were only positive on a non-specific test (Beta D-glucan antigen). Of the remaining 43 patients, 8 had acute myeloblastic leukaemia (AML), 5 prior to the move to RHC and 3 post-move.

2.24. Based on the admission information, a total of 71 individual patients with AML had admissions to either Yorkhill (41) or RHC (30) during this period of time. By cross checking the CHI numbers the percentage of AML patients who were diagnosed with

[26] RHC Haem onc adms by episode Subtype.xlsx provided by NHS GGC - This document contains datasets relied upon by the HAD Expert group, and was provided to the Inquiry by NHS Greater Glasgow & Clyde on 18 February 2025. As it contains patient-identifiable data, it has not been included in a Hearing Bundle.
[27] Complete Aspergillus positives, Adults 2013-2023 & paeds 2005-2022.xlsx provided by NHS GGC - This document contains datasets relied upon by the HAD Expert group, and was provided to the Inquiry by NHS Greater Glasgow & Clyde on 18 February 2025. As it contains patient-identifiable data, it has not been included in a Hearing Bundle.

aspergillus at each hospital can be determined. A similar calculation was completed for patients with acute lymphoblastic leukaemia (ALL)

2.25. The expected rate of invasive aspergillus in paediatric AML patients is around 5.35% and 1.5% for ALL[28]. The table below shows the findings from the analysis of the data. It was not possible to determine with any confidence which patients had bone marrow transplant prior to their aspergillosis infection due to insufficient data.

Table 5: *Aspergillus. spp* cases by patient diagnosis

Diagnosis	Hospital	Number of cases	Number of Invasive Aspergillosis	Percentage of patients with IA
AML	**Yorkhill**	**41**	**5**	**12.1%**
	RHC	**30**	**3**	**10%**
ALL	**Yorkhill**	**227**	**6**	**2.6%**
	RHC	**174**	**18**	**10.3%**

2.26. Although the rates in each hospital are very similar for AML patients they are demonstrably higher than the expected rates. For ALL patients the rate of IA is much higher at RHC than that seen at Yorkhill and is higher than the AML rate. AML is accepted as having a higher risk for IA than ALL[29] [30].

2.27. A prospective survey of adults with haematological malignancies conducted from 2004 to 2009 [31] reported an overall IA incidence of 1.6 per 1,000 patient-days. Specifically, the incidence was 1.9 per 1,000 patient-days among acute myeloid leukaemia (AML) patients and 1.3 per 1,000 patient-days among acute lymphoblastic leukaemia (ALL) patients. It would be expected that a similar paediatric population would see a higher

rate of IA. It should also be noted that this study did not include patients who underwent bone marrow transplant which is known to increase the risk of infection.

2.28. Using the data on *Aspergillus, spp* cases as per NHS GGC's 'COMPLETE ASPERGILLUS POSITIVES, ADULTS 2013-2023 & PAEDS 2005 deduplicated for paeds- 2022' spreadsheet and admission data – NHS GGC's 'RHC Haem onc adms from 2008 with monthly figures 2024-01-09', the rate of *Aspergillus.spp* infections for the period 2008 – 2022 has been calculated, in line with admission data ranging from 2008 – 2022.

2.29. Table 1 provides the *Aspergillus. spp* incidence for wards which had at least one case over the period 2008 – 2022 and had corresponding bed days data. Two wards which had one case each, Clinic 1 OP RHC and CritCar Un4 HDU 31-40 QEUH, did not have corresponding bed days data, and were therefore excluded from the analysis. Table 2 provides the corresponding bed days for the wards in Table 1. Table 3 details *Aspergillus spp* incidence rate by incidence wards for the period 2008 – 2022, alongside individual trend graphs to aid an understanding of peak rates and when they were recorded.

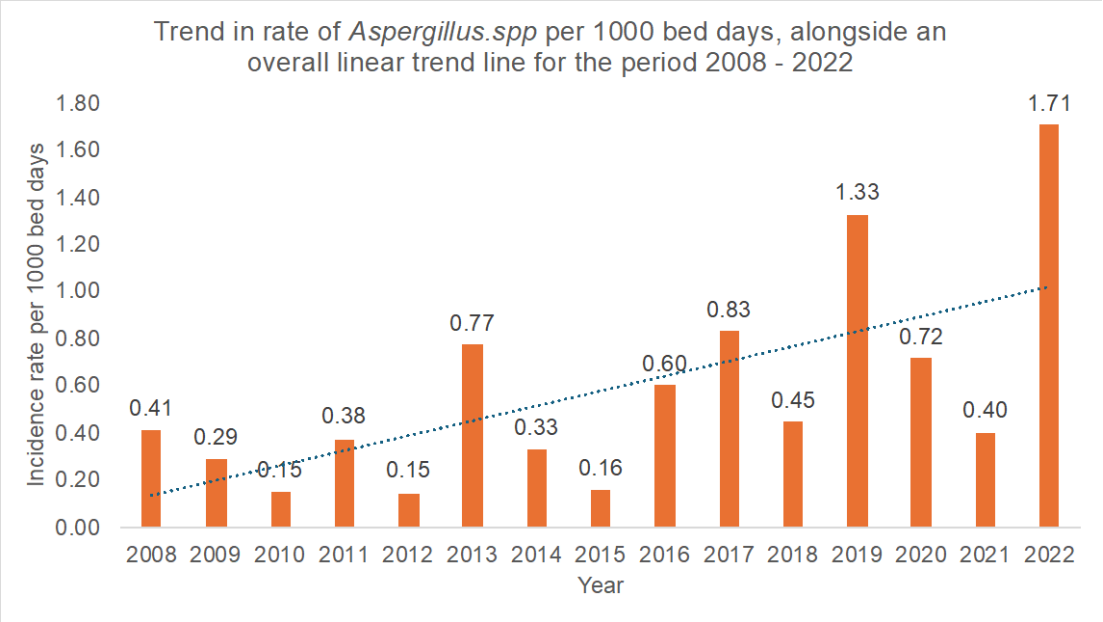
Annual incidence rates per 1000 bed days	0.41	0.29	0.15	0.38	0.15	0.77	0.33	0.16	0.60	0.83	0.45	1.33	0.72	0.40	1.71
Overall Yorkhill and RHC rates per 1000 bed days	0.342							0.756							

2.31 Utilising the overall *Aspergillus. spp* rate of infection at Yorkhill and RHC, seen in the bottom row of Table 3, 0.342 per 1000 bed days and 0.756 per 1000 bed days respectively, calculating the incidence rate ratio (IRR) and the corresponding 95% confidence intervals (CI), we get a IRR of 0.45 with a 95% CI (0.25-0.80), which notes that Yorkhill had an infection rate which was 55% lower as compared to the RHC, with the CIs not including 1, thereby making the difference statistically significant. In summary, the rate of *Aspergillus. spp* rate of infection at RHC was statistically significantly higher than the rate at Yorkhill.

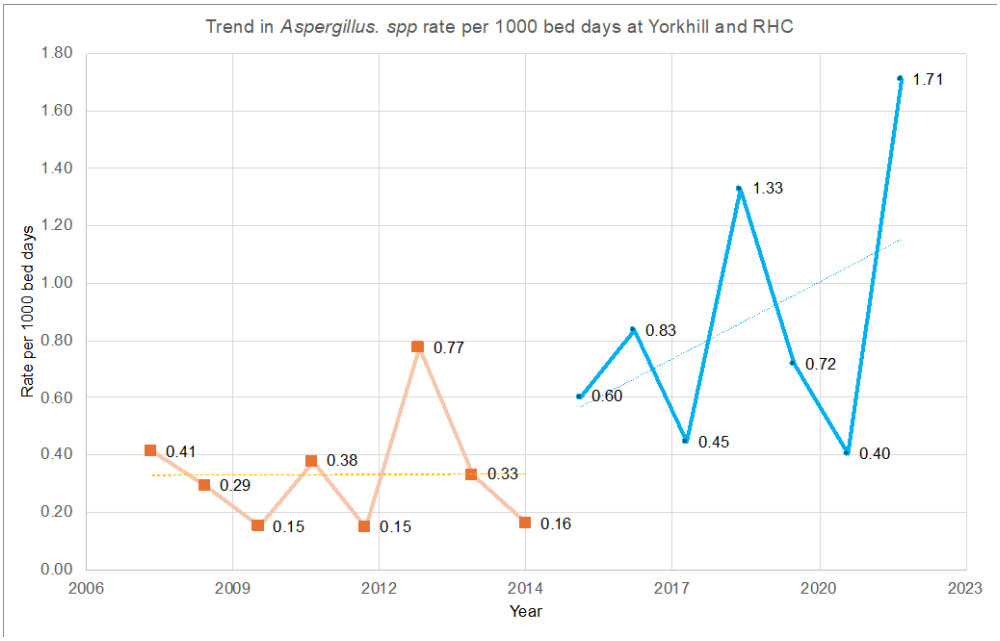
2.32 Figure 1 charts the annual incidence rates per 1000 bed days noted at the bottom of Table 3. We see an upward linear trend in infection rate from 2008 to 2022.

Figure 1: Trend in *Aspergillus spp* rate by year – paediatric haemato-oncology patients.



2.33 Figure 2 splits the trend chart into two separate scatter plots with individual trend lines, distinguishing between the trend in infection rate at Yorkhill, and thereafter at RHC, evidencing the difference in the rates of *Aspergillus* at Yorkhill and then at RHC – flatline trend at Yorkhill 2007 – 2014, followed by an upward linear trend for the period 2015 – 2022.

Figure 2: Yorkhill and RHC *Aspergillus spp* rates of infections with linear trend lines



2.34 In summary, the evidence discussed in sections 2.23 – 2.34 does not support the authors of the HAD report in their assertion that the there were 'low absolute numbers of cases' as whilst the numbers may appear relatively small, the rates are clearly higher than would be expected in a new facility such as RHC and overall significantly higher at RHC than Yorkhill.

Background and Objectives. The aim of this study was to evaluate the incidence and outcome of invasive fungal infections (IFI) in patients with hematologic malignancies.

Design and Methods. This was a retrospective cohort study of patients admitted between 1999 and 2003 to 18 hematology wards in Italy. Each participating center provided information on all patients with newly diagnosed hematologic malignancies admitted during the survery period and on all episodes of IFI experienced by these patients.

Results. The cohort was formed of 11,802 patients with hematologic malignacies: acute leukemia (myeloid 3012, lymphoid 1173), chronic leukemia (myeloid 596, lymphoid 1104), lymphoma (Hodgkin's 844, non-Hodgkin's 3457), or multiple myeloma (1616). There were 538 proven or probable IFI (4.6%); 373 (69%) occurred in patients with acute myeloid leukemia. Over half (346/538) were caused by molds (2.9%), in most cases *Aspergillus spp*. (310/346). The 192 yeast infections (1.6%) included 175 cases of candidemia. Overall and IFI-attributable mortality rates were 2% (209/11802) and 39% (209/538), respectively. The highest IFI-attributable mortality rates were associated with zygomycosis (64%) followed by fusariosis (53%), aspergillosis (42%), and candidemia (33%).

Interpretation and Conclusions. Patients with hematologic malignancies are currently at higher risk of IFI caused by molds than by yeasts, and the incidence of IFI is highest among patients with acute myeloid leukemia. *Aspergillus spp* are still the most common pathogens, followed by *Candida spp*. Other agents are rare. The attributable mortality rate for aspergillosis has dropped from 60-70% to approximately 40%. Candidemia-related mortality remains within the 30-40% range reported in literature although the incidence has decreased.

Key words: fungal infection, aspergillus, Candida, epidemiology, hematologic malignancies.

The percentage of patients who develop invasive fungal infections (IFI) has increased dramatically in recent decades. Most of these infections occur in patients with hematologic malignancies.[1-3] This increase is attributed to host defense impairment due to intensive cytotoxic chemotherapies, hematopoietic stem cell transplantation, ablative radiation therapy, use of corticosteroids, cyclosporine, and new immunosuppressive agents.[3-8] *Candida spp.* have been the main cause of IFI, but recent autopsy and epidemiological findings indicate that an increasing number of infections are being caused by molds.[9-11] Most are attributed to *Aspergillus spp.*, and such infections have become a prime cause of death in patients with hematologic malignancies. During the last 20 years, other opportunistic fungal pathogens, such as *Fusarium spp.* and *Zygomycetes*, have also emorged[12-15] whereas infections caused by other fungi are still rare.[16-19] The true incidence of IFI among patients with hematologic malignancies remains obscure since data in the literature are based largely on reports from single institutions or analyses of selected subgroups of patients (e.g., those with acute leukemia or following stem cell transplantation).[7-8] The aim of the present study was to investigate current incidence and mortality rates for IFI in patients with hematologic malignancies in Italy.

Design and Methods

This retrospective cohort study was conducted in hematology wards of tertiary care centers or university hospitals located throughout Italy, between January 1999 and December 2003. Enrollment was limited to adult patients (aged over 16 years) with newly diagnosed acute myeloid or lymphoid leukemia (AML and ALL, respectively), chronic myeloid or lymphoid leukemia (CML and CLL, respectively), Hodgkin's or non-Hodgkin's lymphoma (HL and NHL, respectively), or multiple myeloma. Seven centers contributed data only on patients with acute leukemia. Patients with other types of hematologic malignancies (e.g., myelodysplastic syn-

dromes) or non-malignant hematologic disorders (hemolytic anemia; thrombocytopenias, aplastic anemia, etc) were excluded from this analysis, as were those patients undergoing autologous or allogeneic HSCT.

Each participating center completed a form which included information on all patients with newly diagnosed hematologic malignancies admitted during the survey period and on all episodes of IFI experienced by these patients. The consensus criteria proposed by the EORTC/ MSG were used to define IFI,[20] and analysis was restricted to infections classifiable as *proven* or *probable*. For each episode, additional information was requested: date of first positive identification, fungal species isolated, microbiological and histological findings (*in vivo* and *post mortem*), and outcome (assessed 30 days after diagnosis). Multiple episodes in the same patient were counted as separate infections unless they were caused by the same fungal agent. Overall and attributable mortality rates were estimated in the study population. Information was specifically requested on the antifungal prophylaxis protocols used in each center. Because the majority of the participating centers were members of the GIMEMA-Infection, their diagnostic work-ups were almost identical. These diagnostic works-ups include collection of blood cultures at the onset of fever, nasal, pharyngeal, and rectal swabs, serological tests for IFI, and computed tomography (CT) scans on the 4-7th day of fever. Additional examinations (e.g., abdominal sonography, sinus or brain CT, skin biopsy, bronchoalveolar lavage, fundus examination) were performed as indicated.[3,21]

Antifungal prophylaxis was administered in 13 centers. The use of itraconazole for this purpose increased (six departments in 1999, nine in 2000, and ten in 2002) with parallel reductions in fluconazole use. The therapeutic protocols used by the centers during the

©Ferrata Storti Foundation

study period were also similar and reflected current IDSA guidelines.[22,23] Six institutions had participated in a previous study on filamentous fungi infections in acute leukemia patients during the period 1987-1998,[3] and IFI incidence and mortality rates registered in these centers during the two study periods were thus compared.

Statistical methods

Associations between variables were evaluated using the χ^2 and Fisher's exact tests. Regression analysis with ANOVA was used to determine trends in incidence, while the Cochran-Armitage trend test was used to evaluate mortality trends. p values <0.05 were considered statistically significant. Statistical analyses were performed using SAS version 8.02.

Results

During the study period, 11,802 patients with newly diagnosed hematology malignancies were admitted to the 18 participating centers for treatment other than hematopoietic stem cell transplantation. Their underlying malignancies are reported in Table 1. Five hundred and thirty-eight proven or probable IFI were documented. The overall incidence of IFI, 4.6%, remained stable (RR=1.1; 95%CI=0.86-1.42; p=0.452), and no significant shifts were observed in the incidence of infections caused by individual pathogen subgroups (Figure 1). Molds were held responsible for 346/538 episodes (2.9%) and yeasts for 192 infections (1.6%) (Table 2). The incidence of IFI in the different subsets of patients ranged from 0.5% among patients with

multiple myeloma to 12% in those with AML (Table 1). The overall mortality rate for fungal infections was 2% (209/11,802), and the IFI-attributable mortality rate (AMR) was 39% (209/538).

Molds infections

The majority of the mold infections (310/346; 90%) were caused by *Aspergillus spp.*, and these infections accounted for 58% of the IFI analyzed. Forty-one percent of the *Aspergillus* isolates were identified at the species level, and *A. fumigatus* was the main pathogen (68/310 episodes, 53%) (Table 3). Non-significant variations were observed in the annual incidence of IFI caused by the different *Aspergillus* species. An increasing trend was observed for *A. flavus* infections (5 cases in 1999 versus 14 cases in 2003), although this was also not statistically significant (RR 2.10, 95%CI 0.8-5.49; p=0.117). *Zygomycetes* and *Fusarium spp.* were responsible for 14 and 15 episodes (0.1%), respectively. The remaining six infections were due to *Scedosporium spp.*, *Acremonium spp.*, *Penicillium spp.*, or *Cladosporium spp.* Aspergillosis was most common in patients with acute leukemia (Table 3).

Almost half of these infections (43%; 111/259 evaluable cases) emerged during the first course of induction chemotherapy; 20 others (8%) occurred during consolidation chemotherapy in patients who were obviously in complete remission, and 73 (28%) emerged during a second or third course of induction chemotherapy for relapse of the hematopoietic malignancy. The remaining 55 patients (21%) were resistant to first-line chemotherapy and had received salvage therapy. The diagnosis of aspergillosis was classified as *probable* in 155 episodes (60%) and *proven* in the remaining 104 (40%). Only 22 of the proven diagnoses relied on autopsy findings.

Mortality rates ranged from about 2.6% in AML patients to 0.2% in those with multiple myeloma or Hodgkin's lymphoma. The AMR were 42% for aspergillosis, 64% for zygomycosis, and 53% for fusariosis (Table 3). Two of the three *Scedosporium* infections were fatal, as was one of the two infections caused by *Acremonium* and the single case due to *Cladosporium*. The patient suffering from a *Penicillium spp.* infection survived. The AMR for aspergillosis ranged from 38% in AML patients to 80% in those with CLL. An analysis of the relationship between the AMR for aspergillosis and the phase of the underlying malignancy (based on data for 259 assessable patients) revealed that 31 of the 112 deaths due to aspergillosis (28%) occurred during the induction cycle at the beginning of the treament of the hematologic malignancy. Over half of the patients who developed aspergillosis during a disease relapse (45/72; 63%) died, as opposed to only 25% (14/55) of those who were receiving salvage treatment and 20% (4/20) of patients whose infections occurred during complete remission.

Comparison of data for 1987 and 2003 on acute leukemia patients (available for six centers only) revealed increases in the absolute numbers of infections due to *Aspergillus spp.* and those caused by other molds although incidence rates remained stable for both types of infection (aspergillosis: RR 0.81, 95%CI

©Ferrata Storti Foundation

A53210128

0.50-1.30, *p*=0.38; other molds: RR 0.60, 95%CI 0.17-2.10). The AMR for aspergillosis dropped significantly (RR 1.90, 95%CI 1.17-3.09, *p*=0.019) from 60% (12 of 20 cases) in 1987 to 32% (24 of 76 cases) in 2003 (Figure 2), but there was no change in the rates for infections caused by other molds.

Yeasts infections

Most of the yeast infections were caused by *Candida spp.* (175 episodes, 33% of all IFI). The diagnosis was based on blood cultures in all cases. *Candida* non–albicans species were responsible for over half the episodes of candidemia (100/175; 57%) (Table 4). The remaining 17 yeast infections were caused by *Cryptococcus spp.* (8 cases), *Trichosporon spp.* (7 cases), and *Hansenula* and *Rhodotorula* (1 case each) (Table 2). Twelve of the 175 cases of candidemia (7%) were followed by chronic disseminated candidiasis. Eighty-three percent of the cases of candidiemia occurred in patients with acute leukemia (71% in AML, 12% in ALL). Overall, 3.5% (146/4185) of all patients with acute leukemia developed candidemia (Table 4). The incidence of *C. albicans* infections increased from 8% in 2001 to 19% in 2003 (RR 0.52; 95%CI 0.26-1.04; *p*=0.049).

The mortality rate was highest among AML patients (1.4%). There were no deaths due to candidemia among patients with CML, CLL, or HL. The AMR of patients with yeast infections was 33% for candidemia (57/175), 50% for cryptococcosis (4/8), and 29% for trichosporonosis (2/7). The patient who developed a *Hansenula* infection died while the one infected by *Rhodotorula* recovered from the infection. The AMR for candidemia ranged from 19% in NHL to 36% in ALL (Table 4). Species-specific AMR ranged from 6% for infections caused by *C. parapsilosis* to 54% for those due to *C. tropicalis.*

Discussion

In recent years numerous studies have been conducted to identify risk factors or prognostic factors for IFI, but only a few attempts have been made to assess the real incidence of these infections in patients with hematologic malignancies.[3-8] Data on the incidence of IFI in transplanted patients (one of the highest risk groups) are widely available, but they tell us very little about the situation in other patients being treated for hematologic malignancies.[7,8,24-26] The present study was not designed to establish an inventory of risk or prognostic factors or to evaluate the safety and efficacy of certain antifungal regimens. On the contrary, we terminated the investigation in 2003 to avoid a biased assessment of outcome related to the recent introduction of new and possibly more effective antifungal agents, such as voriconazole and caspofungin. Instead, our objectives were to determine the true incidence of IFI among patients with hematologic malignancies and to identity the predominant and emerging causes of these infections.

