

**Bundle of documents for Oral hearings
commencing from 19 August 2024 in
relation to the Queen Elizabeth University
Hospital and the Royal Hospital for
Children, Glasgow**

**Bundle 20 – Documents referred to in the
Expert Reports by Andrew Poplett and
Allan Bennett**

This document may contain Protected Material within the terms of [Restriction Order 1](#) made by the Chair of the Scottish Hospitals Inquiry and dated 26 August 2021. Anyone in receipt of this document should familiarise themselves with the terms of that Restriction Order as regards the use that may be made of this material.

The terms of that Restriction Order are published on the Inquiry website.

Table of Contents

1	A44943543	01 Physical changes Levels 4, 5 and 7 - from S.21 response - 14 July 23	Page 8

The Following document is a Request for Information (RFI) response received by the Scottish Hospital Inquiry from NHS GGC

Request for Information - Section 21 Notice - No 18 (Ventilation Systems)

1. **Physical changes to the ventilation system operation:** From handover on 26 January 2015 to date, please provide: -
 - a) **A list of all physical changes made by the Board to the operation of ventilation system which were made as a result of concerns about its safety or as a result of a hypothesis/risk but not a known safety concern. For the avoidance of doubt, this request includes permanent and interim steps taken to rectify, remediate, or upgrade the ventilation system.**
 - b) **A succinct explanation of the reason why each of the steps identified was taken.**
 - c) **A description of any steps that the Board took to install HEPA filtration. The Inquiry would like to understand the position at handover and the current position in the Hospital. For the avoidance of doubt, this request includes permanent and interim steps taken to rectify, remediate or upgrade the HEPA filtration. This should include any steps that were taken to use mobile HEPA filtration units.**
-

Wards 4C, 5C, 5D, 7B, 7C and 7D

This response seeks to address the information requested about physical changes to the ventilation system operation for 4C, 5C, 5D, 7B, 7C and 7D ward areas. This response should be read in conjunction with RFI S21 No 10 submitted on 9th December 2022.

In this response we have include the description of works undertaken on the ventilation systems to adjust pressure cascades and direction of air flows which are standard mechanisms for balancing and adjustment but not strictly physical changes to the ventilation system.

In November 2018, the Lead Infection Control Doctor (LICD) and a colleague undertook a limited survey on 4 rooms in each of wards 4C, 5C and 5D. The purpose was to confirm positive protection of patients in ward 4C from room to corridor and negative protection of others from the patient room to the corridors in wards 5C and 5D.

Following this review the LICD indicated they had specific concern around wards 5C and 5D that housed patients with infectious diseases. The concern was around the potential risk of infection being spread by this patient group to staff and members of the public in the ward area if the rooms were not negatively pressured. Estates were asked to undertake a complete survey of all patient rooms in 5C, 5D and 4C and also to include Wards 7A and 7D. Estates undertook initial surveys to record the room pressure differentials from patient room to corridor and reported the findings to the LICD. Estates then engaged an external ventilation company to make adjustments to the fan speeds and damper positions. On completion of this work, reports were issued to Estates and then forwarded to the LICD.

A summary of what was instructed for each of the wards, how each ward is served from the plantrooms and the outcome of the adjustments as recorded in the reports is noted below.

Ward 4C houses renal and renal oncology patients. The area is served by 3 Air Handling Units (AHUs) located in plantroom 124 on level 12 identified as 124 AHU 04, 124 AHU 05 and 124 AHU 06 and there have been no physical changes to the 3 ventilation units serving Ward 4C since handover on 26 January 2015. Due to the patient group housed in 4C, there was a need for the rooms to be positive to the corridor, that is, air flow from room to the corridor, with a target pressure differential of 1Pa or more. The report issued on 3rd December 2018 for Ward 4C provided pressure cascade readings which indicated that by increasing extraction fan speed in units 04 and 05 and adjustment of dampers within the ductwork this had been achieved.