The reported incidence of proven or probable aspergillosis in patients with acute leukemias ranges from 6% to 12% in series that included both adults and children.[2-4,27,28] Our data confirm that molds were responsible for the majority of the IFI, and that aspergillosis is the most frequent complication in patients with hematologic malignancies. *A. fumigatus* is still the most frequently isolated species, while we did not observe the increase in infections due to *A. terreus* reported by other authors.[29]

Several studies have evaluated the incidence of candidemia, particularly in critical care settings.[30] Conversely there are far fewer reports on the frequency of candidemia among patients with hematologic malignancies.[21,30-34] Our data confirm that yeast infections are less common than mold infections in this population. *Candida spp.* were still the predominant yeast pathogens, but eight infections were caused by *Cryptococcus spp.*, which confirms our previous report on the possible occurrence in patients with hematologic malignancies of an infection typically associated with patients infected by human immunodeficiency virus.[19]

The influence of previous antifungal prophylaxis with fluconazole on the distribution of different *Candida spp.* has already been ascertained.[34,35] Patients who received fluconazole appeared more likely to acquire C. *non-albicans* infections than those who were not treated with it. As a result, *C. non-albicans spp.* became the leading cause of candidemia that developed during the administration of fluconazole prophylaxis. In our study, *C. non-albicans spp.* were responsible for 57% of all IFI episodes although the switch from fluconazole to itraconazole for prophylaxis seemed to be associated with a progressive increase in the percentage of bloodstream infections caused by *C. albicans.*

A previous study by the GIMEMA-Infection revealed that *Zygomycetes* were the second most frequent cause of mold infections in patients with hematologic malignancies.[14] During recent years, various studies have revealed apparent increases in the frequency of zygomycosis, particularly among patients who had received voriconazole for antifungal prophylaxis or treatment.[15,36] In our population, however, the incidence of *Zygomycetes* and *Fusarium* infections remained low; this finding might reflect our participating centers' limited use of voriconazole during the study period. On the other hand, in institutions where

©Ferrata Storti Foundation

these infections are on the rise,[8,15] the increase might be due to other factors, such as more aggressive chemotherapy resulting in more severe immunosuppression that renders patients vulnerable to infections by these intrinsically less virulent fungi. As noted, there were no significant changes in the chemotherapy regimens used by the participating centers during the study period, which suggests that immunosuppression might be a major factor in the etiology of these rare fungal infections. It is rather difficult to establish the AMR for aspergillosis or other mold infections since the underlying hematologic malignancies represent an important determinant of outcome. A meta-analysis of 50 studies on aspergillosis revealed mortality rates of approximately 60% in acute leukemia and lymphoma patients and up to 90% in allogeneic stem cell recipients.[37]

About 2% of the patients with hematologic malignancies in our survey died as a result of their IFI, and 39% of the infections had fatal outcomes. The lowest AMR was observed in patients with trichosporonosis. Zygomycosis was associated with the highest mortality, i.e. 64%, which is consistent with the figure reported by Gleissner *et al*.[38] Interestingly, invasive aspergillosis caused by *A. fumigatus* carried a higher AMR than those recorded for *A. niger* and *A. terreus* infections. In the six participating centers with data collected 17 years ago, the incidence of aspergillosis among patients with acute leukemia appeared unchanged, but there was a significant reduction in the aspergillosis-AMR.[3] The AMR for infections caused by *Candida spp.* was 33%, which is consistent with figures published between 1993 and 1998 (34-39%).[21,30,31] Unfortunately, the mortality rate has not improved in spite of the availability of improved diagnostic tools and therapeutic alternatives that are safer than conventional amphotericin B.

Despite the limitations related to its retrospective nature, our study provides important information. The fact that we were able to collect relevant information on all patients admitted to the participating hematology departments during the study period is a very strong point of this survey. Our data confirm that, among non-transplanted patients, those with AML are at highest risk of developing an IFI. About 8% of our AML patients developed mold infections (mainly aspergillosis) whereas 4% had yeast infections. The reduction in aspergillosis-related mortality is a striking finding, which can probably be attributed to improved diagnostics combined with more appropriate treatment strategies since the reduction apparently predated the widespread use of new-generation antifungals. Indeed, the recent introduction into clinical practice of drugs such us voriconazole and caspofungin, which are effective against both *Aspergillus spp.* and *Candida spp.*,[38-40] and posaconazole, which also displays promising activity against *Zygomycetes*,[41] could conceivably lead to additional improvements in the prognosis of patients with hematologic malignancies.

We did not observe any increase in the frequency of infections caused by rarer fungal pathogens, so there appears to be no reason to include routine coverage for these obscure agents in standard antifungal regimens. Thus far, experience has justified decisions to initiate specific treatment only when serious suspicion of a particular infection has arisen. This may, however, change in the near future when the use of new forms of treatment for hematologic malignancies becomes more widespread, since new categories of patients will emerge who can be classified as *high risk*. Purine analogs, for example, which produce profound and prolonged immunosuppression, will extend the risk of IFI to other patients (e.g. those CLL) even in the absence of neutropenia or steroid therapy. The rate of fungal complications in NHL can also be expected to increase with the growing use of monoclonal antibodies, rituximab or alemtuzumab. Likewise, the continuous intensification of chemotherapeutic regimens with increasingly shorter intervals between treatment cycles could significantly increase the incidence of IFI in NHL patients.[4] When this occurs, it will be time for a new epidemiological survey, and the present data can be used for historical comparison.

Abstract: Invasive aspergillosis (IA) is a disease of increasing importance in pediatrics due to growth of the immunocompromised populations at risk and improvements in long-term survival for many of these groups. While general principles of diagnosis and therapy apply similarly across the age spectrum, there are unique considerations for clinicians who care for children and adolescents with IA. This review will highlight important differences in the epidemiology, clinical manifestations, diagnosis, and therapy of pediatric IA.

Keywords: aspergillosis; pediatric; antifungal

1. Introduction

Invasive aspergillosis (IA) is one of the most common and serious infectious complications occurring in immunocompromised children. The incidence of IA appears to be increasing in children as it has in adults [1–5]. Significant advances have occurred in the diagnosis and therapy of IA in the last 15 years, and more recent studies indicate that clinical outcomes have improved during this time period [6,7]. However, treatment success and long-term survival after IA diagnosis remain suboptimal.

The evidence that informs care for children with IA is largely extrapolated from adult studies or based on small non-comparative pediatric studies, predominantly including children with malignancy and/or hematopoietic stem cell transplant (HSCT) recipients. This review will describe the known differences in epidemiology, clinical manifestations, diagnosis and therapy of pediatric IA, and will highlight areas of opportunity for further research.

2. Epidemiology

2.1. Incidence and Vulnerable Populations

The population-based incidence of IA in children is unknown and likely varies across healthcare settings and internationally. According to data from the Kids' Inpatient Database, a representative dataset of inpatient hospitalizations in the United States, the annual incidence of IA was 437 cases/100,000 (0.4%) hospitalized immunocompromised children in the year 2000 [8]. Among the groups with highest incidence of IA are children severely immunocompromised due to allogeneic HSCT (annual incidence 4.5%), therapy for hematologic malignancies, especially acute myelogenous leukemia (AML; annual incidence 4%), and those with primary immunodeficiencies, particularly chronic granulomatous disease (CGD) (annual incidence 6.5%) [8]. Other populations susceptible to IA include children undergoing solid organ transplantation (SOT) (annual incidence 0.3%), autologous HSCT (annual incidence 0.3%), chemotherapy for solid tumor malignancy (annual incidence 0.1%), and those with advanced acquired immune deficiency syndrome or certain non-malignant hematologic disorders such as bone marrow failure syndromes or hemophagocytic lymphohistiocytosis [6,8–11].

A53210128

Additionally, IA has been reported in children with systemic lupus erythematosus receiving high dose corticosteroids and other intensive immunosuppression, and has also rarely been reported in preterm neonates [12,13]. The major predisposing risk factors for IA are similar in adults and children (Table 1), except that risk factors within pediatric SOT recipients are poorly characterized due to limited studies.

Table 1. Identified Risk Factors for Invasive Aspergillosis in Children.

Risk Factor	Comments
Shared by Multiple Groups	
Prolonged and severe neutropenia [6,10,14]	
High dose corticosteroids [6,10,14]	
Other immunosuppression [6,10,14]	
Specific to Children with Malignancy	
Acute myelogenous leukemia (*vs.* other malignancies) [11,15]	Majority of episodes are diagnosed during intensive phases of therapy [15]
Specific to HSCT [a] Recipients	
Allogeneic transplant (*vs.* autologous) [8,10,11,16]	
Unrelated donor (*vs.* related donor) [10,11,16]	
Cord blood transplant (*vs.* other stem cell source) [16]	
Graft versus host disease [8,10,11,16]	
Specific to SOT [b] Recipients	
Lung transplantation (*vs.* other organ transplants) [4,8,10,11]	Other risk factors related to SOT are poorly characterized in children
Specific to Primary Immunodeficiencies	
Chronic granulomatous disease [17]	Higher risk in lower quartiles of superoxide production [17]
Hyper-IgE syndrome [18]	Risk associated with pneumatoceles following bacterial pneumonias [18]
Other severe defects of phagocyte and/or cellular immunity	e.g. Severe combined immunodeficiency, Wiskott-Aldrich syndrome [6,10,19]

[a] Hematopoietic stem cell transplant; [b] Solid organ transplant.

2.2. Causative Species

The major causative species of IA are similar in children and adults, with multicenter studies reporting *Aspergillus fumigatus* as the most commonly identified species, responsible for 53% of cases in the largest pediatric series, followed by *A. flavus* [6,10,20]. Possibly due to differences in local epidemiology, some single centers have reported a predominance of *A. flavus* causing invasive disease in children [14,21,22]. This may also be due changes in clinical presentation of pediatric IA over time, since *A. flavus* is associated with primary cutaneous disease which was a common clinical presentation in early case series [23]. Other commonly reported species in children include *A. niger* and *A. terreus* [6,10,22].

2.3. Clinical Outcomes

Although estimates of mortality for children with IA are difficult to compare due to variable timing of outcome assessment, there have been apparent improvements in mortality over the past 15 years. A systematic review from 1995 to 1999 reported a 68% case-fatality rate for IA in patients under 20 years old [24]. Among 66 pediatric patients with cancer and IA diagnosed from 1962 to 1996, 85% died within one year following IA diagnosis [14]. In the largest multi-center study of children with IA, 52.5%

of patients diagnosed between 2000 and 2005 died during therapy [10]. More recent pediatric cohort studies that have transitioned to earlier outcome assessments at 12 weeks following diagnosis report lower mortality rates of approximately 30% [5,6,25]. Long term survival of children with IA at a single oncology center improved from 12.5% during 1986–2000 to 58% during 2001–2010 [7,26]. A similar improvement in mortality has been observed in adults with IA [20]. Although this improvement is encouraging, 30% short-term mortality is suboptimal, and IA is associated with other adverse outcomes including prolonged hospitalization, increased hospitalization costs, and interruption in therapy for malignancy [5,8,15].

Risk for poor outcomes among children with IA is driven primarily by host immune status and burden of infection. Children who developed IA in the context of allogeneic HSCT in one study had 6-fold greater odds of death during therapy, compared to those with other underlying conditions [10]. Among children with IA in the context of malignancy, a longer duration of neutropenia following IA diagnosis is associated with increased mortality [27]. Disseminated *Aspergillus* infection has been associated with increased mortality, and non-pulmonary primary sites, such as cutaneous disease, have been associated with better outcomes [14]. Surgical treatment, though not consistently reported across studies, has been associated with improved survival [10].

3. Clinical Manifestations and Diagnosis

3.1. Clinical Manifestations

Similarly to adults, the lungs are the most commonly affected organ in pediatric IA [3,6,10,11,14,20,21,26,28–31]. In a review of 139 pediatric IA cases, 80% of children had pulmonary disease, 14% cutaneous, 13% sinus, 8% cerebral, and 4% tracheobronchitis [10]. Although earlier pediatric studies suggested that cutaneous IA is more common in children than adults [21], more recent studies report lower rates of 14%–20%; this is thought to be due in part to the increasing use of central over peripheral venous catheters in pediatric oncology patients [3,10,14]. Cutaneous IA can be primary from direct inoculation or secondary due to hematogenous dissemination from another site [32]. Several case reports describe primary cutaneous IA in preterm neonates [32–34].

Disseminated infection, defined as disease occurring in $\geqslant$2 sites, has been reported in 10.5% to 38% of children with IA and can be due to hematogenous or contiguous spread [3,7,10,14,21,28]. *Aspergillus* can be locally invasive, with spread from the lung to the pleura, chest wall, and heart, or from the sinus to the central nervous system (CNS). Although no known studies have been performed, some authors suggest screening children with pulmonary IA for CNS involvement given the high mortality, late appearance of symptoms, and impact on treatment [35]. Uncommon sites of IA include the eye [20], head and neck including otitis media and mastoiditis [26], thyroid [36], and gastrointestinal including liver [3,21,31], heart including endocarditis [37] and pericarditis [26], and bone [14,38].

Although some patients with IA present with isolated fever, the clinical manifestations vary depending on which organ system is involved [14]. Fever is common across all presentations. Patients with pulmonary IA can present with cough, dyspnea, hemoptysis/hemorrhage, hypoxia, and pleuritic symptoms [14,28,29]. Cutaneous IA manifestations can be nonspecific and include erythematous plaques, papules, nodules, pustules, blisters, ecchymosis, and eschar formation, often at sites of prior trauma including intravenous catheter and tape sites [14,21,32]. Facial pain, nasal congestion and discharge, visual changes, and headache have been reported in patients with sinus involvement [11,14,39]. CNS IA can present with changes in mental status, visual disturbances, seizures, and focal neurologic deficits [14].

Atypical presentations without fever also occur [11]. It is also reported that up to 33% of patients with CGD who develop IA are asymptomatic and only 20% are febrile [30]. Patients with CGD, especially those infected with *A. nidulans,* can develop local extension to the pleura, chest wall, and vertebrae [30]. Unlike neutropenic patients who can suffer from extensive fungal angioinvasion with hematogenous dissemination, IA may cause more locally invasive disease in CGD patients

due to an ongoing and ineffective neutrophilic inflammatory response with persistent hyphae [30]. Patients with hyper-IgE syndrome can present with fungal superinfection of pneumatoceles resulting in aspergillomas and subsequent risk for invasion to the lung parenchyma or disseminated disease [30].

3.2. Diagnostic Methods

Although prompt IA diagnosis is important given the high morbidity and mortality associated with this infection, existing modalities, including microbiology, pathology, fungal biomarkers, and radiology, have limitations. With currently available diagnostic methods, many children with suspected invasive mold infections do not have an identified pathogen, and are treated empirically [40]. The median time from onset of symptoms to diagnosis was 11 days (range 0–69 days) in one cohort, reflecting challenges in establishing a diagnosis with currently available methods [14]. Establishment of an optimal diagnostic approach is limited by few pediatric IA diagnostic studies, and inconsistent application of the European Organization for Research and Treatment of Cancer/Mycoses Study Group (EORTC/MSG) classifications of proven and probable IA across different studies [41,42]. Further studies in high-risk pediatric patients are needed to establish the ideal timing, frequency, and combination of tests that result in earlier diagnosis.

3.2.1. Culture and Histopathology

Although culture from a sterile site and histopathologic evidence of tissue invasion remain the gold standard for diagnosis of IA, invasive procedures are needed to obtain samples and the diagnostic yield is low. In a pediatric cohort of 193 HSCT patients with fever, respiratory distress, or radiographic findings concerning for an invasive fungal infection (IFI), only 40% of the 101 bronchoalveolar lavages (BAL) performed were diagnostic, all for an infectious etiology, though 94% of the 19 lung biopsies performed yielded a diagnosis [43]. Furthermore, *Aspergillus* is rarely recovered from blood cultures [3,10,20]. Although the yield is low, positive cultures from affected sites are important because they identify the organism and provide antifungal susceptibilities in this era of emerging resistance even to first-line therapy [44]. Given the low yield of cultures and the morbidity and mortality of invasive procedures, the diagnosis of IA in many patients relies on indirect diagnostics including fungal markers and radiology.

3.2.2. Galactomannan Antigen

Galactomannan is a polysaccharide in the *Aspergillus* cell wall that is released during fungal growth and can be measured using an enzyme immunoassay. The limited studies evaluating the use of serum galactomannan in children are heterogeneous; some of the studies are single center, focus on those with malignancies and HSCT, use different definitions for IA, antifungal prophylaxis regimens, and galactomannan positivity cut-offs [31,45–52]. Serum galactomannan for prospective screening of high risk patients and diagnosing IA has been studied mostly in immunocompromised adults [45,53–56]. The sensitivity and specificity of serum galactomannan for the diagnosis of IA in children is similar to adults (Table 2) [55,57]. Although earlier studies reported higher false positivity rates in children than adults [58], more recently, the false positive rate in a pediatric cohort was 5.2% [47]. Preterm neonates have a false positive galactomannan rate as high as 83% [59]. The cause of the high false positive rates in this population are not known but could be secondary to cross-reactivity with *Bifidobacterium spp.* that is a normal part of the neonatal GI flora and present in formula milk [59–61].

Table 2. Fungal Biomarkers for Diagnosis of Invasive Aspergillosis.

Biomarker Attribute	Galactomannan Antigen (%, 95% CI)	1,3-β-D-glucan (%, 95% CI)
Performance in Serum		
Sensitivity—Adult [a] [55,62]	78% (70%–85%)	62% (48%–73%)
Sensitivity—Pediatric [b] [55]	84% (66%–93%)	Unknown
Specificity—Adult [a] [55,62]	85% (78%–91%)	91% (83%–95%)
Specificity—Pediatric [b] [55]	88% (60%–97%)	Unknown—likely less than adult
Causes of False Positive Result	Piperacillin-tazobactam, other beta lactam antibiotics, Plasmalyte, *Fusarium* spp., *Histoplasma capsulatum*, *Penicillium* spp. [45,60,63,64]	Ampicillin-sulbactam, piperacillin-tazobactam, intravenous immunoglobulin, albumin, certain hemodialysis filters, bacteremia [65–67]
Performance in BAL [c] Fluid		
Sensitivity—Adult [d] [68]	86%	n/a [f]
Sensitivity—Pediatric [e] [69]	78%	n/a
Specificity—Adult [d] [68]	91%	n/a
Specificity—Pediatric [e] [69]	92%	n/a

[a] Positivity cut-off ⩾0.5 optical density index (ODI); [b] Subanalysis of 7 pediatric studies within a meta-analysis; 5 studies used a positivity cut-off ⩾0.5 ODI, 1 a cut-off ⩾1.5 ODI, one did not report cut-off; [c] BAL; bronchoalveolar lavage; [d] Positivity cut-off ⩾0.8 ODI; [e] Positivity cut-off ⩾0.98 ODI; [f] Not applicable, test not performed on BAL fluid.

Although galactomannan increases with higher infectious burdens [70], it can have reduced sensitivity early in the infection and if the patient is receiving anti-mold therapy [70]. Lower galactomannan sensitivity and specificity has been reported in SOT patients [53]. Possibly due to the lack of angioinvasion, serum galactomannan has reduced sensitivity in patients with CGD [30,71]. In addition to screening and diagnosis, serum galactomannan has been studied as a predictor of clinical response and survival for patients with IA [72–75].

Galactomannan testing can also be performed on BAL fluid, cerebrospinal fluid (CSF), and urine. BAL galactomannan may be a helpful adjunct for the early diagnosis of IA though cut-off values for positivity have not been firmly established [69,76]. In a retrospective pediatric cohort of immunocompromised and immunocompetent patients, a BAL galactomannan cut-off of ⩾0.98 optical density index (ODI) resulted in a sensitivity of proven or probable IA of 78% and specificity of 92% [69]. This BAL cutoff when combined with a serum galactomannan of ⩾0.5 ODI yielded a sensitivity of 89% and specificity of 90% for proven or probable IA [69].

Few studies have assessed the utility of CSF galactomannan for the diagnosis of CNS IA and specific cut-off values for positivity have not been established. A recent study of pediatric and adult patients with CNS IA reported a CSF galactomannan sensitivity of 88% and specificity of 96% when using a cut-off of ⩾1 ODI [77]. Urine galactomannan has also been studied in children though is associated with high false positive rates [47].

3.2.3. Beta-D-Glucan

1,3-β-D-glucan (BDG) is a nonspecific cell wall component of many fungal pathogens including *Aspergillus*. A number of adult studies have assessed the performance of BDG in the diagnosis of IFI and specifically IA (Table 2) [62,78,79]. BDG for the diagnosis of IFI in children is limited to a few case reports and studies [46,67,80–82]. It has been difficult to establish an optimal positive cut-off for children because they have higher baseline levels than adults [83] and levels can be affected by colonization with *Candida* spp., among other causes of false positivity (Table 2) [84].

3.2.4. Molecular Diagnostics

Aspergillus polymerase chain reaction (PCR) diagnostics are promising for pediatric IA. In a meta-analysis, the sensitivity of the blood *Aspergillus* PCR ranged from 84%–88% and the specificity

from 75% to 76% [85]; the sensitivity of the BAL *Aspergillus* PCR ranged from 77% to 80% and specificity from 94% to 95% [85]. Fewer studies have assessed *Aspergillus* serum and BAL PCR for screening and diagnosis of IA in children [46,86–90]. Another emerging area is serum and BAL molecular diagnostics for identification of the *Aspergillus* species and the most common mutations that confer azole resistance [91,92]. *Aspergillus* PCR from the CSF [93], pleural fluid, fresh [94] and formalin-fixed paraffin-embedded tissue [95] has also been studied for the diagnosis of IA.

3.2.5. Emerging Diagnostics

Given the limitations of established diagnostic methods, further investigation has attempted to identify additional non-invasive methods to diagnose IA in early stages. Different fungal organisms causing pulmonary infection are associated with characteristic profiles of volatile secondary metabolites that can be detected in exhaled breath [96]. A recent study showed 94% sensitivity (95% CI, 81%–98%) and 93% specificity (95% CI, 79%–98%) for a combination of exhaled metabolites to identify proven or probable pulmonary IA in a cohort of adults with suspected pulmonary IFI [96]. The lateral-flow device (LFD) is another promising test. This point of care test detects *Aspergillus* glycoprotein antigen in both serum and BAL has been studied in adult cohorts [97,98]. While these novel diagnostics shows promise, they have not yet been evaluated in children.

3.2.6. Radiology

Plain film and computer tomography (CT) are used for the diagnosis of pulmonary IA, though radiographic findings overlap with those of other IFI. CT has higher sensitivity and specificity for early diagnosis of pulmonary IA [99,100]. Radiographic findings that are described as characteristic in adult pulmonary IA are less common in children. These include the 'halo sign' that occurs earlier in the course of infection, as well as cavitation and the 'air crescent' sign that occur upon immune reconstitution [10,101–103].

More commonly, pediatric patients with pulmonary IA have nodules, masses, peripheral infiltrates, consolidations, and pleural effusions [10,29,101,102,104]. In a retrospective review of pediatric patients with proven or probable pulmonary IA, the most common findings on CT or plain radiograph were nodules (59%) [10]. Nodules were more commonly reported in older compared to younger children (63% ⩾13 year-olds *vs.* 72%, 6–12 year-olds *vs.* 39%, 0–5 year-olds). Cavities were reported in 25% of patients and a minority of patients had the halo (11%) and air crescent (2%) signs. The reasons for the lower rates of cavitation and the halo and air crescent signs in children are unknown but differences in pathophysiology, immune response, and timing of imaging are possible explanations [10,101–103].

Radiographic findings of sinus and CNS IA are nonspecific. Common radiographic findings of sinus IA are mucosal thickening (67%), opacification (48%), and air fluid levels (24%) [10]. Radiographic findings of CNS IA include hypoattenuating lesions on CT and T2 hyperintense lesions on MRI, single or multiple ring enhancing lesions, or dural enhancement abutting sinus disease [105,106].

4. Treatment

During the last 15 years, multiple new antifungals have become available for treatment of IA, expanding options within three different antifungal classes. However, licensing of new antifungals for use in children lags behind adult approvals, and there are important age-specific pharmacokinetic differences. Table 3 summarizes the antifungals with activity against *Aspergillus*, their current pediatric licensing status and evidence and/or consensus guidelines supporting their use in children with IA. Off-label use of medications is common in pediatrics and agents may be commonly used for age groups and/or indications that lack regulatory approval [6,10,107].

Table 3. Antifungals for Treatment of Invasive Aspergillosis: Pediatric Licensing and Evidence Supporting Use in Children.

Class/Agent (Formulation—IV [a]/PO [b])	Ages Currently Licensed [c]	Pediatric Evidence	Clinical Guidelines
Polyenes			
Amphotericin B deoxycholate (IV)	All	First available agent	
Liposomal amphotericin B (IV)	⩾1 month	PK [d], safety [108]. Observational cohort study [109]	IDSA [d]: alternative primary therapy (A-I), salvage therapy (A-II). ECIL-4 [e]: 1st line (B-I), 2nd line (B-II)
Amphotericin B lipid complex (IV)	All	Observational cohort study [110]. Non-comparative trial (salvage therapy) [111]	IDSA: alternative primary therapy (A-I), salvage therapy (A-II). ECIL-4: 1st line (B-II), 2nd line (B-II)
Amphotericin B colloidal dispersion (IV)	All (no longer commercially available)	Non-comparative trial (salvage therapy) [112]	IDSA: alternative primary therapy (A-I), salvage therapy (A-II)
Triazoles			
Voriconazole (IV, PO)	⩾12 years [g]	PK, safety [113–117]. Non-comparative trial (salvage therapy) [118]. RCT[f] including children >12 years [119]	IDSA: primary therapy (A-I). ECIL-4: first line (A-I), second line for voriconazole-naïve patients (A-I)
Itraconazole (PO)	⩾18 years	PK, safety [120]	IDSA: salvage therapy (B-II). ECIL-4: 2nd line (no grade)
Posaconazole (IV, PO)	PO: ⩾13 years. IV: ⩾18 years	PK, safety [121–124]. Retrospective cohort study [125]	IDSA: salvage therapy (B-II). ECIL-4: 2nd line (no grade)
Isavuconazole (IV, PO)	⩾18 years		
Echinocandins			
Caspofungin (IV)	⩾3 months	PK, safety [126–129]. Retrospective cohort study [130]. Non-comparative trial (primary & salvage therapy) [131]	IDSA: salvage therapy (B-II). ECIL-4: 2nd line (A-II)
Micafungin (IV)	⩾4 months	PK, safety [132–135]. Non-comparative trial (salvage therapy) including pediatric patients [136]	IDSA: salvage therapy (B-II). ECIL-4: 2nd line (no grade)
Anidulafungin (IV)	⩾18 years	PK, safety [137]	

[a] IV; intravenous; [b] PO; oral; [c] Licensing status by United States Food and Drug Administration; not all drugs are licensed for primary therapy of invasive aspergillosis; voriconazole, isavuconazole, and amphotericin B deoxycholate are licensed for primary therapy; lipid amphotericin B formulations and caspofungin are licensed for salvage therapy in patients who are intolerant or unresponsive to other agents; posaconazole is licensed only for prophylaxis in the United States, but is licensed for salvage therapy by the European Medications Agency. Micafungin and anidulafungin are not licensed for IA but have *in vitro* activity similar to caspofungin.; [d] PK; pharmacokinetics; [d] IDSA; Infectious Diseases Society of America; combined adult and pediatric guidelines, evidence levels based on adult data [138]; [e] ECIL-4; Fourth European Conference on Infections in Leukemia; pediatric-specific guidelines [139]; [f] RCT; randomized controlled trial; [g] Voriconazole is approved by the European Medications Agency for children age 2–11 years.

4.1. Amphotericin B Formulations (Polyenes)

Amphotericin B exerts fungicidal activity by binding to ergosterol and altering permeability of the fungal cell membrane. It is active against *Aspergillus* species except for *Aspergillus terreus* [140]. Conventional amphotericin B deoxycholate was the first available antifungal with activity against *Aspergillus*, and was for many years the only therapeutic option for IA. Its disadvantages are nephrotoxicity and infusion-related adverse effects. Lipid formulations of amphotericin B are better tolerated with less nephrotoxicity [111,112]. Though they differ from one another and from the parent drug in pharmacokinetics, there is no available evidence showing differences in efficacy between any of the formulations [141]. Differences in tissue distribution should be considered when treating infections at specific sites, such as the CNS, because tissue distribution varies between formulations [142]. Lipid amphotericin B formulations remain options for treatment of patients who are intolerant or unresponsive to voriconazole [138,139]. Their potential advantages include lack of drug interactions and broader spectrum of antifungal activity, for patients in whom IA is not confirmed and other fungi are suspected.

4.2. Triazoles

Triazoles inhibit biosynthesis of ergosterol in the fungal cell membrane, and are fungicidal against *Aspergillus* [143]. Itraconazole was the first available triazole with activity against *Aspergillus*, but its use for treatment of IA in children is limited due to unreliable bioavailability [120]. Voriconazole became the first line antifungal for IA based on a clinical trial demonstrating superior efficacy and tolerability of voriconazole compared to amphotericin B deoxycholate among patients 12 years and older with definite or probable IA [119,138]. Survival at 12 weeks of therapy was 70.8% in the voriconazole group compared to 57.9% in the amphotericin B group, and severe drug-related adverse events were less common with voriconazole [119]. Although there are no comparative trials in children with IA under 12 years, voriconazole is recommended as primary therapy for pediatric IA based on pediatric safety data and a non-comparative compassionate use study demonstrating complete or partial response to voriconazole in 45% of children with IA and other IFIs who were refractory to or intolerant of conventional therapy [118,139].

Substantially higher doses of voriconazole are needed in young children (<12 years) to achieve adequate drug exposure [113–117]. This is due to linear voriconazole elimination kinetics in children over a wider range of doses compared to adults and adolescents, who have non-linear elimination kinetics at usual doses [113]. Non-linear kinetics result in large increases in exposure with small dose increases, and can be observed in younger children receiving higher voriconazole doses. Additionally, the oral formulation of voriconazole has lower bioavailability in children (44%–65%) compared to adults (>90%); this may be due to more extensive intestinal first pass metabolism in children [114,115,144].

There is substantial inter-patient variability in voriconazole exposure, partly due to polymorphisms in CYP2C19, and this variability may be greater in children than in adults [113–116,145]. Therapeutic drug monitoring (TDM) of voriconazole is recommended with a target trough range of 1.0–5.0 mg/L [139]. Correlation of treatment failure with trough levels <1.0 mg/L has been shown in young children as well as adolescents and adults [146–149]. A recent meta-analysis showed clear associations between therapeutic voriconazole levels and treatment success, and between supra-therapeutic levels and toxicity [150]. Voriconazole TDM has demonstrated benefits in children and adults, by reducing avoidable discontinuation of voriconazole and increasing likelihood of a successful response to therapy [149,151].

The most common adverse events associated with voriconazole include hepatic abnormalities, visual changes, and rash, often attributable to photosensitization [113,115,116,118,119]. Less common but serious toxicities include neurotoxicity (confusion and/or hallucination) and prolongation of the QT interval with associated arrhythmias [116,119,152]. Children receiving voriconazole prophylaxis have developed severe phototoxic skin reactions; the mechanism of this reaction is unknown [153,154].

Long term voriconazole exposure has been associated with acceleration of chronic phototoxicity and increased risk for skin cancers in immunocompromised patients [155]. Long term use of voriconazole has also been associated with elevated serum fluoride levels, with associated skeletal fluorosis and painful osteitis [156,157]. Voriconazole is an inhibitor of CYP3A4, CYP2C19 and CYP2C9 and is therefore subject to multiple drug interactions.

Newer triazole agents, posaconazole and isavuconazole, may serve a greater role for therapy of pediatric IA in the future, but their use is currently limited by a paucity of pediatric data. Although there are no published clinical trials comparing efficacy of posaconazole against voriconazole for IA, it is recommended as an option for salvage therapy in patients ⩾13 years of age on the basis of an externally controlled clinical trial in adults and adolescents with IA who were refractory to or intolerant of standard therapy [138,139,158]. It is available in oral suspension, oral tablet and IV formulations. Bioavailability of the oral suspension is unreliable and dependent on food intake [159]. This formulation has undergone limited evaluation in children, with observational studies characterizing pharmacokinetics, safety and efficacy in prophylaxis of invasive mycoses [122–124]. Preliminary results of a more extensive pediatric pharmacokinetic study indicate that target concentration attainment with the posaconazole oral suspension is poor, especially in young children [160]. The safety profile of posaconazole appears favorable, and further pharmacokinetic studies are in progress to establish optimal dosing of posaconazole in children, especially with the newer formulations, which are dosed differently than the suspension.

Isavuconazole, the most recently developed triazole, was found to be non-inferior to voriconazole for IA in adults [161]. Its potential advantages over voriconazole include broader spectrum of activity (including activity against mucormycosis), reliable pharmacokinetics, and a favorable safety profile [162]. However, there are currently no data to establish its use in children.

4.3. Echinocandins

Echinocandins inhibit synthesis of 1,3-β-D-glucan in the fungal cell wall and are fungistatic against *Aspergillus*. Caspofungin and micafungin are the best evaluated in children and have a favorable safety profile across multiple pediatric age groups [126,127,131–133]. Caspofungin and micafungin have been evaluated in non-comparative studies for treatment of patients with IA, including small numbers of children, mostly as salvage therapy for patients refractory to or intolerant of other agents [131,136]. Because of their fungistatic activity and lack of robust data for use as primary therapy, the echinocandins are recommended as second line therapy for IA in patients who are intolerant to or refractory to first line agents [138,139].

4.4. Combination Antifungal Therapy

Though not routinely recommended for primary IA therapy, use of combination antifungal therapy is common in both children and adults. Two recent multicenter pediatric cohort studies reported use of combination therapy in 46% and 54% of children with IA [6,10]. In one of these studies, children who received combination therapy were more likely to experience adverse events compared to those treated with monotherapy [6]. A recent clinical trial comparing voriconazole monotherapy to voriconazole and anidulafungin combination therapy for primary therapy of adults with IA showed a trend toward lower mortality with combination therapy (19.3% *vs.* 27.5% at 6 weeks; $p = 0.087$) but was underpowered for this primary endpoint [163]. The implications for management of children with IA are uncertain; recent European guidelines propose combination therapy as an option for pediatric IA, but with weak recommendations [139]. Combination therapy deserves further evaluation for safety and efficacy in children, given the major differences in antifungal pharmacology in children and adults.

4.5. Adjunctive Therapies

Colony stimulating factors and other therapies intended to reverse predisposing conditions and augment the immune response to *Aspergillus* are commonly given to children with IA [6,10,22].

As in adults, their specific contribution to clinical outcomes is uncertain, but an effect is biologically plausible due to the importance of immune reconstitution in recovery from IA. Adoptive transfer of donor-derived pathogen-specific T cells, a strategy used successfully against viral infections in HSCT recipients, is a promising option for IA therapy and is currently in early clinical development [164,165]. Many children with IA undergo surgery for disease control, with indications similar to those in adults; one pediatric study identified an association between surgical treatment and improved survival [10,22].

5. Conclusions

Important differences in diagnosis and treatment exist between adult and pediatric IA. Although there have been advances in the diagnosis, treatment, and outcomes of pediatric IA, challenges remain. Better characterization of IA in pediatric populations, such as those with SOT and primary immunodeficiencies, is needed. The greatest gains are likely to come from optimizing the diagnostic approach to IA, including incorporation of risk stratification, and establishing algorithms to determine which patients may be best evaluated through non-invasive tests, *versus* those that could benefit from invasive testing. Additional evaluation of combination antifungal therapy and pediatric studies of new antifungals will facilitate broader prophylaxis and treatment options in at-risk children. Novel treatment strategies such as immunotherapy may also play a role in the treatment of pediatric IA. Taken together, improved diagnostic and treatment modalities will enable earlier diagnosis and improve mortality for children with IA.

(See the Editorial Commentary by Rogers on pages 1377–8.)

Background. Invasive fungal diseases (IFDs) remain important causes of morbidity and mortality. The consensus definitions of the Infectious Diseases Group of the European Organization for Research and Treatment of Cancer and the Mycoses Study Group have been of immense value to researchers who conduct clinical trials of antifungals, assess diagnostic tests, and undertake epidemiologic studies. However, their utility has not extended beyond patients with cancer or recipients of stem cell or solid organ transplants. With newer diagnostic techniques available, it was clear that an update of these definitions was essential.

Methods. To achieve this, 10 working groups looked closely at imaging, laboratory diagnosis, and special populations at risk of IFD. A final version of the manuscript was agreed upon after the groups' findings were presented at a scientific symposium and after a 3-month period for public comment. There were several rounds of discussion before a final version of the manuscript was approved.

Results. There is no change in the classifications of "proven," "probable," and "possible" IFD, although the definition of "probable" has been expanded and the scope of the category "possible" has been diminished. The category of proven IFD can apply to any patient, regardless of whether the patient is immunocompromised. The probable and possible categories are proposed for immunocompromised patients only, except for endemic mycoses.

Conclusions. These updated definitions of IFDs should prove applicable in clinical, diagnostic, and epidemiologic research of a broader range of patients at high-risk.

Keywords. consensus; definitions; invasive fungal diseases; diagnosis; research.

The European Organization for Research and Treatment of Cancer and the Mycoses Study Group Education and Research Consortium (EORTC/MSGERC) consensus definitions of invasive fungal diseases (IFDs) were last updated in 2008 [1]. These definitions achieved their original aim in fostering communication and enabling comparison of study findings among those engaged in research into IFD of patients with cancer and recipients of hematopoietic stem cell transplants (HSCTs) or solid organ transplants (SOTs) [2, 3]. Moreover, they have been adopted by regulatory agencies for evaluation of antifungals and have been used to evaluate diagnostic tests and to conduct epidemiologic studies [4–7]. Importantly, these definitions are specifically intended for these purposes only and not to direct or guide patient care.

The 2008 definitions had their shortcomings, including the facts that the definitions were unsuitable for patients with IFD in the setting of intensive care units (ICUs) or in pediatrics, data were insufficient to establish appropriate thresholds for detecting *Aspergillus* galactomannan (GM), and there was uncertainty about the role of (1,3)-beta-D glucan (BDG). Furthermore, nucleic acid amplification including polymerase chain reaction (PCR)–based tests were excluded because of lack of standardization and validation. Definitions for cryptococcosis and endemic mycoses also needed clarification, and there were no definitions for pneumocystosis.

PROCESS

Volunteers from the EORTC Infectious Diseases Group and the MSGERC were assigned according to their expertise to 10 working groups, each charged with appraising a particular topic (see list of contributors in the Notes section). The chairs of the EORTC and MSG (J. P. D. and P. G. P.) selected leaders for each working group, and S. C. served as executive secretary. After completing the first round of working group assignments, leaders presented each group's initial deliberations and recommendations at the 7th Trends in Medical Mycology Conference in Lisbon, Portugal, October 2015. A slide set was made available until 31 December 2015 online at www.e-materials.com/timm2015/invitation/Member and, on request, for public comment. After several iterations, the final draft of the manuscript was circulated to all members for their approval.

REVISIONS AND UPDATES

Special Populations

Pediatrics and patients in the ICU were considered as special populations. However, group 10 (IFD definitions in ICU patients) was unable to generate recommendations that preserved a level of certainty consistent with the existing definitions except for proven IFD (Table 1) and therefore undertook a separate initiative [8].

Pediatrics: Group 1

There was a clear need to establish pediatric-specific IFD definitions as the clinical and radiologic manifestations of IFD in children, that is, patients aged <18 years, may differ significantly from those in adults. Most importantly, the incidence of invasive candidiasis (IC) is higher in neonates than in other age groups [9–11]. The degree of prematurity, based on gestational age and birth weight, is a unique risk factor among neonates; hematogenous *Candida* meningoencephalitis affects premature infants disproportionately and has serious consequences including seizures, intraventricular hemorrhage, and developmental delay [12, 13]. With respect to IC due to non-*Candida albicans* species, *Candida glabrata* is the most common pathogen in adults, whereas *Candida parapsilosis* predominates in children and neonates [14]. Risk factors for invasive mold diseases include innate immunologic defects, with *Aspergillus nidulans* being associated with chronic granulomatous disease, while *Aspergillus fumigatus* is seen more often in other patient groups [15].

Neonates with IC often present with subtle clinical findings, and cultures are frequently sterile, including cerebrospinal fluid (CSF) samples from neonates with candidemia and concurrent *Candida* meningitis. Diagnosis is often inferred from insensitive

A53210128

Table 1. Criteria for Proven Invasive Fungal Disease

Fungus	Microscopic Analysis: Sterile Material	Culture: Sterile Material	Blood	Serology	Tissue Nucleic Acid Diagnosis
Molds[a]	Histopathologic, cytopathologic, or direct microscopic examination[b] of a specimen obtained by needle aspiration or biopsy in which hyphae or melanized yeast-like forms are seen accompanied by evidence of associated tissue damage	Recovery of a hyaline or pigmented mold by culture of a specimen obtained by a sterile procedure from a normally sterile and clinically or radiologically abnormal site consistent with an infectious disease process, excluding BAL fluid, a paranasal or mastoid sinus cavity specimen, and urine	Blood culture that yields a mold[c] (eg, *Fusarium* species) in the context of a compatible infectious disease process	Not applicable	Amplification of fungal DNA by PCR combined with DNA sequencing when molds are seen in formalin-fixed paraffin-embedded tissue
Yeasts[a]	Histopathologic, cytopathologic, or direct microscopic examination of a specimen obtained by needle aspiration or biopsy from a normally sterile site (other than mucous membranes) showing yeast cells, for example, *Cryptococcus* species indicating encapsulated budding yeasts or *Candida* species showing pseudohyphae or true hyphae[d]	Recovery of a yeast by culture of a sample obtained by a sterile procedure (including a freshly placed [<24 hours ago] drain) from a normally sterile site showing a clinical or radiological abnormality consistent with an infectious disease process	Blood culture that yields yeast (eg, *Cryptococcus* or *Candida* species) or yeast-like fungi (eg, *Trichosporon* species)	Cryptococcal antigen in cerebrospinal fluid or blood confirms cryptococcosis	Amplification of fungal DNA by PCR combined with DNA sequencing when yeasts are seen in formalin-fixed paraffin-embedded tissue
Pneumocystis	Detection of the organism microscopically in tissue, BAL fluid, expectorated sputum using conventional or immunofluorescence staining	Not applicable	Not applicable	Not applicable	Not applicable
Endemic mycoses	Histopathology or direct microscopy of specimens obtained from an affected site showing the distinctive form of the fungus	Recovery by culture of the fungus from specimens from an affected site	Blood culture that yields the fungus	Not applicable	Not applicable

Abbreviations: BAL, bronchoalveolar lavage; PCR, polymerase chain reaction.

[a]If culture is available, append the identification at the genus or species level from the culture results.

[b]Tissue and cells submitted for histopathologic or cytopathologic studies should be stained using Grocott-Gomori methenamine silver stain or periodic acid Schiff stain to facilitate inspection of fungal structures. Whenever possible, wet mounts of specimens from foci related to invasive fungal disease should be stained with a fluorescent dye (eg, calcofluor or blankophor).

[c]Recovery of *Aspergillus* species from blood cultures rarely indicates endovascular disease and almost always represents contamination.

[d]*Trichosporon* and yeast-like *Geotrichum* species and *Blastoschizomyces capitatus* may also form pseudohyphae or true hyphae.

and nonspecific surrogate tests, such as increased C-reactive protein or thrombocytopenia, which has been shown to be a predictor of candidemia in infants [16, 17]. In neonates, a positive urine culture has a significance similar to that of a positive blood culture as an indicator of IC [16]. Radiographic findings are less specific in children than those reported in adults [18]. Chest computerized tomography (CT) scans in children with proven invasive pulmonary aspergillosis (IPA) commonly show nonspecific changes and not the halo sign, air crescent formation, or cavitation seen in adults [19].

There are also far fewer data to support the clinical use of nonculture-based fungal biomarkers in neonates and children [20], although the GM assay performs similarly in children and adults when used as an adjunctive tool to diagnose invasive aspergillosis (IA) [20, 21]. Likewise, there are few data regarding the use of BDG, *Candida* mannan antigen, and anti-mannan antibody biomarkers in pediatrics [22]. Recent data support the utility of BDG in CSF for the diagnosis and therapeutic monitoring of children with *Candida* meningoencephalitis [23], but the data are sparse regarding the utility of PCR assays and the T2Candida assay for diagnosis [24].

Diagnostic Tests and Imaging

In the previous definitions [1], indirect tests for diagnosing IFD were only included if there was sufficient evidence that they had been standardized and validated. Moreover, commercial tests were included only if criteria for interpretation had been provided. Hence, while tests for GM and BDG were incorporated, tests for detecting fungal nucleic acid were not [1]. Furthermore, there was no agreement about appropriate thresholds, so the manufacturers' analytical thresholds were adopted. The evidence for using GM to diagnose IA has grown considerably since then, and testing for BDG has been extended to a wide range of patients. With respect to *Aspergillus* PCR, the International Society of Human and Animal Mycology working group Fungal PCR Initiative (FPCRI; www.fpcri.eu) has made significant progress toward setting a standard for the technique after vigorous validation [25].