In March 2019, the F7 secondary filters within the AHUs serving levels 4 to 7 in plantroom 124 were replaced with a higher grade F9 filter to improve the source air quality delivered to these spaces.

There is no HEPA filtration within the plant room AHUs or within the ductwork serving Ward 4C. The ward has 18 rooms allocated for renal patients and 10 rooms for renal oncology patients. January 2019, the ventilation system to the 10 oncology rooms was supplemented by floor standing HEPA filter air scrubbers. These scrubbers filter and recirculate air within the space improving the air quality within the patient bedroom. In January 2019 the Ceiling Ventilation Grilles were removed and replaced with a standard ceiling tile to reduce the risk of particulate moving from the corridor ceiling void into the corridor transfer area and rooms.

In the period between October and December 2020, a programme of works was undertaken to fit HEPA filtered air scrubbers within the ceiling voids of the en-suites in all 28 patient rooms of the ward. These units are not integrated within the existing ductwork system. These units recirculate air within the en-suite space through HEPA filtration improving the air quality within the space. **Ward 5C** is served by 3 Air Handling Units (AHUs) located in plantroom 124 on level 12 identified as 124 AHU 04, 124 AHU 05 and 124 AHU 06 and there have been no physical changes to the 3 ventilation units serving Ward 5C since handover on 26 January 2015.

The desired outcome of adjustments was for patient rooms to be negative pressure to the corridor, that is, air flow from corridor to room, with a target pressure differential of 1Pa or more. The report issued on 3rd December 2018 for Ward 5C provides pressure cascade readings which indicated this had been achieved.

In March 2019, the F7 secondary filters within the AHUs serving levels 4 to 7 in plantroom 124 were replaced with a higher grade F9 filter to improve the source air quality delivered to these spaces.

There has been no HEPA filtration, portable or fixed, added to any areas within the rooms or en-suites within Ward 5C. There is no HEPA filtration within the plant room AHUs or within the ductwork serving Ward 5C.

Ward 5D is served by 3 Air Handling Units (AHUs) located in plantroom 123 on level 12 identified as 123 AHU 04, 123 AHU 05 and 123 AHU 06 and there have been no physical changes to the 3 ventilation units serving Ward 5D since handover on 26 January 2015.

The desired outcome of adjustments was for patient rooms to be negative pressure to the corridor, that is, air flow from corridor to room, with a target pressure differential of 1Pa or more. The report issued on 23rd December 2018 for Ward 5D provides pressure cascade readings which indicated this had been achieved.

There has been no HEPA filtration, portable or fixed, added to any areas within the rooms or en-suites within Ward 5D. There is no HEPA filtration within the plant room AHUs or within the ductwork serving Ward 5D.

Wards 7B, 7C and 7D

Ward 7B is served by 3 AHUs in plantroom 121, located on level 12. There are 3 AHUs serving ward 7B which are identified as 121 AHU 04, 121 AHU 05 and 121 AHU 06. There have been no physical changes to the ventilation system serving ward 7B since handover on 26 January 2015. There have been no alterations to the fan speeds. There has been no HEPA filtration, portable or fixed, added to any areas within the rooms or en-suites within Ward 7B. There is no HEPA filtration within the plant room AHUs or within the ductwork serving Ward 7B.

Ward 7C is served by 3 Air Handling Units (AHUs) located in plantroom 124 on level 12 identified as 124 AHU 04, 124 AHU 05 and 124 AHU 06 and there have been no physical changes to the 3 ventilation units serving Ward 7C since handover on 26 January 2015. There have been alterations to the fan speeds serving Ward 7C. These alterations were a consequence of the required pressure changes on Wards 4C and 5C as 7C is served by the same group of AHU's. On completion of the works to these wards the air flows to Ward 7C were rebalanced to their original state.