Imaging: Group 2

There is mounting evidence that the radiologic manifestations of invasive mold disease are more varied than previously recognized. The increased sensitivity of newer imaging techniques enables a greater number and depth of abnormalities to be seen in different anatomic regions. Recent data relating to the role of imaging in the diagnosis of IPA and pulmonary mucormycosis (PM) in adults suggest that a high-resolution CT scan (HRCT) is preferred to chest radiographs, magnetic resonance imaging (MRI), and positron emission tomography (PET), likely reflecting that HRCT is more sensitive than a chest

A53210128

radiograph, more widely available than MRI, and the experience with HRCT is much larger than with PET [26, 27]. Among patients with IPA, nodules or infiltrates with a halo sign remain useful among neutropenic patients but they are nonspecific for IPA in other groups [28]. Furthermore, the air crescent sign is a late and nonspecific sign. Among nonneutropenic patients, multiple pulmonary nodules and various nonspecific findings including bronchopneumonia, consolidation, cavitation, pleural effusions, ground glass opacities, tree-in-bud opacities, and atelectasis are found [29]. Overall, consolidation is the most frequent presentation of PM, followed by mass lesions, nodules, and cavitation [30]. Multiple nodules (more than10) and pleural effusions appear to be more frequent in PM than in IPA [31]. Moreover, the reverse halo sign is more specific for PM than IPA, although the differential diagnosis also includes other diseases including tuberculosis [32].

Aspergillus Galactomannan: Group 3

We evaluated *Aspergillus* galactomannan for both adults and children and specific patient groups and its utility and validity for different clinical specimens. We adopted different thresholds for different specimens rather than for different host groups [33–35] (Table 2). These differ from those recommended by the manufacturer of the GM assay (Platelia *Aspergillus* (Bio-Rad, CA), validated only for use in serum and bronchoalveolar lavage (BAL) fluid; however, detection of GM in plasma and CSF should support a diagnosis of IA [36, 37]. Exposure to mold-active antifungals compromises the utility of the GM test for IA [38] by reducing its sensitivity [39]. Therefore, caution should be exercised when GM is found to be absent from serum or plasma in patients receiving mold-active antifungals. There was consensus that similar GM thresholds are appropriate for adults and children.

BDG and T2Candida Assays: Group 4

The group considers detection of BDG to be suitable for diagnosing probable IFD in the appropriate clinical setting. This includes patients with hematologic malignancies with and without neutropenia, neutropenia following HSCT, and certain patients in the ICU who are at higher risk (>10%) for IC as a result of gastrointestinal surgery with recurrent anastomotic leaks, perforations of the upper gastrointestinal tract, or necrotizing pancreatitis when there is clinical suspicion of infection [40, 41]. A single threshold (>80 pg/mL) using the Fungitell test (Associates of Cape Cod, Falmouth, MA) is recommended; there is insufficient evidence to include assays produced by other manufacturers [42]. Confidence for true positive results increases with repeated positive tests and for values that greatly exceed the positivity threshold [43]. There may be variability in positive predictive value (PPV) and negative predictive value (NPV) based on patient population, but a single threshold is favored at this time. The group did not support the use of

Table 2. Probable Invasive Pulmonary Mold Diseases

Host factors
Recent history of neutropenia (<0.5 × 10^9 neutrophils/L [<500 neutrophils/mm^3] for >10 days) temporally related to the onset of invasive fungal disease
Hematologic malignancy[a]
Receipt of an allogeneic stem cell transplant
Receipt of a solid organ transplant
Prolonged use of corticosteroids (excluding among patients with allergic bronchopulmonary aspergillosis) at a therapeutic dose of ≥0.3 mg/kg corticosteroids for ≥3 weeks in the past 60 days
Treatment with other recognized T-cell immunosuppressants, such as calcineurin inhibitors, tumor necrosis factor-a blockers, lymphocyte-specific monoclonal antibodies, immunosuppressive nucleoside analogues during the past 90 days
Treatment with recognized B-cell immunosuppressants, such as Bruton's tyrosine kinase inhibitors, eg, ibrutinib
Inherited severe immunodeficiency (such as chronic granulomatous disease, STAT 3 deficiency, or severe combined immunodeficiency)
Acute graft-versus-host disease grade III or IV involving the gut, lungs, or liver that is refractory to first-line treatment with steroids
Clinical features
Pulmonary aspergillosis
The presence of 1 of the following 4 patterns on CT:
Dense, well-circumscribed lesions(s) with or without a halo sign
Air crescent sign
Cavity
Wedge-shaped and segmental or lobar consolidation
Other pulmonary mold diseases
As for pulmonary aspergillosis but also including a reverse halo sign
Tracheobronchitis
Tracheobronchial ulceration, nodule, pseudomembrane, plaque, or eschar seen on bronchoscopic analysis
Sino-nasal diseases
Acute localized pain (including pain radiating to the eye)
Nasal ulcer with black eschar
Extension from the paranasal sinus across bony barriers, including into the orbit
Central nervous system infection
1 of the following 2 signs:
Focal lesions on imaging
Meningeal enhancement on magnetic resonance imaging or CT
Mycological evidence
Any mold, for example, *Aspergillus*, *Fusarium*, *Scedosporium* species or Mucorales recovered by culture from sputum, BAL, bronchial brush, or aspirate
Microscopical detection of fungal elements in sputum, BAL, bronchial brush, or aspirate indicating a mold
Tracheobronchitis
Aspergillus recovered by culture of BAL or bronchial brush
Microscopic detection of fungal elements in BAL or bronchial brush indicating a mold
Sino-nasal diseases
Mold recovered by culture of sinus aspirate samples
Microscopic detection of fungal elements in sinus aspirate samples indicating a mold
Aspergillosis only
Galactomannan antigen
Antigen detected in plasma, serum, BAL, or CSF
Any 1 of the following:
Single serum or plasma: ≥1.0
BAL fluid: ≥1.0
Single serum or plasma: ≥0.7 and BAL fluid ≥0.8

A53210128

Table 2. Continued

CSF: ≥1.0
Aspergillus PCR
Any 1 of the following:
Plasma, serum, or whole blood 2 or more consecutive PCR tests positive
BAL fluid 2 or more duplicate PCR tests positive
At least 1 PCR test positive in plasma, serum, or whole blood and 1 PCR test positive in BAL fluid
Aspergillus species recovered by culture from sputum, BAL, bronchial brush, or aspirate

Probable invasive fungal diseases (IFD) requires the presence of at least 1 host factor, a clinical feature and mycologic evidence and is proposed for immunocompromised patients only, whereas proven IFD can apply to any patient, regardless of whether the patient is immunocompromised. Probable IFD requires the presence of a host factor, a clinical feature, and mycologic evidence. Cases that meet the criteria for a host factor and a clinical feature but for which mycological evidence has not been found are considered possible IFD. (1,3)-beta-D glucan was not considered to provide mycological evidence of any invasive mold disease.

Abbreviations: BAL, bronchoalveolar lavage; CSF, cerebrospinal fluid; CT, computed tomography; PCR, polymerase chain reaction.

[a]Hematologic malignancy refers to active malignancy, in receipt of treatment for this malignancy, and those in remission in the recent past. These patients would comprise largely acute leukemias and lymphomas, as well as multiple myeloma, whereas patients with aplastic anemia represent a more heterogeneous group of individuals and are not included.

serum BDG to rule in patients for clinical trials or for defining IA or IC, as BDG detection is not specific for any one IFD. It was agreed that this test should only be used on serum samples, although the test has been used for CSF samples with some success to support a diagnosis of central nervous system (CNS) IFD in certain circumstances when other diagnostic tests are negative or inconclusive [44].

The T2Candida panel has been cleared by the US Food and Drug Administration for the detection of common *Candida* species from whole blood specimens. The test has a very high NPV but, as with all such tests, the PPV is variable and depends upon disease prevalence in a given patient population [45, 46]. The PPV increases from 62% among patients with sepsis, shock, or lengths of stay greater than 3–7 days in an ICU to 92% for bone marrow transplant recipients and patients with leukemia who are neutropenic but not receiving any antifungal prophylaxis. The test has been included as mycologic evidence to support a diagnosis of candidemia in selected clinical trials [47].

Aspergillus PCR: Group 5

In considering *Aspergillus* PCR, target species, patient populations, appropriate specimens for testing, technical issues, comparison with other biomarker assays, and unique attributes of PCR assays were reviewed. The data were sufficiently robust for performing *Aspergillus* PCR on serum, plasma, whole blood, and BAL fluid in adults. The group acknowledged that *Aspergillus* PCR data have been evaluated most extensively for adults with hematologic malignancies and HSCT. Systematic reviews of *Aspergillus* PCR methods on blood and BAL fluid conclude that PCR provides a robust diagnostic test for screening and confirming the diagnosis of *Aspergillus* infection [22, 48–53].

There are relatively few commercial PCR assays, and most investigators have developed methods in-house. As such, the FPCRI was established to develop criteria for *Aspergillus* PCR rather than a standardized method per se. Despite technologic variability, PCR performance was comparable with that for detecting GM and BDG [54]. Moreover, commercial PCR tests performed using methodology in line with the FPCRI recommendations provide a standardized approach that has been independently associated with improved performance. A unique feature of PCR is its ability to detect both genus and species of *Aspergillus*. PCR is also capable of identifying certain mutations associated with triazole resistance directly from clinical specimens [55–57].

Tissue Diagnosis: Group 6

Tissue diagnosis requires the presence of fungal elements in formalin-fixed paraffin-embedded tissue and signifies proven fungal disease but not the identity of the fungus involved. To achieve this, we recommend amplification of fungal DNA by PCR combined with DNA sequencing, but only when fungal elements are seen by histopathology. PCR would add value by allowing identification of the fungus to genus and possibly species levels. Because the technique used should be rigorously quality controlled, only laboratories with a proven record in performing DNA extraction from formalin-fixed tissue should undertake this. The identity of the fungus should be consistent with the histopathologic findings [58–60].

Other Disease Entities

Pneumocystosis: Group 7

The inclusion of *Pneumocystis jirovecii* pneumonia (PCP) diagnosis in the updated definitions was limited to patients not living with human immunodeficiency virus (HIV). Diagnosing PCP has been more difficult among these patients possibly due to a more focal pulmonary involvement, lower suspicion of disease, and lower sensitivity of traditional histologic and microscopy diagnostic tests [61]. As such, it is important to more fully define host factors for patients at increased risk for PCP. We selected receipt of therapeutic doses of corticosteroids for at least 2 weeks within the past 60 days; antineoplastic, antiinflammatory, or immunosuppressive treatment; and low CD4 lymphocyte counts due to a medical condition. This includes, but is not limited to, patients with primary immunodeficiencies, hematologic malignancies, SOTs, and allogeneic HSCT recipients [62, 63]. Clinical criteria in this population tend to be nonspecific and include cough, dyspnea, and hypoxemia. Radiographic abnormalities include bilateral ground-glass opacities and, less frequently, consolidation, small nodules, unilateral infiltrates, pleural effusions, and cystic lesions [61, 64, 65]. Amplification of *P. jirovecii* DNA by quantitative real-time PCR on BAL fluid, expectorated sputum, or oral wash specimens is preferred to qualitative PCR and is helpful to establish probable disease. However, further studies are needed

A53210128

to validate thresholds for positivity [66, 67]. Similarly, 2 or more serum BDG levels of ≥80 ng/L are useful for diagnosing probable disease in appropriate clinical context provided other IFDs have been excluded [68, 69].

Cryptococcosis: Group 8

A broader understanding of the natural history and host factors associated with cryptococcal disease warrants updating these definitions. We support the previous definitions of proven and probable cryptococcal disease in any host. However, we also recognize cryptococcal infection among individuals in high-risk host groups who have few, if any, symptoms and only a positive serum cryptococcal antigen test (asymptomatic cryptococcal antigenemia). This condition may be more common than symptomatic disease, and patients may develop clinical cryptococcal disease unless treated and so are now included in these definitions [70]. The term "disseminated cryptococcosis" as distinct from CNS cryptococcosis has been abandoned in favor of the terms "pulmonary," "CNS" and "other extrapulmonary sites." "Colonization" with *Cryptococcus* spp. is no longer included in the definitions as it is poorly understood and its natural history is unknown.

Identification to the species level for *Cryptococcus neoformans* and *Cryptococcus gattii* has become increasingly important based on reports that suggest different clinical presentations, outcomes, and responses to antifungal therapy between these 2 species [71, 72]. Verification of species that use CGB (L-canavanine, glycine, bromthymol blue) agar or matrix-assisted laser desorption ionization–time of flight mass spectrometry is recommended. Outcomes for HIV-associated cryptococcosis due to *C. neoformans* and *C. gattii* appear to be similar, and identification to the species level may be unnecessary [73, 74].

Endemic Mycoses: Group 9

The endemic mycoses are caused by environmental fungi that are usually restricted geographically and cause disease in immunocompetent and immunocompromised hosts. Causative agents include *Histoplasma capsulatum* var. *capsulatum* and *H. capsulatum* var. *duboisii*, *Blastomyces* species complex (eg, *B. dermatitidis*, *B. gilchristii*, *B. helicus*, *B. silverae*, and *B. parvus*), *Coccidioides immitis/Coccidioides posadasii*, *Paracoccidioides brasiliensis/Paracoccidioides lutzii, Sporothrix* species complex (*S. brasiliensis*, *S. schenckii sensu stricto*, *S. globosa*, and *S. luriei*), *Talaromyces* (formerly *Penicillium*) *marneffei*, and *Emergomyces* species (*E. pasteurianus*, *E. africanus*, *E. orientalis*, *E. canadensis*, and *E. europaeus*) [75–80]. Probable endemic mycoses are defined by evidence of environmental exposure to the fungus, a compatible clinical illness, and the presence of either *Histoplasma* or *Blastomyces* antigen in any body fluid or antibody to *Coccidioides* species in serum or CSF as recovery by culture and histopathologic evidence of infection is generally lacking. There are no approved serologic tests for *T. marneffei*,

Table 3. Other Probable Invasive Diseases

Candidiasis
Host factors
Recent history of neutropenia <0.5 × 10^9 neutrophils/L (<500 neutrophils/mm^3 for >10 days) temporally related to the onset of invasive fungal disease
Hematologic malignancy
Receipt of an allogeneic stem cell transplant
Solid organ transplant recipient
Prolonged use of corticosteroids (excluding among patients with allergic bronchopulmonary aspergillosis) at a therapeutic dose of ≥0.3 mg/kg corticosteroids for ≥3 weeks in the past 60 days
Treatment with other recognized T-cell immunosuppressants, such as calcineurin inhibitors, tumor necrosis factor-a blockers, lymphocyte-specific monoclonal antibodies, immunosuppressive nucleoside analogues during the past 90 days
Inherited severe immunodeficiency (such as chronic granulomatous disease, STAT 3 deficiency, CARD9 deficiency, STAT-1 gain of function, or severe combined immunodeficiency)
Acute graft-versus-host disease grade III or IV involving the gut, lungs, or liver that is refractory to first-line treatment with steroids
Clinical features
At least 1 of the following 2 entities after an episode of candidemia within the previous 2 weeks:
Small, target-like abscesses in liver or spleen (bull's-eye lesions) or in the brain, or, meningeal enhancement
Progressive retinal exudates or vitreal opacities on ophthalmologic examination
Mycological evidence
ß-D-glucan (Fungitell) ≥80 ng/L (pg/mL) detected in at least 2 consecutive serum samples provided that other etiologies have been excluded
Positive T2Candida[a]
Cryptococcosis
Host factors[b]
Human immunodeficiency virus infection
Solid organ or stem cell transplant recipient
Hematologic malignancy
Antibody deficiency (eg, common variable immunoglobulin deficiency)
Immunosuppressive therapy (including monoclonal antibodies)
End-stage liver or renal disease
Idiopathic CD4 lymphocytopenia
Clinical features
Meningeal inflammation
Radiological lesion consistent with cryptococcal disease
Mycological evidence
Recovery of *Cryptococcus* from a specimen obtained from any nonsterile site
Pneumocystosis[c]
Host factors
Low CD4 lymphocyte counts <200 cells/mm^3 (200 × 10^6 cells/L) for any reason
Exposure to medication (antineoplastic therapy, antiinflammatory, or immunosuppressive treatment) associated with T-cell dysfunction
Use of therapeutic doses of ≥0.3 mg/kg prednisone equivalent for ≥2 weeks in the past 60 days
Solid organ transplant
Clinical features
Any consistent radiographic features particularly bilateral ground glass opacities, consolidations, small nodules or unilateral infiltrates lobar infiltrate, nodular infiltrate with or without cavitation, multifocal infiltrates, miliary pattern [d]
Respiratory symptoms with cough, dyspnea, and hypoxemia accompanying radiographic abnormalities including consolidations, small nodules, unilateral infiltrates, pleural effusions, or cystic lesions on chest X-ray or computed tomography scan

A53210128

Table 3. Continued

Mycological evidence
ß-D-glucan (Fungitell) ≥80 ng/L (pg/mL) detection in ≥2 consecutive serum samples provided other etiologies have been excluded
Detection of *Pneumocystis jirovecii* DNA by quantitative real-time polymerase chain reaction in a respiratory tract specimen
Endemic mycoses
Host factors
Not applicable as these diseases affect both healthy and less healthy hosts
Clinical features
Evidence for geographical or occupational exposure (including remote) to the fungus and compatible clinical illness
Mycological evidence
Histoplasma or *Blastomyces* antigen in urine, serum, or body fluid
Antibody to *Coccidioides* in cerebrospinal fluid or 2-fold rise in 2 consecutive serum samples

Probable invasive fungal diseases (IFD)requires the presence of at least 1 host factor, a clinical feature and mycologic evidence and is proposed for immunocompromised patients only, whereas proven invasive fungal disease can apply to any patient, regardless of whether the patient is immunocompromised. Except for endemic mycoses, probable IFD requires the presence of a host factor, a clinical feature, and mycologic evidence, whereas cases that meet the criteria for a host factor and a clinical feature but for which mycological evidence has not been found are considered possible IFD.

[a]T2Candida is US Food and Drug Administration approved for the detection of *Candida albicans*, *Candida parapsilosis*, *Candida tropicalis*, *Candida krusei*, and *Candida glabrata* in blood.

[b]Cryptococcosis also occurs in phenotypically normal hosts.

[c]Definitions for human immunodeficiency virus–associated pneumocystosis are not included here.

[d]Bilateral, diffuse ground glass opacities with interstitial infiltrates are more common than other features such as consolidations, small nodules, thin-walled cavities, and unilateral infiltrates.

S. schenckii species complex, or *P. brasiliensis*. Exposure to 1 of these fungi is defined as a history of residence in an endemic area, no matter how remote, travel to an endemic area, or contact with fomites such as soil or vegetation that is derived from an endemic area.

Proven Invasive Fungal Disease

The revised definitions of proven IFD are shown in Table 1.

Probable Invasive Fungal Disease

Several changes were made to the definitions of probable IFD (Tables 2 and 3). For example, host factors were expanded to include inherited severe immunodeficiency and low CD4 lymphocyte counts. Radiographic features were expanded to include wedge-shaped and segmental or lobar consolidation and a reverse halo sign to indicate mold disease of the lower respiratory tract. Revised thresholds for GM now replace those of the manufacturer. *Aspergillus* PCR is now included, and there are mycologic criteria for non-HIV–associated pneumocystosis.

Possible Invasive Fungal Disease

While definitions of proven and probable disease have been shown to be reliable in research and attracted little controversy among the group, this cannot be said of the possible IFD category. There is much confusion about the difference between a host factor and a risk factor. As before, a host factor has been defined as a characteristic of individuals clearly predisposed to, and not simply at risk of, an IFD [1]. For example, while impaired gut wall integrity through surgery or illness may increase the risk of candidiasis, it was not considered specific enough to warrant inclusion as a host factor. Pulmonary abnormalities such as tree-in-bud opacities and interstitial abnormalities were excluded from the clinical features as they can be due to a wide range of pathologies in addition to IFD.

GENERAL POINTS

Throughout this process, we have emphasized the need to differentiate between definitions of IFD required for clinical research from those that influence clinical practice. In clinical practice, many would administer an antifungal agent to any patient at risk of IFD when fungi are detected by biomarkers in serum, plasma, whole blood, or relevant body site fluid without there being sufficient evidence to satisfy the consensus definitions of IFD. We also recognize that our definition of a host factor errs on the side of conservatism given the increasing use of drugs such as monoclonal antibodies for treating a variety of conditions.

Other controversial issues included distinguishing between the performance characteristics of tests for screening and confirmation, the impact of exposure to antifungal agents used for prophylaxis or treatment on imaging and diagnostic tests, and the use of biomarkers to monitor therapeutic outcome. We agree that further research will be required to evaluate the evidence for each of these assays. Finally, there was consensus that diagnostic strategies to determine the relative efficiency of an available test, alone or in combination with other diagnostic tests, should be considered further.

CONCLUSIONS

In summary, these revised definitions represent consensus expert opinion based on the best available evidence. As such, they will need to be reviewed regularly for their utility and relevance and, where possible, extended to other populations affected by IFDs. We acknowledge the limitations of these definitions, including the exclusion of certain cases of IFD. However, the reliance on host factors, clinical features, and mycologic evidence to define IFD in selected populations has proven its value for clinical trials, epidemiologic studies, and the evaluation of diagnostic tests.

Diagnostic errors in the intensive care unit: a systematic review of autopsy studies

Bradford Winters,[1] Jason Custer,[2] Samuel M Galvagno Jr,[1] Elizabeth Colantuoni,[3] Shruti G Kapoor,[1] HeeWon Lee,[4] Victoria Goode,[5] Karen Robinson,[6] Atul Nakhasi,[3] Peter Pronovost,[1] David Newman-Toker[7]

ABSTRACT

Context: Misdiagnoses may be an underappreciated cause of preventable morbidity and mortality in the intensive care unit (ICU). Their prevalence, nature, and impact remain largely unknown.

Objectives: To determine whether potentially fatal ICU misdiagnoses would be more common than in the general inpatient population (~5%), and would involve more infections or vascular events.

Data sources: Systematic review of studies identified by electronic (MEDLINE, etc.) and manual searches (references in eligible articles) without language restriction (1966 through 2011).

Study selection and data abstraction: Observational studies examining autopsy-confirmed diagnostic errors in the adult ICU were included. Studies analysing misdiagnosis of one specific disease were excluded. Study results (autopsy rate, misdiagnosis prevalence, Goldman error class, diseases misdiagnosed) were abstracted and descriptive statistics calculated. We modelled the prevalence of Class I (potentially lethal) misdiagnoses as a non-linear function of the autopsy rate.

Results: Of 276 screened abstracts, 31 studies describing 5863 autopsies (median rate 43%) were analysed. The prevalence of misdiagnoses ranged from 5.5%–100% with 28% of autopsies reporting at least one misdiagnosis and 8% identifying a Class I diagnostic error. The projected prevalence of Class I misdiagnoses for a hypothetical autopsy rate of 100% was 6.3% (95% CI 4.0% to 7.5%). Vascular events and infections were the leading lethal misdiagnoses (41% each). The most common individual Class I misdiagnoses were PE, MI, pneumonia, and aspergillosis.

Conclusions: Our data suggest that as many as 40 500 adult patients in an ICU in USA may die with an ICU misdiagnoses annually. Despite this, diagnostic errors receive relatively little attention and research funding. Future studies should seek to prospectively measure the prevalence and impact of diagnostic errors and potential strategies to reduce them.

INTRODUCTION

Diagnostic errors are an underappreciated cause of preventable mortality and morbidity in hospitalised patients, accounting for an estimated 40 000–80 000 annual deaths in USA.[1] Patients in an intensive care unit (ICU) may be especially prone to suffer harm from diagnostic errors. They have limited reserve, often require fast diagnosis and treatment, are cared for by multiple clinicians and undergo frequent laboratory and imaging evaluations.[2] Harm may result from delay or failure to treat the correct underlying disease, complications of unnecessary diagnostic testing or treating a condition that is not actually present.[1]

Diagnostic errors are missed, wrong or delayed diagnoses that are detected by some subsequent definitive test or finding.[3] Autopsy-detected misdiagnoses are typically classified by the Goldman criteria and based on their clinical relevance and the potential that timely therapy would have changed the outcome. The Goldman criteria for autopsy confirmed discrepancies stratify misdiagnosis errors as major (Class I and II misdiagnosis) and minor (Class III and IV misdiagnosis). A Class I error is a major missed diagnosis with a potential adverse impact on survival (likely was the cause of death or contributed to the patient's death) and had that diagnosis been known would have changed management and outcome. A Class II error is a major missed diagnosis that did not have an impact on survival (was not the cause of death nor directly contributed to the patient's death). A Class III error is a minor missed diagnosis related to a terminal disease but not related to the cause of death, and Class IV errors are other missed minor discrepancies.[4]

A 2003 systematic review of autopsy-confirmed misdiagnoses found that 9% were Class I errors and 15% were Class II errors.[5] After adjusting for declining autopsy rates over time, the authors estimated that 10% of all hospital deaths had a major diagnostic error and 5% of these were Class I errors. They also estimated that the Class I error prevalence in the ICU population was twice the overall prevalence in US hospitals.

Nevertheless, the prevalence of diagnostic errors, the conditions ultimately diagnosed and the degree of harm from these errors are largely unknown. The methods to measure diagnostic errors are underdeveloped and most studies measuring patient safety ignore diagnostic errors.[1] In a recent study for example, diagnostic error was not a variable in examining temporal changes in patient harm over time.[6] As such, the problem of diagnostic errors remains largely invisible. The purpose of this study was to systematically estimate the prevalence and distribution of autopsy-confirmed diagnostic errors in the ICU population. We hypothesised that diagnostic errors would be more common in the ICU population than previously reported for the general hospital population. Additionally, based on a preliminary assessment of the literature, we hypothesised that most errors identified related to infections or vascular events.

METHODS

Search strategy

We conducted a systematic review of the published literature from 1966 through 2011 for observational studies that examined the prevalence of potentially lethal diagnostic errors in the ICU, as diagnosed by the reference standard of autopsy. Databases searched included PubMed, Embase, Cumulative Index to Nursing and Allied Health Literature, and the Cochrane Database of Systematic Reviews using the Johns Hopkins Welch Medical Library online electronic resources. There were no language limitations. The full search strategies (see online appendix) were designed by librarians from the Johns Hopkins Welch Medical Library (KR, VG) together with clinical investigators (BW, DNT). All of the clinical investigators that served as reviewers have expertise in critical care or evaluation of diagnostic errors. Two reviewers (JC and SGK) independently screened each abstract and all studies considered eligible by either reviewer were passed on to two reviewers (JC and BW) for a full article review to determine inclusion in the final analysis. Disagreements between these reviewers were resolved by group consensus. Bibliographies from retrieved articles were screened for other relevant studies; none were identified. We did not attempt to contact authors or identify meeting abstracts, unpublished studies, or other grey literature.

Study selection

We included studies if they provided autopsy-confirmed misdiagnosis data on adult patients who died while in an intensive care setting. Studies without original patient data were excluded. We did not set standards for autopsy performance or for conduct and reporting of individual studies (eg, prospective vs retrospective). Two types of studies were defined: (1) general misdiagnosis studies (reporting on all misdiagnoses or all misdiagnoses of a minimum severity),[7–37] and (2) disease-specific studies (reporting only on misdiagnoses of particular conditions, such as pulmonary embolus).[38–46] We excluded disease-specific studies from our analysis. A flowchart of our study selection is in figure 1.

Analysis

Four authors (JC, BW, AN, SMG) reviewed the general misdiagnosis studies and abstracted the data for pooled analysis. These data included number of deaths, autopsies and errors, error class, underlying diagnoses, country and ICU type. We did not assign a quality rating. Errors were defined by the Goldman Classification scheme. Class I are missed major diagnoses with potential adverse impact on survival and that would have changed management. Class II is a missed major diagnosis that would not have impacted survival and that

would not have changed therapy. Class III and Class IV are minor errors related to the terminal disease but not death and completely unrelated to either, respectively. The majority of studies reported Class I[7–16 18–32 34–37] and II[7 9 10 12 13 15 16 18–32 34–36] error data, and less reported Class III[9 10 12 13 15 16 18–20 22 26 30 31] and IV[9 12 13 16 18 20 23] error data.

We defined four broad disease categories to assess the distribution of types of misdiagnoses. These categories included: (1) vascular (myocardial infarction, pulmonary embolus, stroke, any organ infarct, any vessel rupture or dissection, and any haemorrhage), (2) infectious (bacterial, aspergillosis, other fungal, viral, and tuberculosis), (3) mechanical pathophysiological states (cardiac tamponade, bowel obstruction, perforated viscus, congestive heart failure, and cardiac valve failure), and (4) neoplastic/other. Some studies treated pneumonia and aspergillosis separately from other infections.[10 14 19 20 25 34] We aggregated these results during the analytic phase.

Data were tabulated using Microsoft Excel 2008 for Mac (Microsoft Corp., Redmond, Washington, USA). Descriptive statistics were calculated using Stata V.11 (Stata Corp., College Station). A p value <0.05 was considered statistically significant. A logistic regression model was performed to create a hypothetical prediction of the prevalence of misdiagnoses at higher autopsy rates to predict what the actual error rate might be if every patient who died in an ICU always had an autopsy. A random intercept logistic regression model was fit to the class I misdiagnosis rate (number of class I errors vs number of autopsies performed) as a non-linear function of the per cent of autopsies performed (natural spline with two degrees of freedom). A likelihood ratio test was performed with R V.2.11.1 (R Foundation for Statistical Computing, Vienna, Austria) to determine if the non-linear function was justified over a linear fit. The random intercept was included to account for natural variation across studies as is standard in meta-analysis. We controlled for size of study (number of autopsies) and the study time period in this model.

This report was prepared according to Meta-analysis of Observational Studies in epidemiology (MOOSE) guidelines for systematic reviews of observational studies.[47]

RESULTS

Of 276 abstracts screened, 78 were advanced to full article review (κ for concordance was 0.97; SE =0.11). We identified 41 studies and subsequently excluded one by group consensus because the unit studied could not be clearly identified as an ICU. Of the remaining 40 studies, 30 reported general misdiagnosis (28 retrospective) representing a total of 5863 autopsies and were included in our analysis, and nine were disease-specific misdiagnosis and excluded from our analysis (tables 1 and 2). The study periods ranged from 11 months to 300 months and included a wide range of ICU types. Autopsy rates ranged from 6% to 100% (weighted mean 41%, median 43%).

The prevalence of autopsy-detected misdiagnoses ranged from 5.5% to 100%. In aggregate, 28% (n=1632/5863) of autopsies reported at least one misdiagnosis (figure 2). Of the 31 studies, 27 reported class I error data, 25 class II, 13 class III, and 7 class IV error data. Class I diagnostic errors were identified in 8% (n=343/4514); Class II errors in 15% (n=637/4403); Class III errors in 15% (n=264/1711); and Class IV errors in 21% (n=175/816) of autopsies reporting (figure 2). Class I misdiagnoses were less prevalent at higher autopsy rates (figure 3) although total misdiagnoses were not (data not shown). The predicted prevalence of potentially lethal misdiagnoses, when extrapolated to a hypothetical 'perfect' 100% autopsy rate was 6.3% (95% CI=4.0% to 7.5%). Our model estimates the Class I error prevalence as a function of autopsy rate; the model result (6.3%) differs from the measured prevalence (8%), which is simply the average misdiagnosis prevalence from all autopsies reporting Class I errors. A likelihood ratio test was used to determine if the non-linear function was justified over a linear fit (p=0.021). In addition, a likelihood ratio test was used to determine if the autopsy rate (based on natural spline fit) provided any information for the class I misdiagnosis rate (p=0.002). After accounting for the autopsy rate, the estimated SD of the log odds of a class 1 misdiagnosis across studies was 0.58 (SE: 0.11), translating to study to study variation accounting for roughly 10% of the total variation.

Final diagnoses were provided in 25 of 31 studies for Class I misdiagnoses and in 16 of 31 studies for Class II misdiagnoses (figure 4 and box 1). Among all Class I errors, vascular events (41%) and infections (41%) were the most common diagnosis, followed by mechanical pathophysiological states (10%), and neoplasms and other conditions (9%). For all Class II errors, vascular events (47%) were the most common diagnosis, followed by infections (29%), neoplasms and other conditions (21%), and mechanical obstructive pathophysiological conditions (4%). Within these broad categories, pulmonary embolus, myocardial infarction, pneumonia, and aspergillosis were the most common diagnoses in the class I errors. Cumulatively, they accounted for about one-third of all potentially lethal diagnostic errors (box 1).

DISCUSSION

In this study, 28% of autopsied ICU patients had at least one misdiagnosis. Of the autopsies reporting misdiagnosis error classifications, 8% were Class I (major and

ICU, Intensive Care Unit.

potentially lethal), and 15% were Class II (major but not lethal) despite presumably aggressive diagnostic assessment in the critical care environment. Given the 540 000 deaths annually during or immediately following an ICU stay,[48] and extrapolating to a 100% autopsy rate, our findings suggest that 34 000 (95% CI =22 600 to 40 500) ICU patients in the US may die as a result of a Class I error annually, assuming that the error was the cause of death. This predicted number is comparable to the estimated deaths from central line-associated bloodstream infections in the ICU[49] and from breast cancer[50] in the US, and does not consider misdiagnosis-related morbidity among intensive care patients. These results also suggest that despite the dropping autopsy rate over time, autopsy remains a crucial asset especially in ICU patients.

We proved our hypothesis that infections and vascular events would culminate a large majority of the diagnostic errors. Vascular events and infections were the leading potentially lethal misdiagnoses accounting for almost 82% of potentially lethal Class I errors and almost 76% of the serious but not lethal Class II errors. Neoplastic disease was the third most common overall misdiagnosis category but was rarely deemed lethal. Mechanical pathophysiological states were uncommon. Importantly, pulmonary embolus, myocardial infarction, pneumonia, and aspergillosis accounted for over one-third of all Class I misdiagnoses. These four particular diagnostic errors may be useful as outcome measure for designing early interventions to reduce diagnostic errors as a whole.

Our results add new information to the field of diagnostic error research. Shojania *et al*[5] conducted a systematic review of autopsy-detected diagnostic error prevalence rates over time, but they did not describe specific misdiagnoses in the ICU or elsewhere. We included the seven ICU studies from their review in our analysis to offer refined estimates of the prevalence of

misdiagnoses in the ICU by error class and autopsy rate. Shojania *et al* projected that, despite a reduction of 33% in the rate of class I errors over 4 decades, a US hospital would likely continue to observe a class I error at a rate of 4.1%–6.7% across all patients. While a few of the studies in Shojania's review included ICU patients in addition to general ward and emergency department patients, our results suggest that the rate of class I errors are 16%–48% higher in the ICU patient population then the general hospital patient population as a whole. Methodologically, we found that autopsy rates of 30%–40% or higher are likely to produce fairly accurate estimates of the overall prevalence of potentially lethal misdiagnoses in the ICU population, despite potential biases inherent in autopsy case selection.[51]

Observed diagnostic error frequencies were highest in studies with the lowest autopsy rates. Clinical selection of the most complex cases to undergo autopsy is believed to contribute to this effect.[51] To counter this effect, we have modelled the measured error frequency as a function of autopsy rate, controlled for study size and time and extrapolated out to conditions of 100% autopsy. Nevertheless, it is possible that other factors may contribute to the difference seen in studies with low autopsy rates such as a more detailed and rigorous approach to autopsy and error finding. Additionally, the level of diagnostic certainty as to the cause of death is likely to influence the autopsy rate. Podbregar *et al*[27] attempted to measure this influence finding that diagnostic certainty significantly influenced the decision to pursue an autopsy though there were no differences in the class I error rate. As a consequence, our extrapolated estimate for the total error frequency likely represents a conservative, minimum estimate of the true frequency as aggregated from the present data.

Although we could not measure morbidity associated with misdiagnosis in survivors, the consequences and costs are likely substantial. ICU-based studies have reported complications of misdiagnosis, such as re-operation,[52] and increased length of stay.[53] The most frequently reported non-lethal long-term consequences of misdiagnosis are neurological. Preventable or treatable neurological complications of critical illness such as stroke may go unrecognised with devastating consequences.[54–56] Robust estimates of the morbid consequences of diagnostic errors will likely require prospective studies.

Risk predictors for misdiagnosis in the ICU at the patient, organisational or provider level are incompletely defined and there is sparse data on root causes of misdiagnosis in the ICU. Off-hours occurrence appears to be a risk factor for at least some types of ICU misdiagnosis.[53] Patient demographics and institutional factors have been cited as possible influences.[5 57 58] There is

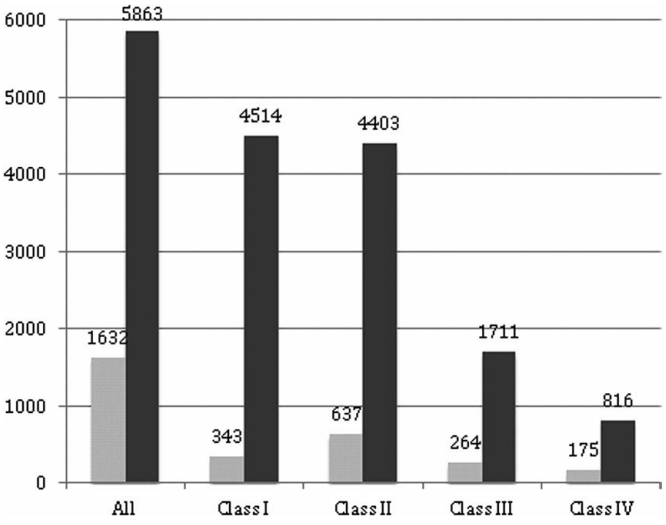

Figure 2 This figure shows the proportion of all autopsies that identified a misdiagnosis, and the proportion of autopsies that identified a misdiagnosis stratified by the Goldman criterion (Class I, II, III, and IV). The grey bars represent identified misdiagnosis and the black bars represent all autopsies reported for total and class. Of the 30 studies included in this analysis, 26 reported class I error data, 24 class II, 13 class III, and 7 class IV error data. Thus, the sample sizes by Goldman classification varied. Stratified by class, 8% of autopsies detected a Class I error, 15% detected a Class II error, 15% detected a Class III error, and 21% detected a Class IV error.

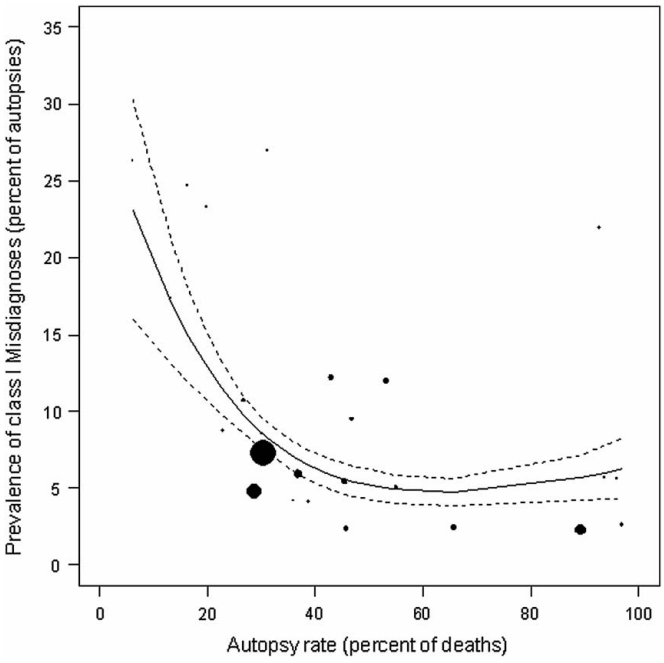

Figure 3 This figure illustrates the prevalence of Class I misdiagnoses (as a per cent of autopsies) and the autopsy rate. Each point on the figure represents data from one study. The plotting symbols are proportional to the number of autopsies performed in each study (with larger plotting symbols indicating larger number of autopsies). The solid line represents the logistic regression models estimate for reported values. The dotted lines represent the 95% CIs. The curve was generated using a natural spline with two degrees of freedom.

evidence that the patient's clinical presentation such as greater co-morbidity or illness complexity increases the risk of misdiagnosis.[52 53 56 59] The diagnostic process is complex[60] and errors may occur at any stage during the process, often at multiple stages.[61] Some misdiagnoses may be directly linked to limited sensitivity and specificity of individual tests in the critical care setting,[62] but remediable causes are most often associated with failures in information processing. Cognitive errors are also a major contributor to misdiagnoses and a recent review by Graber *et al*[63] identified a large number of possible approaches (some tested and some not) that may help reduce cognitive errors and hence, misdiagnoses.

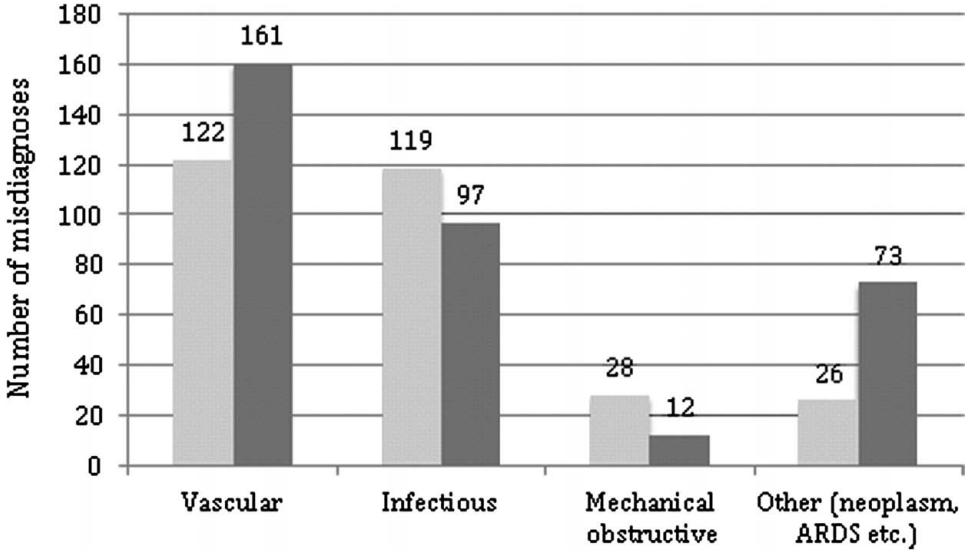

Figure 4 This figure shows the most common misdiagnoses by broad disease categories for Class I and II errors. These categories are vascular (myocardial infarction, pulmonary embolus, stroke, any organ infarct, any vessel rupture or dissection, and any haemorrhage), infectious (bacterial, aspergillosis, other fungal, viral and tuberculosis), mechanical pathophysiological states (cardiac tamponade, bowel obstruction, perforated viscus, congestive heart failure and cardiac valve failure), and neoplasm and other (includes acute respiratory distress syndrome (ARDS)). The number of Class I (black bar) and Class II (grey bar) errors are compared for each diagnostic category. The data for Class I errors represents 24 of the 30 studies in the analysis and data for Class II errors represents 16 of 30 studies.

Box 1 Breakdown of misdiagnoses by final diagnosis reported

Vascular events
  Haemorrhage
Vascular rupture
Aortic aneurysm/dissection (11, 1)
Other (2, 1)
Abdominal bleed (21, 41)
Other (5, 12)
  Thrombosis
Pulmonary embolus (37, 64)
Other (1, 0)
  Ischemia
Myocardial infarction (31, 33)
Bowel infarction (13, 10)
Stroke (1, 0)
Infections
Mechanical obstructive pathophysiology
  Cardiac tamponade (10, 0)
  Perforated viscus not designated peritonitis (9, 4)
  Bowel obstruction (1, 4)
  Tension pneumothorax (1, 0)
  Congestive heart failure (2, 2)
  Cardiac valvular lesion (not endocarditis) (5, 2)
Other
  Malignancy (6, 47)
  Pulmonary oedema (not acute respiratory distress syndrome) (2, 2)
  Acute respiratory distress syndrome (3, 1)
  Pancreatitis (4, 1)
  Cirrhosis (0, 1)
  Airway obstruction (2, 0)
  Other (9, 22)

Values in parentheses are the actual total number of class I and class II identified in studies reporting this data.