There has been no HEPA filtration, portable or fixed, added to any areas within the rooms or en-suites within Ward 7C. There is no HEPA filtration within the plant room AHUs or within the ductwork serving Ward 7C.

In March 2019, the F7 secondary filters within the AHUs serving levels 4 to 7 in plantroom 124 were replaced with a higher grade F9 filter to improve the source air quality delivered to these spaces.

Ward 7D is served by 3 Air Handling Units (AHUs) located in plantroom 123 on level 12 identified as 123 AHU 04, 123 AHU 05 and 123 AHU 06 and there has been no physical changes to the 3 ventilation units serving Ward 7D since handover on 26 January 2015.

The desired outcome of adjustments was for patient rooms to be negative pressure to the corridor, that is, air flow from corridor to room, with a target pressure differential of 1Pa or more. The report issued on 23rd December 2018 for Ward 7D provides pressure cascade readings which indicated this had been achieved.

There has been no HEPA filtration, portable or fixed, added to any areas within the rooms or en-suites within Ward 7D. There is no HEPA filtration within the plant room AHUs or within the ductwork serving Ward 7D.

Original Specification

The original clinical output specification from 2009 for the Haemato-oncology area at the New SGUH clearly specified that this patient group is vulnerable to infection and therefore require the provision of a protected environment. The ventilation section of this document details the following requirements in relation to this:

Please note that the haemato-oncology ward has a very specific function. There should be no opening windows. The space should be sealed and ventilated. Positive pressure to the rest of the department and all highly filtered air >90%, probably best HEPA with adequate number of positive pressure sealed HEPA filtered side rooms for neutropaenic patients as in the Beatson West of Scotland Cancer Centre.

An appendix to the specification details that the HEPA filters meet EU12 standard (99.99% @ 0.3µm)

Advice for this was sought from Dr John Hood Consultant Microbiologist

Specification for rooms at WoS Cancer Centre

In the absence of definitive UK guidance on builds for severely immunocompromised patients the positive pressure side rooms are built to the CDC specification that is 12 air changes per hour and the rooms at a positive pressure to the corridor of 5-10 kPa.

Build process

Confirmation that the build was progressing as expected was sent to the clinical team on 9th December 2013 from Heather Griffin:

Thank you for your e-mail and also for your time in meeting with us the other day.
With regard to your query -

1. The spec for the Haemato-oncology area is as requested by John, in other words - hepa filtration positive to the rest of the hospital and all highly filtered air to H13 ie 99.95%. (Myra, refer to the plan I gave you).
2. The pentamidine treatment room is negatively pressured.

John is John Hood as described in the original specification above.

The expectation therefore was that the Haem-onc unit at SGUH was being built to the same standard as WoS Cancer centre.

Commissioning

The Infection control team was assured that all areas of the SGUH had been fully commissioned and validated from a Mechanical and Ventilation point of view. The details of the validation were not provided but that is not unusual as this is an

engineering specialism and ICPT's would only normally be involved in the event of significant failure. It is now apparent that Brookfield had not been required to undertake particle count test as part of their commissioning process.

Current deficiencies identified

1. HEPA Filtration for high risk patients	HEPA filtration in each room , 2 rooms verbally reported NOT to be HEPA filtered
2. Positive Pressure in each room 5-10 Pa in relation to corridor	No method of measuring pressure gradient is currently installed in any of the 4B rooms Verbally reported as 10 Rooms not sealed Not a solid ceiling, movement of ceiling tiles
3. Air exchanges required to be >12ph	Not yet achieved
4. Sealed room (0.5-sq ft leakage)	? Validation for leak testing
5) Particle counts 29 th June 960-579197	Current standard at WoS Cancer Centre <1000
6) negative pressure in the pentamidine room.	Not achieved

Conclusions

- 1) The original specification provided to Brookfield if delivered would have provided a safe environment for this vulnerable group of patients
- 2) Filter integrity/Particle counting would normally be required to validate areas provided with HEPA filtered air to ensure both the function of the HEPA filter and ensure the room seal. Expert Engineering advice should be sought to advise whether the commissioning process in this case was adequate. No validation data has to date been made available to the IPCT
- 3) In the light of the current provision of isolation facilities available to the Haem-Onc patients the IPCT support the return of these patients to WoS Cancer centre until the unit at the QEUH is provided to the required specification and appropriately validated

Preface

About Health Building Notes

Health Building Notes give best practice guidance on the design and planning of new healthcare buildings and on the adaptation/extension of existing facilities.