A major impediment to better understanding of diagnostic errors is the declining autopsy rate.[5] The reasons for this are multi-factorial and likely include medical culture and societal attitude shifts. One alternative that might improve the rate of autopsy is the 'virtual autopsy' using sophisticated radiological techniques as opposed to dissection. Wichmann *et al*,[64] recently reported a comparison of 'virtual autopsy' to traditional autopsy in ICU patients suggesting that it compares favourably and had a higher acceptance rate in terms of per cent of deaths referred to post-mortem analysis. With further refinement this approach may offer a way to continue to obtain the post-mortem information required.

Our systematic review has significant policy implications. Diagnostic errors have not been the focus of patient safety campaigns or systematic studies.[1 65] A 2003 report of 93 Agency for Health Research and Quality (AHRQ)-funded safety projects found only one focused on misdiagnosis.[65] A recent Special Emphasis Notice has sought proposals for these errors in ambulatory and emergency department settings,[66] but it has not been linked to a funded request for applications.

Our review has limitations. We did not search the grey literature nor did we follow-up with authors, pursue secondary references or consult with experts and publication bias could, in theory, have inflated our measured prevalence. Virtually all studies were retrospective in nature and there is potential for selection bias in those autopsied though Podbregar *et al*[27] found that while diagnostic certainty did influence the rate of autopsy, it did not influence the rate of class I errors. Unfortunately, the reliability of determining whether an error occurred and its severity could not be determined to any meaningful extent in the reviewed studies. Thus our estimate of the class I (lethal) diagnostic error frequency may either be an over- or under-estimate of the true frequency. Debate continues on the extent to which this is a potential problem.[11] There was some heterogeneity in the study populations included in our review and the measured misdiagnosis prevalence varied even at high autopsy rates, so misdiagnosis prevalence might not be evenly distributed. We did not assign a quality rating to the studies analysed based on autopsy confirmed diagnosis being a 'gold standard'. Autopsy, as a 'gold standard', is potentially flawed as the decision to perform an autopsy or the results of the autopsy may be influenced by the degree of involvement of clinicians in the judgement of diagnostic errors, the degree to which pathologists knew the clinical history and working diagnoses at the time that they performed autopsy and the format/context in which requests for autopsy were transmitted. The original study authors may have misclassified the types of diagnostic errors, resulting in inaccurate estimates of lethality or preventability and disease frequency estimates might be distorted. Nevertheless, given the consistency with which studies reported missed infections and vascular events as a common source of lethal diagnostic errors, these are likely important.

In conclusion, this systematic review and analysis suggests that between 22 600–40 500 ICU patients die each year in the US with and potentially from a diagnostic error and many more suffer a clinically relevant diagnostic error. These data suggest that diagnostic errors are a significant cause of preventable harm in hospitalised patients. To this point, diagnostic errors have received relatively little attention and research funding, leaving the methods to measure them immature; this must change. Future studies should seek to prospectively measure the prevalence and direct impact of diagnostic errors, including those that are non-lethal, and potential strategies to reduce them.

KEYWORDS
Aspergillus fumigatus; Air sampling; Invasive aspergillosis; Haematology–oncology; Portable air filtration units

Summary We undertook a one-year study to investigate the impact of the NSA model 7100A/B portable air filtration unit on exposure of haematology–oncology patients to airborne *Aspergillus fumigatus* spores under field conditions. Weekly measurements for airborne *A. fumigatus* were conducted in indoor and outdoor air, and surveillance for invasive aspergillosis was based on a combination of ward liaison, targeted chart review and consultation with the medical staff. The mean indoor *A. fumigatus* counts (8.1 cfu/m^3; range, $<$0.8 to 42 cfu/m^3) reflected the fungal load of outdoor air (9.4 cfu/m^3; range, $<$0.8 to 50 cfu/m^3), and were reduced by only about one third in rooms with portable air filtration units (5.3 cfu/m^3; range, $<$0.8 to 41 cfu/m^3). During the study period, a total of five cases (incidence density, 0.8 per 1000 patient-days) of invasive aspergillosis (one proven case, four suspected cases; case fatality rate 40%) were recorded. None of these five patients was allocated to a room with portable air filtration unit, however, the difference between incidence densities in rooms with and without portable air filtration units was non-significant (Fisher's exact test, $P = 0.33$). Due to the noise level and thermal discomfort, patient compliance with the air filtration units was poor. We conclude that under field conditions this air filtration unit cannot be recommended for prevention of invasive aspergillosis in neutropenic haematology–oncology patients.

Introduction

Invasive aspergillosis plays an important role in the morbidity and mortality of immunosuppressed patients suffering from neutropenia.[1–4] Preventive measures are important in the control of invasive aspergillosis because diagnosis is difficult and the outcome of treatment is poor,[5] and good air quality in critical areas in hospitals is necessary to minimize the incidence of invasive aspergillosis.[6–10] Passweg et al.[11] showed that the use of high-efficiency particulate air (HEPA) filtration and/or laminar

air-flow systems to prevent infections decreased transplant-related mortality and increased survival after allogeneic bone marrow transplantation for leukaemia. However, in older hospital buildings the installation of central air supply systems is sometimes not possible due to limited space. Rutala et al.[12] demonstrated that portable air filtration units can rapidly reduce levels of airborne particles, and there are some indications that such devices can also be beneficial as an interim solution to reduce indoor aspergillus levels.[13–19] To date, there exist no randomized controlled trials on the clinical efficacy of portable air filtration units. Table I gives an overview of studies addressing the impact of different portable air filtration units on fungal exposure of patients at risk of acquiring invasive aspergillosis. A direct comparison of these studies is difficult due to the different methods used. Most studies show a significant reduction of airborne fungal exposure and recommend these devices as an interim solution, e.g. in older hospital buildings where the installation of central air supply systems is not possible due to the limited space, or as an additional measure during construction or renovation works.[13–19] However, the clinical value of these devices is not supported by strong evidence. The purpose of our study was to investigate the impact of a specific (low-priced) type of portable air filtration unit on exposure of haematology–oncology patients to airborne *Aspergillus fumigatus* spores under field conditions.

Table I Studies addressing the impact of portable air filtration units on fungal exposure of patients at risk of acquiring invasive aspergillosis

Materials and methods

Setting

The Department of Internal Medicine I at the University Hospital Bonn includes an 18-bed inpatient unit for adult haematology–oncology patients (predominantly patients with acute leukaemia, multiple myeloma, and malignant non-Hodgkin's lymphoma), which is located on the first floor of a separate building surrounded by a forested area. All patient rooms are naturally ventilated (windows, doors) because the installation of a ventilation system with HEPA filtration is not possible because of the limited space in the building. However, patients are instructed to keep the windows closed during periods of neutropenia, and to wear masks when leaving their room. Moreover, regular policies for aspergillus prevention included disinfection of horizontal surfaces including the floor on a daily basis, prohibiting potted plants and flower arrangements within the

whole unit, avoidance of showering during neutropenia, and use of sterile water for any other applications. Specific policies exist for construction or renovation activities, however, no such activities took place during this study. Patients with an expected duration of profound neutropenia of >10 days received antifungal prophylaxis with itraconazole.

Portable air filtration units

We tested three units of the NSA model 7100A/B Environmental Air System (National Safety Associates Limited, Memphis, TN, USA). After a pre-filter panel, the units contain a tri-media-filter (for gases/odours) and a HEPA-type filter that should be replaced at a minimum of every six months and two years, respectively, according to the manufactures' instructions. The NSA unit has a 95% filtering capacity for particles >0.3 μm, and a flow (at its 'high' 'low' settings, respectively) of 168 resp. 112 m^3/h at a noise level of 57 resp. 55 dB(A). Three patient rooms (mean room volume, 38.0 m^3; single rooms, 29.2 m^3; double rooms, 46.9 m^3) were equipped with one unit each. The patients in these rooms were advised to keep the windows closed as much as possible, and to run the NSA unit at the 'high' setting. However, due to the high noise level, the units mostly were put to the 'low' setting, or sometimes even stopped during the night. Questioning patients and staff was the only means of determining how long the units were in operation and how long the windows were left open.

Air sampling and laboratory analysis

Air sampling was conducted using the Sartorius MD8 Air Sampler (Sartorius Ltd, Epsom, Surrey, UK) at a flow of 5.0 m^3/h and an 80 mm diameter gelatine membrane filter (pore size 3 μm; Sartorius, Goettingen, Germany). During a period of one year (May 1996 to April 1997), weekly sampling was undertaken at three locations; (1) outdoors, inside patient rooms (2) without, and (3) with, portable air filtration units. All sampling locations were examined in triplicate for 5 min per sample (total air volume, 1250 L). The filters were incubated at 37°C on Sabouraud dextrose agar for a total of 72 h. *A. fumigatus* was identified by light microscopy.

Surveillance for invasive aspergillosis and statistical analysis

During the study period, all cases of suspected or proven invasive aspergillosis were recorded. Invasive aspergillosis was defined according to previously published criteria.[20] As a case-finding method, a combination of ward liaison, targeted chart review and consultation with the medical staff was employed. Infection rates were calculated per 1000 patient-days. Fisher's exact test (version 6; Epi Info, CDC, Atlanta, GA, USA) was used to compare observed with expected proportions. A *P*-value of less than 0.05 was considered statistically significant.

Results

Air sampling

Overall, the mean indoor *A. fumigatus* counts (8.1 cfu/m^3; range, <0.8 to 42 cfu/m^3) were slightly lower compared with outdoor samples (9.4 cfu/m^3; range, <0.8 to 50 cfu/m^3), and were further reduced by 35% in rooms with portable air filtration units (5.3 cfu/m^3; range, <0.8 to 41 cfu/m^3). Only 11.5% of samples from rooms with portable air filtration units exceeded a value of 10 cfu/m^3. The corresponding proportion in unfiltered indoor air, as well as in outdoor air was 25.0%, however, the difference failed to reach statistical significance ($P = 0.076$). Values of <1 cfu/m^3 were obtained in 19.2% and 13.5% of samples from rooms with, and without, portable air filtration units, respectively, whereas the proportion in outdoor air was only 7.6%; however, the differences also failed to reach statistical significance ($P = 0.085$). We found no marked seasonal variation of indoor or outdoor *A. fumigatus* counts.

Surveillance data

During the study period, five cases of invasive aspergillosis (one proven, four suspected) were recorded in patients with acute leukaemia, two (40%) of the patients died. The overall incidence density for (suspected or proven) invasive aspergillosis was 0.8 per 1000 patient-days. None of these five patients had been allocated to a room with portable air filtration unit, however, the difference between incidence densities in rooms with and without portable air filtration unit (i.e. five infections per 4800 versus none per 1200 patient-days) was non-significant ($P = 0.33$).

Peak counts and aspergillosis cases

Counts of >30 cfu/m^3 ('peaks') were detected in 1/52 (1.9%) samples from rooms with air filtration,

2/52 (3.8%) samples from rooms without air filtration, and 6/52 (11.5%) outdoor samples. Seven of these nine peaks were not related to cases of invasive aspergillosis. However, in two cases of suspected invasive aspergillosis (dates of onset: 20 and 23 August 1996), which had both received chemotherapy for acute myeloid and acute lymphocytic leukaemia, respectively, during the first week of August an association in time did occur. In the week before chemotherapy (29th July), we detected concentrations of 31 cfu/m^3 (outdoor) resp. 16 cfu/m^3 (indoor) and the week after chemotherapy (12 August) there was an indoor peak of 42 cfu/m^3; all other counts during this time period (i.e. about six weeks before onset of the two cases of invasive aspergillosis) were <10 cfu/m^3. The remaining three cases of invasive aspergillosis did not show any correlation with peaks.

Discussion

Our study shows that under field conditions the NSA air filtration unit Model 7100A/B reduced the indoor *A. fumigatus* counts by about one third compared with rooms without air filtration unit. However, this degree of reduction does not seem to be of clinical relevance for patients at high risk, as the air filtration units were not able completely to remove *A. fumigatus* spores from indoor air. It is not known whether there is a 'safe' level of exposure, however, in order to prevent exogeneous aspergillus infections in neutropenic patients, their environment should be as free as possible from aspergillus spores, i.e. considerably below 1.0 cfu/m^3.[7,13,21–22] From the clinical point of view, our surveillance data did not allow a conclusive assessment of the efficacy of the air filtration units. It may be that a study of a greater number of rooms equipped with such units might reveal a small but statistically significant effect. In addition, the use of antifungal prophylaxis with itraconazole in patients with prolonged severe neutropenia may have interfered with the effect of the environmental intervention.

There are several limitations that might explain why the NSA air filtration unit failed to reduce *A. fumigatus* spores further. First, the 95% filtering capacity does not meet the criterion of portable HEPA filtration units, which is defined as a removal of at least 99.97% of particles >0.3 μm in diameter.[12] We are not sure, however, if this is the most important point as the NSA air filtration unit has been shown effectively to reduce particles of this range[12] and Miller-Leiden et al.[23] found that air filters containing efficient, but non-HEPA filter media were as effective as air filters containing HEPA filter media. Second, the flow of the air filtration units was relatively low, reaching a room air exchange rate in the patient rooms of between 2.4 to 3.8 per hour at the low (3.6 to 5.8 per hour at the high) setting. The CDC recommend at least 12 room air changes per hour in order to minimize fungal spore counts.[13] Third, the patient's compliance with the air filtration units was low due to the noise level and heat generated by the units, particularly at high outdoor temperatures when patients transiently opened the windows.

We conclude that the specific air filtration unit investigated in this study cannot be recommended for prevention of invasive aspergillosis in neutropenic haematology–oncology patients. Further studies on this topic should be conducted using air filtration units with higher filtering capacity, higher airflow, lower noise level, and ideally with the air intake from outside the patient's room.

REVIEW

Nosocomial aspergillosis in outbreak settings

R-P. Vonberg*, **P. Gastmeier**

Institute for Medical Microbiology and Hospital Epidemiology, Medical School Hannover, Germany

Available online 18 May 2006

KEYWORDS
Aspergillus outbreaks; Aspergillus; Environmental air sampling/culturing; Immunocompromised hosts; Outbreak investigations

Summary Nosocomial aspergillosis represents a serious threat for severely immunocompromised patients and numerous outbreaks of invasive aspergillosis have been described. This systematic review summarizes characteristics and mortality rates of infected patients, distribution of *Aspergillus* spp. in clinical specimens, concentrations of aspergillus spores in volumetric air samples, and outbreak sources. A web-based register of nosocomial epidemics (outbreak database), PubMed and reference lists of relevant articles were searched systematically for descriptions of aspergillus outbreaks in hospital settings. Fifty-three studies with a total of 458 patients were included. In 356 patients, the lower respiratory tract was the primary site of aspergillus infection. Species identified most often were *Aspergillus fumigatus* (154 patients) and *Aspergillus flavus* (101 patients). Haematological malignancies were the predominant underlying diseases (299 individuals). The overall fatality rate in these 299 patients (57.6%) was significantly greater than that in patients without severe immunodeficiency (39.4% of 38 individuals). Construction or demolition work was often (49.1%) considered to be the probable or possible source of the outbreak. Even concentrations of *Aspergillus* spp. below 1 colony-forming unit/m^3 were sufficient to cause infection in high-risk patients. Virtually all outbreaks of nosocomial aspergillosis are attributed to airborne sources, usually construction. Even small concentrations of spores have been associated with outbreaks, mainly due to *A. fumigatus* or *A. flavus*. Patients at risk should not be exposed to aspergilli.

Introduction

Aspergillus spores are ubiquitous in their distribution, and inhalation of spores is believed to be the usual route of transmission. In most healthy individuals, spores are removed by functional innate defence mechanisms such as monocyte-derived and resident macrophages.[1] Unfortunately, in severely immunocompromised hosts, such as patients suffering from haematological malignancies[2–6] or solid organ transplant patients,[7–11] invasive aspergillosis (IA) may represent a serious complication in the course of disease. The incidence of IA is increased in these high-risk patients[12] with an overall case-fatality rate of one-half to two-thirds.[13] IA is difficult to treat and multi-variate analysis has revealed it to be an independent risk factor for mortality in critically ill patients.[14]

To prevent hospital-acquired aspergillus infections, high-risk patients are usually placed in protective isolation rooms in which positive air pressure is maintained compared with surrounding areas.[15] These special rooms are provided with high-efficiency particulate air (HEPA) filters and an air flow of at least 12 air changes/h because HEPA filtration significantly reduces the concentration of fungal spores[16] and the incidence of IA.[17] In addition, horizontal laminar air flow (LAF) is provided in some facilities which drives contaminants out through the ducts.[18] However, additional protection due to LAF remains a matter of debate and the use of LAF is not explicitly recommended by the Centers for Disease Control and Prevention (CDC), the Infectious Disease Society of America (IDSA) or the American Society of Blood and Marrow Transplantation (ASBMT) for the care of haematopoietic stem cell transplant recipients.[15,19] Despite such guidelines for the care of highly susceptible patients and maximum protective efforts, nosocomial outbreaks of IA do occur.[19,20] This systematic review was carried out to summarize the data from all nosocomial aspergillus outbreak reports published to date.

Methods

Collection of data

The outbreak database (www.outbreak-database.com), a web-based register of nosocomial epidemics, was searched for outbreaks due to any type of *Aspergillus* spp.[21] Furthermore, a PubMed search (1 January 1966—15 August 2005) was performed to identify additional aspergillus outbreaks by using the term 'outbreak' in combination with 'aspergillus' or 'aspergillosis'. References were subsequently screened for additional descriptions of aspergillus epidemics in hospital settings.

Extraction of data

The following data were obtained: (1) number of patients involved in the outbreak; (2) number of patients that died due to aspergillus infection; (3) underlying diseases of affected patients; (4) primary site of mycosis; (5) distribution of *Aspergillus* spp. in clinical specimens; (6) concentration of airborne mould spores in diverse hospital areas; (7) genotyping of fungal isolates to confirm an epidemiological relationship; (8) source of the outbreak.

Evaluation of data

Outbreak data were evaluated by both authors independently. Patients were grouped depending upon underlying diseases into the following classes: (1) haematology and bone marrow transplantation; (2) solid organ transplantation; (3) other immunodeficiency; (4) no known severe immunodeficiency. If a relevant immunodeficiency could not be excluded but definite classification of underlying disease was not possible either, patients were grouped as 'other immunodeficiency'. Mortality was calculated for all groups and then compared. Statistically significant differences in mortality rates in diverse patient groups were determined using Chi-squared test (Epi-Info software, Version 3.3.2). Outbreak sources were considered 'probable' if stated so by the authors of the outbreak. Sources were considered 'possible' if there were circumstances that may have been the source of the outbreak but no exact link could be made with infection.

Results

A total of 53 outbreaks and 458 affected patients were included in this review. Comprising a total of 299 individuals (65.3%), haematological malignancies were the predominant underlying disease. In all but one outbreak, air was the route of fungal spore transmission and the major site of primary infection (356 patients) was the lower respiratory tract.[22] Surgical site infections and superficial skin infections were observed far less frequently (24 patients each). Interpatient spread was only described on one occasion.[23] Species identified most often from clinical samples were *Aspergillus fumigatus* (154 patients) and *Aspergillus flavus* (101 patients). Species differentiation was not

ICU, intensive care unit.

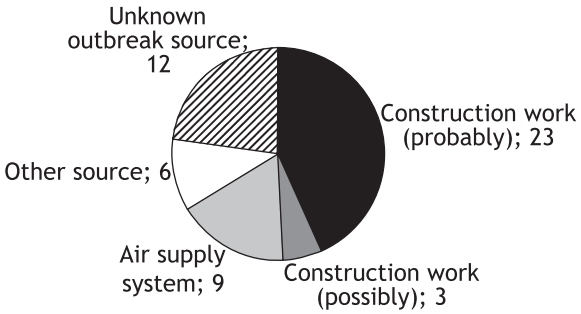

Figure 1 Distribution of sources of nosocomial aspergillus outbreaks.

underlying diseases was not described in detail but all of those diseases did show a relevant immunodeficiency. Therefore, these patients were grouped as described in the Methods section. Mortality was greatest (57.6%) among patients suffering from haematological malignancies. The mortality in this group was significantly higher compared with the mortality of patients without any known immunodeficiency (39.4%; $P < 0.05$).

In 24 outbreaks, volumetric air samples in the hospital and outdoors were taken during the environmental investigation (Table III). The concentration of airborne fungi in patient care areas

HEPA, high-efficiency particulate air.

during outbreak investigations ranged from 0 to more than 100 spores/m^3.

As shown in Figure 1, construction work or renovation activities within the hospital or in surrounding areas were most commonly (49.1%) considered to be the probable or possible source of the nosocomial aspergillus outbreak, followed by a contaminated or defective air supply system (17%). In 12 of the 53 outbreaks, the source remained unknown or was not described.

Discussion

Today, construction in or around hospitals is a never-ending phenomenon. This review suggests that construction, renovation, demolition and excavation activities are the main causes of nosocomial aspergillus outbreaks. This is plausible because renovation and demolition work have been shown to increase the amount of airborne fungal spores dramatically,[34] and in consequence increase the risk for aspergillus infection in susceptible patients.[35] Routes of aspergillus transmission in nosocomial outbreaks other than airborne spores are rarely described.[22] Although aspergilli have also been detected in water supply systems, there is no evidence that nosocomial outbreaks derive from the plumbing system.[36,37]

No *Aspergillus* spp. may be disregarded with respect to severity of infection. Instead, any *Aspergillus* spp. in air samples from special care areas should raise concern of invasive infection, although certain *Aspergillus* spp. are more commonly involved in nosocomial outbreaks than others. This may, in part, be explained by an increased pathogenicity of this species, but it may also reflect the natural distribution of aspergilli in the environment.[38]

Environmental investigations are usually initiated in order to assess the quality of air and to identify potential sources of the epidemic. In many studies, the burden of fungal spores in air has been evaluated by gravity sedimentation methods alone (e.g. open Petri dish method).[39–41] However, this method is not volumetric, cannot be calibrated, and hence provides qualitative rather than quantitative results. In preference, air samples should be drawn by impacting particles from an air stream on to agar surfaces after centrifugal acceleration (e.g. Anderson sampler). This technique is more sensitive, allows determination of aspergillus spores in a standardized volume, and is recommended for calculation of the actual density of fungal contamination.[3,42] To date, the minimal airborne concentration of aspergillus spores necessary to cause infection in patients with significant immunodeficiency remains unknown.[43] Even concentrations of airborne aspergillus spores below 1 colony-forming unit (cfu)/m^3 have been shown to be sufficient to cause outbreaks in immunocompromised patients.[3,44] In contrast, the rate of nosocomial IA did not increase in other studies when a median spore count of 0 cfu/m^3 was maintained or high-efficiency filtration face masks were used for neutropenic patients outside patient rooms during the construction period.[45,46]

In accordance with guidelines published by the Healthcare Infection Control Practices Advisory Committee of the CDC, the Association for Professionals in Infection Control and Epidemiology, the IDSA and the ASBMT,[19,20,47] the authors' recommend application of the following measures for nosocomial IA prevention:

(1) avoid non-emergent admissions during heavy construction periods;
(2) if possible, locate high-risk patients as far as possible from areas of demolition or construction;
(3) seal off patient care areas with adequate and impermeable barriers, and keep doors and windows closed;
(4) verify that HEPA air filtration is sufficient and proper air exchange rates are maintained. Check possible plugging or leakage of air filters. Ensure that air pressure relationships are adequate compared with adjunct rooms. Aim for positive pressure in patient rooms and for negative pressure in in-house construction areas;
(5) provide treatment in the patient's room if possible. Transport via an alternate route, schedule transportation during periods with minimal construction activity, minimize waiting times outside, and use appropriate face masks for susceptible patients if it is necessary for them to leave their rooms and pass through potentially contaminated areas;
(6) wet-clean wards thoroughly without raising dust;
(7) surveillance of infections in patients that are at increased risk for IA should be performed.

There are limitations in this approach to determine the minimal infectious dose of aspergillus spores by outbreak analysis. First, environmental investigation starts some time after an increased incidence of nosocomial aspergillosis is recognized, but the concentration of environmental airborne fungal spores varies constantly, e.g. due to climate changes or phases of spores' dissemination from construction work.[48] As such, a single peak of increased spore concentrations at the time of

infection may not be detected. Spores may have settled down in the meantime, and can be detected by environmental swabs while volumetric air samples remain free of fungi.[49,50] Second, after an outbreak has occurred, air sampling should be conducted using large volumes (>1000 L) to increase the likelihood of detecting a low level of spores;[28] however, that was not the case in many outbreak reports. Third, standardized criteria for definite, probable or possible IA were not used in all the studies included in this review. In 2002, international definitions for IA in immunocompromised patients were proposed, but data of earlier outbreak investigations may be influenced by different criteria for IA determination.[51] Finally, despite wide diversity within each species of aspergillus,[52] genotyping was seldom performed to ascertain a common source of infection.[23–33] Even if indistinguishable strains are found, it is also noteworthy that nosocomial aspergillosis is one of the few settings where nosocomial outbreaks can, and probably usually, occur due to a variety of unrelated strains. Thus, findings of similar strains in the nosocomial outbreak setting may also represent inadequate sensitivity of typing methods.

Prospective approaches where the actual airborne fungal concentration is determined in small time intervals in patient care areas during hospital construction periods could be helpful to identify an increase of airborne mould concentrations at an early stage before cases of nosocomial aspergillosis are observed. Detection of airborne aspergilli in high-risk patient care areas should always draw attention to the potential risk of a serious infection. Based on the data available at present, it is concluded that airborne mould spores at any concentration may represent a threat for severely immunocompromised patients.

Abstract: IMI are emerging as an important cause of mortality and morbidity among the growing number of immunocompromised children. A retrospective chart review was performed in all patients with a proven diagnosis of IMI over an eight-yr period (1997–2004) at The Hospital for Sick Children, Toronto, Canada to document the incidence, clinical spectrum, microbiology, treatment, and outcome of pediatric IMI. Twenty-eight patients developed IMI over the study period (10 cancer, 12 HCT, and six SOT patients). IMI occurred in 0.51%, 2.2% and 3.2% after a median time of 118, 60 and 71 days, among cancer, HCT and SOT recipients, respectively. *Aspergillus* spp. infection was diagnosed most commonly (23 patients) and the most common site of infection was the lung (21 patients). Patients at increased risk included those with acute myelogenous leukemia, allogeneic unrelated HCT recipients, graft-versus-host disease, and lung transplant recipients. The mortality after one yr was 60% among cancer patients, 58% among HCT patients, and 16% among SOT patients.

Children diagnosed with cancer or undergoing HCT or SOT are at risk of opportunistic infections including IMI. The incidence of IMI has been increasing over the past decade, commensurate with the rise in immunocompromised patients (1, 2) and filamentous fungi (molds) now represent the major cause of death due to fungi among immunocompromised patients receiving fluconazole prophylaxis (3). IMI is associated with a high mortality (1, 4, 5), and excess health care costs of approximately US$40 000 per case (2).

Shifts have been observed in the epidemiology of fungal disease with the widespread use of chemoprophylaxis regimens in high risk groups. Infections due to *Candida albicans* have decreased due to the use of fluconazole prophylaxis, while the rate of resistant filamentous fungi has increased (1). The use of itraconazole and voriconazole prophylaxis in some centers has been associated with reduced rates of aspergillosis, but increased rates of zygomycosis (6, 7). In this context, current data on the epidemiology, management, and outcome of IMI in pediatric populations are needed. We, therefore, undertook a detailed descriptive study of the epidemiology, clinical features, prophylaxis, treatment practices, and outcome of IMI in children managed at our institution over an eight-yr period (1997–2004).

Abbreviations: ALL, acute lymphoblastic leukemia; AMB, amphotericin B; AML, acute myeloblastic leukemia; CF, cystic fibrosis; CI, confidence interval; CMV, cytomegalovirus; CNS, central nervous system; GVHD, graft-versus-host disease; HCT, hematopoietic cell transplantation; ICU, intensive care unit; IMI, invasive mold infection; NS, not significant; OR, odds ratio; SOT, solid organ transplantation.

A53210128

Methods

A retrospective chart review of all cases of IMI at our institution between January 1, 1997 and December 31, 2004 (eight-yr period) was conducted. The study was approved by the research ethics board at our institution. This is a quaternary level institution with large oncology, HCT and SOT services, including kidney, liver, heart, lung, small bowel, and multivisceral transplantation.

Cases were identified through a review of microbiology records. Only cases of proven and probable IMI were included. Proven IMI was defined as culture of the mold from biopsy or autopsy tissues, with or without histopathologic evidence of tissue invasion. Probable IMI was defined as culture of the mold from respiratory tract secretions when signs and symptoms consistent with pneumonia were present. Cases of possible IMI, including CF patients with culture-positive respiratory specimens who had not received lung transplantation, were not included in this series. Both patients diagnosed with IMI during life and those diagnosed at necropsy were included. Patient records were reviewed and data was extracted relating to patient demographics, diagnosis, microbiologic confirmation, treatment, and outcome.

For the purpose of quantifying risk factors for IMI, appropriate control groups were selected from available hospital databases. Limited data were available concerning the diagnosis of GVHD in HCT patients, so a smaller subset (77 patients treated between 2003 and 2004) was used to examine whether GVHD was a risk factor for IMI. Data were descriptively summarized with comparative statistics performed where appropriate (statistical software: SPSS 15.0, SPSS Inc., Chicago, IL, USA).

Results

Twenty-eight patients with IMI were identified (10 cancer, 12 HCT, and six SOT) at our institution between January 1997 and December 2004. During this same period, an additional 1966 patients were diagnosed with cancer (393 ALL, 97 AML, 333 lymphoma, 673 solid tumor, and 470 CNS malignancy), 528 patients underwent HCT (178 allogeneic related, 143 allogeneic unrelated, and 207 autologous), and 187 patients underwent SOT (100 heart, 58 kidney, 15 liver, 10 lung, two small bowel, and two multivisceral), but were not diagnosed with IMI. The median age of patients diagnosed with an IMI was nine yr (range two months to 17 yr), and 46% were female. The underlying diagnosis and the type of transplantation are shown in Table 1.

Incidence of IMI

As summarized in Table 1, the incidence of infection (expressed as the proportion of patients in each category who developed mold infection) ranged from 0.51 (cancer patients) to 3.2% (SOT patients). Microbiological diagnosis was made at a median of 60 days after the date of diagnosis (cancer patients) or the date of transplantation (HCT or SOT patients), as shown in Table 1, although late presentation (beyond six months) was common (32% of cases).

Clinical presentation

Table 2 shows the clinical symptoms according to the site of mold infection. In this regard, the predominant symptoms and signs were referable to the lungs and sinuses. In five cases, fever was absent, including one case of *Aspergillus* pneumonia in a heart transplant patient, and four cases of extra-pulmonary disease at presentation (two cases of sacral ulcer, one thumb lesion, and one nasal septum lesion). In nine cases, the diagnosis of IMI was made more than six months after transplantation or cancer chemotherapy, including eight cases of *Aspergillus* pneumonia and one case of *Alternaria* pneumonia, and sinusitis. Infection at all sites was associated with a high mortality (Table 2): 50% of patients with pneumonia, 40% of those with sinusitis, and two of three patients with soft tissue infection died, both of whom had evidence of disseminated disease (pneumonia and osteomyelitis, respectively).

Risk factors

Table 1 summarizes the risk factors for mold infection in this cohort. Cancer patients with a diagnosis of AML were more likely to develop mold infection (OR = 45; 95% CI 11–180; $p < 0.0001$) than patients with other cancer types. Among HCT patients, those undergoing allogeneic unrelated transplantation were more likely to develop mold infection than allogeneic related or autologous transplant recipients (OR = 8.1; 95% CI 2.2–30; $p = 0.0009$). In addition, GVHD was associated with mold infection (OR = 9.9; 95% CI 2.0–50; $p = 0.002$) among allogeneic transplant recipients. Among SOT patients, lung transplant recipients were more likely to develop mold infection than liver, heart, or kidney transplant recipients (OR = 18; 95% CI 3.1–99; $p = 0.0043$). This difference remained statistically significant (OR = 12, 95% CI 2.1–67; $p = 0.012$) even after the exclusion of kidney transplant recipients, who are known to be at lower risk of IMI. All three lung transplant patients with mold infection had an underlying diagnosis of CF, and were colonized with *Aspergillus* prior to transplantation. No association was observed between the CMV serostatus (recipient or donor) and mold infection among HCT patients ($p = 0.56$, NS) or SOT patients ($p = 0.57$, NS). Neutropenia was present at the time of diagnosis in all cancer patients, in

§§$p = 0.0043$; control group consisted of 187 patients who underwent solid organ transplantation, without mold infection, between 1997 and 2004.

¶¶Fourteen patients (50%) died in the first year following cancer diagnosis or transplant, and one patient died 385 days after HCT, for an overall mortality of 54% in this series.

5/12 = 42% of HCT patients, and in none of the SOT patients (overall 15/28 = 54%).

Species of mold

Table 1 describes the type of mold isolated and the site of infection. *Aspergillus fumigatus* was the most common pathogen, followed by other *Aspergillus* species. Table 2 documents the clinical presentation according to causative pathogen. The dominant syndrome was pneumonia caused by *Aspergillus* species. The mortality was 57%, 38% and 100% among patients infected

*One patient had both pulmonary lesions and an ulcer of the hand, which was culture positive for *Aspergillus flavus* on biopsy.

with *A. fumigatus*, *A. flavus*, and *A. terreus*, respectively. The mortality was 50% among the small number of patients infected with zygomycetes and *Alternaria* spp. and the single patient with fusariosis died.

Antifungal chemoprophylaxis

Fifteen patients (54%) had received antifungal prophylaxis prior to developing IMI, including fluconazole (13 patients) and itraconazole (two patients). Both patients receiving itraconazole were lung transplant recipients with an underlying diagnosis of CF who were colonized with *Aspergillus* spp. prior to transplantation.

Antifungal treatment

In 19 cases (68%), antifungal treatment was commenced empirically at a median of six days (range 1–51 days) prior to definitive microbiologic diagnosis, due to clinical suspicion of IMI. Empiric regimens consisted of AMB in 16 cases and caspofungin in three cases. In a further seven cases, treatment was started in response to laboratory diagnosis, on the same day or up to four days later. In two cases, no antifungal therapy was administered prior to death and diagnosis of IMI was made at autopsy. Table 3 shows the duration of the various antifungal regimens used, as well as the mortality among patients with IMI despite antifungal therapy. Most patients received AMB alone, while nine patients (32%) received combination antifungal therapy.

Outcome

Figure 1 shows the mortality during the first year after diagnosis (cancer patients) or transplantation (HCT and SCT patients) for the 28 IMI patients. In all cases, the cause of death was attributed to the fungal infection. The one-yr mortality is given in Table 1. Fifteen patients with mold infection were admitted to the ICU, for a median duration of 13 days (range 2–82 days). Of these patients, 12 died and the remaining three patients recovered with critical supportive care including mechanical ventilation after a period ranging from seven to 71 days in ICU.

Table 3. Antifungal therapy

	No. patients (%)	Median duration (days, range)	Mortality (%)
No antifungal therapy*	2 (7)	0	2 (100)
AMB monotherapy	17 (61)	32 (3–777)	10 (59)
AMB + caspofungin	4 (14)	62 (31–100)	1 (25)

AMB + caspofungin + itraconazole	1 (3)	30	1 (100)

AMB, amphotericin B.
*Two patients were diagnosed with IMI at autopsy, having never received antifungal therapy.

Discussion

In an era of expanding antifungal armamentarium and increasing incidence of mold infections (1), we report a comparatively large and detailed study of immunocompromised children with IMI from a single center. Noteworthy features of this series include the broad range of immunocompromised children (cancer, HCT, and SOT patients), the spectrum of pathogens (all invasive molds, in contrast to several previous studies that examined invasive aspergillosis) and the stringent inclusion criteria (only proven or probable cases).

13993046, 2009, 5, Downloaded from https://onlinelibrary.wiley.com/doi/10.1111/j.1399-3046.2008.01056.x by NHS Education for Scotland NES, Edinburgh Central Office, Wiley Online Library on [09/06/2025]. Fig. 1. Kaplan–Meier survival curves for 28 patients diagnosed with invasive mold infection (IMI), according to category of immunocompromise [cancer, solid organ transplant (SOT) or hematopoietic cell transplant (HCT)], beginning from time of cancer diagnosis or transplantation. The difference in survival between categories was not statistically significant (p = 0.32).

The incidence of IMI varies between categories of iatrogenic immunocompromised individuals. Cancer patients in our series were significantly less likely to develop IMI (0.51%) than HCT (2.2%) and SOT (3.2%) patients. Similarly, the reported incidence of invasive aspergillosis among children with malignancy in the USA (0.5%) was lower than the incidence in pediatric HCT patients (3.4%) (2). In a prospective multicenter USA study, the cumulative incidence of IMI 12 months after transplantation was highest among HCT recipients (3.3%) and varied within SOT patients from 2.4 (lung transplant patients) to 0.1% (kidney transplant patients) (8). Variable rates of IMI have been reported in retrospective analyses: pediatric HCT recipients, 4.79% (9) and 5% (10); adult HCT recipients, 12% (1) to 15% (4); adult lung transplant patients 1.6% (11).

Unlike previous studies (1), we did not find evidence of an increase in mold infections over time. In a similar study from our institution conducted between 1979 and 1988, 39 cases of invasive aspergillosis were documented over a 10-yr period (3.9 cases/yr) (12), while the rate of Aspergillus infection during our study period was 3.1 cases/yr. Given that the number of immunocompromised patients has increased over time, the incidence of IMI (as a proportion of patients at risk) appears, in fact, to have decreased. Of note, patients have been managed in a new hospital building since 1988; therefore, the apparent higher rate of aspergillosis in the previous study may be attributable to environmental factors associated with the older building.

The timing of IMI in relation to cancer diagnosis or transplantation (HCT and SOT patients) was similar in our series (median 60 days) and other studies (1, 4). Late presentation (more than six months after onset of immunocompromised state) occurred in nearly a third of cases, when the index of suspicion for fungal infection may be lower. The lung was the most common site of infection, followed by the sinuses, as has been observed in other series (11, 13, 14). This is of relevance to the investigation of patients with suspected aspergillosis: patients with normal CT scans of their sinuses and chest have a low likelihood of aspergillosis, thereby potentially influencing choice of empiric antifungal therapy.

Clinical features reflected the site of infection: fever and cough or respiratory distress occurred in most patients with lung involvement; fever and sinus pain or headache predominated in patients with sinus involvement. Atypical presentations including IMI without fever were observed, predominantly among patients with extrapulmonary disease.

Aspergillus species predominate as the causative agent of IMI (1, 4). *Aspergillus fumigatus* was most common in our and other series (1, 4). The occurrence of a case of *A. terreus* is concerning, given the resistance of this pathogen to polyene antifungals such as AMB (15), widely used for empiric therapy at our institution. The fatal case of *Fusarium oxysporum* infection in our series highlights the poor outcome associated with this unusual but emerging fungal pathogen (5). The two cases of *Zygomycete* infection in our series may reflect the increasing incidence of this group of molds (16), difficult to distinguish from Aspergillus on clinical grounds but noteworthy for their reduced susceptibility to azole antifungals (16).

Our retrospective series confirms previously identified risk factors for IMI. Among cancer patients, IMI occurs more often in AML patients than in ALL or other malignancies (2, 13). We confirmed a strong association between a diagnosis of AML and IMI by comparing cancer patients with IMI in our series to a set of 1966 cancer patients without IMI at our institution over the same period (OR = 45; 95% CI 11–180; p < 0.0001). Among HCT patients, allogeneic transplant recipients have higher rates of IMI than autologous transplant recipients (2, 10), and we found a significant association (p = 0.0009) between allogeneic HCT and IMI. Among allogeneic HCT recipients, GVHD is a recognized risk factor for IMI (10). In one USA series, the risk of IMI was 42% in patients with grade III or

A53210128

13993046, 2009, 5, Downloaded from https://onlinelibrary.wiley.com/doi/10.1111/j.1399-3046.2008.01056.x by NHS Education for Scotland NES, Edinburgh Central Office, Wiley Online Library on [09/06/2025]. See the Terms and Conditions (https://onlinelibrary.wiley.com/terms-and-conditions) on Wiley Online Library for rules of use; OA articles are governed by the applicable Creative Commons License

IV acute GVHD, 14% in patients with grade I or II acute GVHD, and 6% among patients without GVHD (4). Likewise, in our series, GVHD was associated with IMI (OR 9.9; 95% CI 2.0–50; p = 0.002). Compared with other SOT recipients, the rate of IMI was higher among lung transplant recipients in our series, as in previous reports. In one series, the cumulative incidence of invasive aspergillosis one yr after SOT was 2.4% (lung) vs. 0.8% (heart), 0.3% (liver) and 0.1% (kidney) (8). Similarly, in a retrospective series of SOT patients, the attack rate of invasive aspergillosis was 12.8% (lung) compared with 0.7% (liver), 0.4% (kidney), and 0.4% (heart) (11). At our institution, during the study period, three of 13 lung transplant patients developed Aspergillus infection, compared with 10 of 187 non-lung SOT patients (OR 18; 95% CI 3.1–99; p = 0.0043). Other studies have cited neutropenia as a risk factor for IMI (5), which was common in our patient series. We did not detect an association between CMV serostatus and risk of IMI, although CMV infection has been shown to predispose to IMI in other studies (4). These risk factors (AML, allogeneic HCT, and GVHD) collectively point to aggressive iatrogenic immunosuppression as the underlying reason for susceptibility to IMI. Increased rates of IMI, particularly aspergillosis, in lung transplant patients can be explained by the exposure of the allograft to the external environment (in contrast to kidney, heart, and liver transplants) and high pretransplant rates of Aspergillus colonization or infection in the CF population, which constitutes a large proportion of lung transplant patients.

Although 13 patients in our series received fluconazole prophylaxis, few received chemoprophylaxis with activity against filamentous fungi. Two lung transplant patients received itraconazole, yet still developed pulmonary aspergillosis. The American Society of Transplantation and American Society of Transplant Surgeons recommend prophylaxis with voriconazole, itraconazole or echinocandins with or without nebulized AMB for a duration of 4–6 months (17) for lung transplant recipients, based on evidence from case series (11, 18–20) and one non-randomized retrospective study (21). The use of antifungal prophylaxis has been recently reviewed for cancer, HCT, and SOT patients (22–24). Of note, the triazole antifungal posaconazole, with broad spectrum activity against filamentous fungi has recently been approved for prophylaxis in allogeneic HCT recipients with GVHD and in patients with acute myelogenous leukemia undergoing induction chemotherapy based on two large, prospective randomized controlled trials (25, 26).

Variability in the antifungal regimen and duration of therapy in our series reflect a lack of data on the optimal treatment for mold infections, as highlighted by a recent systematic review (27). Similar to other reports (13, 28), the most commonly prescribed antifungal for invasive fungal infection at our institution was AMB. Caspofungin (usually in combination with other antifungal agents) has been used to treat IMI in pediatric patients with variable efficacy (29–32), and was the second most commonly used antifungal in our series. Voriconazole, which demonstrated superior efficacy against invasive aspergillosis compared with AMB in a randomized controlled trial (33), has been used as salvage therapy in immunocompromised children in previous series (26, 34) and was the third most commonly used antifungal in our cohort. There is considerable interest in, though little clinical data at present (3) to support the use of combination antifungal therapy, which was used in 25% of patients in our series. Mortality appeared lower in patients receiving dual or triple antifungal therapy, relative to AMB alone, although difference did not achieve statistical significance.

Six of 28 (21%) patients in our series were diagnosed with invasive fungal infection at autopsy, and two of these patients had received no antifungal therapy during life. Likewise, in previous autopsy series, fungal infections feature prominently among clinically unsuspected causes of death (35–38). Among patients with hematologic malignancies undergoing autopsy at a tertiary center in the USA, 31% had invasive fungal infection, and 75% of these cases were not diagnosed ante-mortem (39).

Mortality after IMI is high, as demonstrated in our and other series. Fifteen of 28 children (54%) with IMI died, similar to the mortality in a multicenter retrospective review of pediatric invasive aspergillosis of 52.5% (2). Among cancer patients, mortality one yr after diagnosis was 60%, similar to the 79% mortality in patients with hematologic malignancy and fusariosis (40). Among HCT recipients, the one-yr mortality of 58% observed in our series is comparable with the rate observed in one prospective study (54–85%) (8). Trials of antifungal therapy have reported somewhat lower mortality rates, as in a randomized controlled trial that showed death because of Aspergillus in 29% of the group receiving voriconazole vs. 42% of those receiving AMB (33). Mortality in reports involving only

pediatric patients varies from 18% (13) to 88% (10), with small number of patients in these series. A multi-center study of children with invasive aspergillosis in the USA documented an in-hospital mortality of 18% and an overall mortality of 44% (2).

In summary, IMI is an unusual but often fatal complication among immunocompromised children. Aspergillus species predominate, and risk factors include acute myelogenous leukemia, allogeneic unrelated HCT, GVHD, and lung transplantation. The optimal therapy has not been defined, and mortality remains high despite antifungal treatment.

Summary

Invasive aspergillosis (IA) is an increasingly common and often fatal fungal infection in children with haematological disorders. To describe the epidemiology, diagnosis, treatment and outcome of IA in children, retrospective review of the medical records of proven and probable IA between January 1986 and December 2000 was used. Twenty-four patients with IA were identified (10 proven and 14 probable) with a median age of 8.5 years. The incidence of IA was particularly high in acute myeloblastic leukaemia (5.35%) and leukaemia relapse (4%). Twenty-two patients presented with lung involvement. Broncho-alveolar lavage led to a diagnosis in 11 cases, but diagnosis was difficult and repeated invasive explorations were required. Antifungal therapy mainly consisted of amphotericin B. Eight patients underwent open-thorax surgery without any complication. Nine patients (37.5%) were cured of IA and three are still alive. The mortality was 87.5%. Three patients died of massive haemoptysis, including two before neutropenia recovery. Four patients presented with IA recurrence and three were cured again. Despite significant progress having been made in the treatment and diagnosis of IA, it is still a devastating complication in children with haematological disorders. New antifungal therapies and strategies are promising, but objective data are still lacking.

Key words: Invasive aspergillosis, haematology, cancer, children, lung.

Introduction

Aspergillus is a ubiquitous and saprophytic mould. Its airborne conidia are extremely common in the environment, including air within hospitals, and can be responsible for patient contamination. Since the first description in 1953[1] invasive aspergillosis (IA) has become an increasing concern. IA is now the second most common cause of fungal infection after candidosis,[2,3] and it is the foremost cause of death owing to fungal infection.[4–6] Diagnosis of IA is often difficult. Despite therapy, the prognosis is considered very poor, especially in agranulocytic patients.[7]

To describe the characteristics of IA among children with haematological diseases and immunodeficiency syndromes before the advent of new drugs, such as voriconazole or caspofungin, we reviewed the medical records of proven and probable IA in children over a 15-year period.

Debrousse Hospital, Lyon, France is a tertiary referral centre. This single-centre retrospective study was performed from January 1986 to December 2000 on a large population with malignant and non-malignant haematological diseases and immunodeficiency syndromes. During this period, we performed 379 allogeneic HSCT. Patients were treated according to the European Organization for Research and Treatment of Cancer (EORTC), the French Society for Pediatric Oncology (SFOP) and the French Society of Bone Marrow Transplantation (SFGM) protocols. Patients undergoing HSCT and those with prolonged neutropenia were cared for in a laminar air flow (LAF) room. No patient received primary prophylactic therapy against *Aspergillus*. On the other hand, secondary chemoprophylaxis against *Aspergillus* [intravenous amphotericin B (AmB) or itraconazole] was systematically initiated after a first history of IA for all new neutropenic period or HSCT. Empirical broad-spectrum antibiotic therapy was immediately started for febrile neutropenic patients after an evaluation, including a chest radiograph. Intravenous AmB desoxycholate (0.5 mg kg^{-1} day^{-1}) was started after 72 h of persistent fever or sooner in the case of a pulmonary manifestation or an abnormal chest X ray.

Identification and case definition

Cases of IA were identified by review of the infection surveillance department data, pathology reports and microbiological reports. Patients were included if they had proven or probable IA as defined by the EORTC criteria.[8] Proven IA requires histopathology or cytopathology showing *Aspergillus* hyphal invasion, or a positive culture from a radiologically abnormal site that is normally sterile. Probable infection is defined by microbiological criteria in a patient with typical host factors for IA, such as current neutropenia, fever refractory to antibiotics, graft vs. host disease (GVHD), prolonged use of corticosteroid, fever and either neutropenia in the previous 60 days, or the use of immunosuppressive agents or previous fungal infection. Microbiological criteria include sputum or bronchoalveolar lavage (BAL) culture positive for *Aspergillus*, or positive *Aspergillus* antigen in two consecutive blood samples. Clinical criteria include nodular opacities on computerised tomography (CT) scan. Possible IA is defined as having the host factors for IA but lacking the clinical or microbiological features. Possible IA cases were excluded from our study. Medical records of the identified cases were reviewed retrospectively for patient's demographics, underlying diseases, diagnostic procedures, extent of the infection, treatment and outcome.

Microbiology

A direct examination of the samples [BAL, peritoneal liquid, pus, tracheal aspiration, cerebrospinal fluid (CSF)] and biopsies (lung, pericardium) was performed after Giemsa and Grocott staining. The specimens were inoculated onto Sabouraud-chloramphenicol media, and the species were identified by their morphology. Until 1997, Latex agglutination (Pastorex® *Aspergillus*; BioRad, Marnes-la-Coquette, France) was used for galactomannane antigen detection in samples of BAL, CSF and serum. After 1997, sandwich enzyme-linked immunosorbent assay (Platelia® *Aspergillus*; BioRad) was used for antigen detection. If IA was suspected, antigen assay was performed, but it was not routinely done.

Results

Patient demographics and underlying conditions

Twenty-four cases of IA were identified (10 proven and 14 probable): 12 males and 12 females with a median age of 8 years at IA diagnosis (Table 1). The median age at the time of the underlying disease diagnosis ranged from 0 to 16 years (median, 7 years). The interval between the onset of the underlying disease and the diagnosis of IA was 1.5 to 132 months (median, 8.5 months). Underlying diseases are reported in Table 2. Among the 13 patients treated for acute myeloblastic leukaemia (AML) and acute lymphoblastic leukaemia (ALL), six (46%) were in relapse. Twenty-two patients (92%) had experienced neutropenia (neutrophil count <0.5 G l^{-1}) for 13–277 days (median, 101 days). Among those 22 patients, 11 (50%) were still neutropenic at the time of IA diagnosis. For the others, the time between neutropenia recovery and onset of IA was 1–480 days (median, 40 days). Twenty-one patients (87.5%) had received chemotherapy and 10 (41.6%) had been treated with allogeneic HSCT before IA. Prior to IA, antifungal therapy was administered to seven children (29%): four patients with persistent undocumented fever and three patients with *Candida albicans* infection. All patients were treated with AmB or its lipidic formulations. Ten patients (42%) were treated with corticosteroid at the time of diagnosis of IA with a median dose of 1 mg kg^{-1}.

For nine patients (38%), a concomitant infection was diagnosed. One patient presented with a systemic

AML, acute myeloblastic leukaemia; SCID, severe combined immunodeficiency; ALL, acute lymphoblastic leukaemia; FLH, familial lymphohistiocytosis; CGD, chronic granulomatous disease; MDS, myelodysplasia; JMML, juvenile myelomonocytic leukaemia; BAL, bronchoalveolar lavage; PL, peritoneal liquid; CSF, cerebrospinal fluid; AmB, amphotericin B; 5FC, flucytosine; itraco, itraconazole; AmB lip, lipidic formulation of amphotericin B; IA, invasive aspergillosis; i.v., intravenous; IFN, interferon; MFC, multifactorial cause.

adenovirus infection. Four patients presented with sepsis involving *Alcaligenes dentrificans* ($n = 1$), *Staphylococcus haemolyticus* ($n = 1$), *C. albicans* ($n = 1$) and *Capnocytophaga* ($n = 1$). For four patients, microbiological investigations on BAL samples revealed (besides *Aspergillus*) the presence of *P. aeruginosa* ($n = 1$), *Herpes simplex virus 1* ($n = 1$), *Coronavirus* ($n = 1$) and *C. albicans* ($n = 1$). At the onset of IA, cytomegalovirus (CMV) serology was positive in 10 patients (42%), but only two had experienced severe infection during previous immunosuppression period.

Mycological studies

Aspergillus species was isolated from 22 patients: *Aspergillus fumigatus* (18 cases), *Aspergillus nidulans* (three cases), *Aspergillus flavus* (one case) and *Aspergillus terreus* (one case). Two species were isolated in BAL culture (*A. fumigatus* and *A. nidulans*) from only one patient (patient 18).

Clinical, radiological and biological findings

The lung was the most commonly involved organ (22 cases). Nineteen patients (80%) had a single localisation involving lung in 18 cases and middle ear in one case. For the others, infection was multifocal. Fever was observed in 22 patients (90%). Median time between the first symptom and diagnosis confirmation was 12 days (0–230 days).

Lung involvement

In eight cases (36%), chest radiographs showed the typical nodules or air crescent sign of invasive pulmonary aspergillosis (IPA). A CT scan was performed in 15 patients, of which 11 (74%) displayed evocative aspects with nodules, halo sign or air crescent sign.

Among the 11 diagnoses of IA based on BAL examination, seven (64%) were made on the first BAL, two (18%) on the second BAL and two on the third BAL. In five cases, diagnosis was made on lung specimens from surgical biopsy or lobectomy. Among those five cases, surgery was the first diagnostic procedure for two patients. For two others, surgery was performed after a negative culture for *Aspergillus* on BAL samples. For the fifth case, surgery was performed after a negative BAL and a negative culture from a needle biopsy specimen.

Other IA localisation included the central nervous system (three), bone (two), mastoid (one), middle ear (one), peritoneum (one), pericardium (one), endocardium (one) and chest wall (one).

No autopsy was performed in our study. No blood culture was positive for *Aspergillus.* The C-reactive

Table 2 Underlying diseases, IA incidence in our study compared with previous paediatric studies

Underlying diseases (number of patients)	IA incidence	IA incidence for Abbasi *et al.* [12] (%)	IA incidence for Zaoutis *et al.* [26] (%)	IA incidence for Groll *et al.* [27] (%)
AML (112)	6/112 (5.35%)	4	3.7	27.77
Total ALL (464)	7/464 (1.5%)	1	0.6	2.06
ALL relapse (101)	4/101 (4%)			8.57
SCID (ND)	3/ND			
Fanconi anaemia (ND)	2/ND			
Aplastic anaemia (30)	1/30 (3.3%)	4.6	1.4	
CGD (ND)	1/ND	7	6.5	
JMML (ND)	1/ND			
Hurler disease after HSCT (ND)	1/ND			
FLH (ND)	1/ND			
Myelodysplasia (ND)	1/ND			

IA, invasive aspergillosis; AML, acute myeloblastic leukaemia; ALL, acute lymphoblastic leukaemia; SCID, severe combined immunodeficiency; ND, not determined; CGD, chronic granulomatous disease; JMML, juvenile myelomonocytic leukaemia; HSCT, haematopoietic stem cell transplantation; FLH, familial lymphohistiocytosis.

protein assay was assessed in 23 patients and ranged from 13 to 440 mg l^{-1} (median, 158 mg l^{-1}).

Therapy and outcome

Twenty-two patients (92%) received intravenous AmB desoxycholate over a period of 2–131 days (median, 26 days). Six patients were treated with a lipidic formulation of AmB as Ambisome® (Gilead Sciences, Foster City, CA, USA) (one patient) and Abelcet® (Zeneus Pharma, UK) (five patients) for 3–43 days (median, 19 days). Fifteen patients (58%) received itraconazole for 3–949 days (median, 38 days), and three patients were treated with flucytosine for 2–60 days (median, 33 days). Fourteen patients (58%) received G-CSF. Other treatments are summarised in Table 1. Reversible renal function impairment occurred in: five patients on AmB desoxycholate; one patient on itraconazole; and two patients on Abelcet®. No patient required dialysis.

Surgery

Eight patients underwent thoracic surgery (thoracotomy): one resection of a unilateral lesion, one resection of bilateral lesions (two left and one right), four lobectomies (including one patient who underwent a controlateral lesion resection at a later time). In two surgeries, a total resection was impossible. There were no severe surgical complications.

Outcome

Nine patients (37.5%) were considered cured of IA. Among those nine patients, three patients (patients 7, 20 and 22) are still alive at follow-up of 15, 9 and 7 years on April 2007 and six died from relapses or complications of the underlying disease with a median survival of 110 days after IA (53 days to 5.5 years). Nine patients died of IA (fatal IA outcome). For the six other patients, the cause of death was multifactorial. Median survival for patients with fatal IA outcome was 17 days (0–290 days). Median survival for patients with multifactorial cause of death was 15 days (0–90 days). For patients with fatal IA outcome, causes of death were: massive haemoptysis (three patients); pulmonary failure (three patients); pulmonary failure and intracranial hypertension with cerebral herniation (one patient), multiple organ failure related to IA (two patients). Hence, after the diagnosis of IA, 21 patients (87.5%) died with a median survival of 45 days (0–5.5 years), and to date, only three patients are alive.

Four children suffered IA recurrence. Recurrences occurred during a neutropenic period for patient 6, and after an allogeneic HSCT for patients 20 and 21. For patient 22, IPA relapsed at the same location despite normal granulocyte count. It is remarkable that among the four patients with IPA recurrence, three had favourable outcomes with two still alive and well.

Discussion

Gerson *et al.* [9] demonstrated that neutropenia is a major risk factor for IA in adult patients. Twenty-two of our patients (91.6%) presented with at least one neutropenic period before IA, all of which were subsequent to cytotoxic chemotherapy, except for one patient with aplastic anaemia. However, only 50% of our patients were neutropenic at the time of IA

A53210128

diagnosis. This could be the result of two factors. First, some IPA diagnoses were probably delayed owing to the unavailability of a CT scan in the hospital. Therefore, CT scan was delayed until after haematological recovery and LAF room discharge. Second, our study included a high number of cases of congenital immunodeficiency and allogeneic HSCT. These cases involve severe, extensive and global immunodeficiency beyond the quantitative decreased level of neutrophil granulocyte. Only two children did not experience neutropenia: patient 2 with adenosine deaminase deficiency severe combined immunodeficiency (SCID) and patient 8 with chronic granulomatous disease.

The underlying diseases and respective incidence of children with IA are reported in Table 2. Our data are compared with the main published paediatric series. In our study, the incidence of IA in children with AML was high (5.35%) despite the use of the LAF room for the duration of all neutropenic periods. Only one patient with aplastic anaemia developed IA (incidence: 3.3%). In adult series, the incidence of IA in aplastic anaemia ranges from 5% to 10%.[10,11] The underlying conditions displayed paediatric specificities: three patients with SCID (patient 2 with adenosine deaminase deficiency; patient 18 with purine nucleoside phosphorylase deficiency; and patient 23 with HLA class II antigen deficiency); two patients with Fanconi anaemia; and one patient with Hurler disease that developed IA after HSCT. One patient presented with a familial lymphohistiocytosis.

Invasive aspergillosis and a disseminated form of IA were probably underestimated in our study for three reasons. First, autopsies were rarely performed in our institution. In the study of Abbasi *et al.* [12], autopsy was performed in 68% of the cases. Among the 26 cases of IPA, autopsies allowed the diagnosis in 13. Among the 24 children with premortem diagnosis of unifocal involvement, 15 were found to have multifocal infection at postmortem. Second, systematic empirical antifungal therapy may have cured some patients before diagnosis. Third, because of ethical considerations, we did not pursue diagnostic exploration in palliative-care patients. Autopsies are needed to be performed more systematically in our institution in order to better estimate the incidence and extent of *Aspergillus* infection.

Infection was multifocal in 20% of cases, involving two, three or four organs. Lung was the most commonly involved organ with 22 patients (92%) having unifocal or multifocal lung infection. IPA was particularly frequent among our patients (70% for Abbasi *et al.* [12] and 41% for Walmsley *et al.* [13]). This high frequency of lung involvement in our study, compared with previous studies, is probably related to systematic BAL whenever a lung infection was suspected. Massive haemoptysis is a major threat during IPA.[14] Three of our patients (1, 5, 21), i.e. one-third of the death imputed to IA, died suddenly in this dramatic and uncontrollable situation. The role of granulocytes in this complication has been emphasised.[15] In most cases, haemoptysis occurs within 7 days after the neutrophil count exceeds 0.5 G l^{-1}. Caillot *et al.* recommend an early surgical resection of a threatening lesion detected on repeated chest CT scans prior to neutropenia recovery.[16] However, it is noteworthy that only patient 5 presented with haemoptysis after neutropenia recovery. Both patients 1 and 21 were still neutropenic at the time of haemoptysis.

As demonstrated in previous studies,[16,17] CT scan is more effective in establishing a diagnosis than chest radiograph, demonstrating an evocative aspect in 74% vs. 36% in our study. BAL sensitivity is above 60% in adult reports[18] and 55% in our series. No incident was reported during endoscopy and BAL. Based on BAL, trans-thoracic biopsy or surgery findings, diagnosis was made on the first investigation in nine patients; on the second investigation in four; and on the third investigation in three. IPA diagnosis is difficult and explorations should be repeated.

The absence of sinus and skin aspergillosis is remarkable in our study. Skin aspergillosis has been reported to be more common in children than in adults. Abbasi *et al.* [12] reported 13 children (20% of their patients) with skin involvement. Walmsley *et al.* described 16 cutaneous aspergillosis (41% of their patients), and a review of the literature revealed that 67% of skin involvement cases occur in children.[13] Arm boards, commonly used in children in order to prevent movement at the peripheral catheter site, are implicated.[13] The systematic use of central venous catheter avoids the use of peripheral lines. The absence of any bandages or arm board may explain the absence of any skin infection in our population.

Twenty-three *Aspergillus* species were isolated from 22 patients. As reported in other reviews,[10] *A. fumigatus* is the most common species responsible for IA in our study (78% of cases). It is noteworthy that in the two North American paediatric studies (Memphis, TN, USA[12] and Toronto, ON, Canada[13]), epidemiology was different: *A. flavus* was the most frequently identified species (55% and 65%, respectively), as *A. fumigatus* was identified only in 29% and 15% of cases, respectively.

Until the end of our study, only AmB and its lipidic formulations, itraconazole and flucytosine, were

routinely used as antifungal therapy in our institution. All patients received AmB (desoxycholate or lipidic formulation) as the 'gold standard' antifungal therapy.[19] New drugs, such as voriconazole and caspofungin, have recently become available and should improve the prognosis.[20–23]

Eight patients underwent open chest surgery without any complication. Among them, five experienced a favourable outcome. Our results suggest an added benefit of surgical resection, and are in accordance with the data already published.[24] All surgeries were performed after haematological recovery in order to prevent relapse and dissemination during future immunosuppression periods. Earlier surgery may improve survival by reducing the risk of fatal haemoptysis.[16]

The prognosis of IA remains dismal.[25] IA is considered a major death risk factor in children with malignancies with relative risk (RR) estimated at 13.5 by Zaoutis *et al.* [26]. In our study, the overall mortality was 87.7%. This result is comparable with other paediatric studies: 85% for Abbasi *et al.* [12] in 1999; 74% for Walmsley *et al.* [13] in 1993, in which 41% were skin aspergillosis, explaining a better prognosis; and, 70% for Groll *et al.* [27], in which definition criteria were more permissive than ours.

In our study, the cure rate of IA was at least 37.5% with a median follow-up of at least 6 years. Thirty-seven per cent to 62% of the deaths were directly related to IA with a median survival of 17 days (0–312 days). These results are comparable with adult series.[7,28] In addition, among the four patients developing IA recurrence, three were cured and two of them are long-term survivors.

Conclusion

Our study demonstrates that IA is a frequent and deadly complication in severely immunocompromised children, in particular for children treated for AML. Despite progress in diagnostic procedures and therapeutics, mortality remains high. Future studies and research should focus on the identification of patients at risk, an effective prophylactic treatment, and earlier diagnosis. Newly available drugs may improve prognosis, but controlled clinical trials are still required.

Interim Chief Nursing Officer
Anne Armstrong

Scottish Government

Scottish Government
Riaghaltas na h-Alba
gov.scot

Dear Colleagues

Further Update on Standards on Healthcare Associated Infections

In February 2023, DL (2023)06 was issued informing Health Boards that the previous healthcare associated infection (HCAI) standards and antibiotic use indicators originally due to expire in 2022, were extended to 2024. Since this letter, an objective to review the HCAI standards and indicators was included in the current two-year HCAI Strategy 2023-2025.

Antimicrobial Resistance and Healthcare Associated Infection (ARHAI) Scotland were commissioned and in their response, outlined a range of options based on the analysis of the current targets and trends, as well as stakeholder engagement.

The Cabinet Secretary for Health and Social Care considered the recommendations and has approved that the standard **should be no increase in the incidence (number of cases) of *Clostridioides difficile* infection (CDI), *Escherichia coli* bacteraemia (ECB), and *Staphylococcus aureus* bacteraemia (SAB) by March 2026 from the 2023/2024 baseline.**

ARHAI Scotland will provide Boards with the 2023/2024 baseline number of CDI, ECB and SAB cases to enable local monitoring.

The national HCAI surveillance programme in Scotland is under review with the recommendations due to Scottish Government by November 2025 (a deliverable within the HCAI Strategy). The surveillance review will consider new standards once the direction of the national mandatory HCAI surveillance programme has been set. Further communications on the surveillance programme will be shared at a later date.

We recognise the hard work that Health Boards have undertaken to work towards these targets in challenging circumstances and we expect Health Boards to maintain standards and continue to prioritise reductions in CDI, ECB and SAB.

Finally, the UK AMR National Action Plan (NAP) sets out renewed UK-wide antibiotic use targets – namely the ambition to, by 2029, reduce total antibiotic use in human populations by 5% and to achieve 70% of total use of antibiotics from the Access category across the human healthcare system. Both targets are set against a 2019/20 baseline. The Scottish Government is currently working with the Scottish Antimicrobial Prescribing Group on a set of supplementary antimicrobial prescribing targets to support the high level NAP goals across both primary and secondary healthcare settings. Further details on these supplementary targets in a further communication in due course.