They provide information to support the briefing and design processes for individual projects in the NHS building programme.

The Health Building Note suite

Healthcare delivery is constantly changing, and so too are the boundaries between primary, secondary and tertiary care. The focus now is on delivering healthcare closer to people's homes.

The Health Building Note framework (see next page) is based on the patient's experience across the spectrum of care from home to healthcare setting and back.

Health Building Note structure

The Health Building Notes have been organised into a suite of 17 core subjects.

Care-group-based Health Building Notes provide information about a specific care group

or pathway but cross-refer to Health Building Notes on generic (clinical) activities or support systems as appropriate.

Core subjects are subdivided into specific topics and classified by a two-digit suffix (-01, -02 etc), and may be further subdivided into Supplements A, B etc.

All Health Building Notes are supported by the overarching Health Building Note 00-01 in which the key areas of design and building are dealt with.

Example

The Health Building Note on accommodation for adult in-patients is represented as follows:

"Health Building Note 04-01:
Adult in-patient facilities"

The supplement to Health Building Note 04-01 on isolation facilities is represented as follows:

"Health Building Note 04-01:
Supplement 1 – Isolation facilities for
infectious patients in acute settings"

Health Building Note number and series title	Type of Health Building Note
Health Building Note 00 – Core elements	Support-system-based
Health Building Note 01 – Cardiac care	Care-group-based
Health Building Note 02 – Cancer care	Care-group-based
Health Building Note 03 – Mental health	Care-group-based
Health Building Note 04 – In-patient care	Generic-activity-based
Health Building Note 05 – Older people	Care-group-based
Health Building Note 06 – Diagnostics	Generic-activity-based
Health Building Note 07 – Renal care	Care-group-based
Health Building Note 08 – Long-term conditions/long-stay care	Care-group-based
Health Building Note 09 – Children, young people and maternity services	Care-group-based
Health Building Note 10 – Surgery	Generic-activity-based
Health Building Note 11 – Community care	Generic-activity-based
Health Building Note 12 – Out-patient care	Generic-activity-based
Health Building Note 13 – Decontamination	Support-system-based
Health Building Note 14 – Medicines management	Support-system-based
Health Building Note 15 – Emergency care	Care-group-based
Health Building Note 16 – Pathology	Support-system-based

Other resources in the DH Estates and Facilities knowledge series

Health Technical Memoranda

Health Technical Memoranda give comprehensive advice and guidance on the design, installation and operation of specialised building and engineering technology used in the delivery of healthcare (for example medical gas pipeline systems, and ventilation systems).

They are applicable to new and existing sites, and are for use at various stages during the inception, design, construction, refurbishment and maintenance of a building.

All Health Building Notes should be read in conjunction with the relevant parts of the Health Technical Memorandum series.

Activity DataBase (ADB)

The Activity DataBase (ADB) data and software assists project teams with the briefing and design of the healthcare environment. Data is based on guidance given in the Health Building Notes and Health Technical Memoranda.

For ADB technical queries only, contact the ADB Helpdesk. Telephone number: 01939 291684; email: support@talonsolutions.co.uk

For new ADB customers and licence renewals only, email: adblicencerenewals@dh.gsi.gov.uk

How to obtain publications

Health Building Notes are available from the UK Government's website at:

<https://www.gov.uk/government/collections/health-building-notes-core-elements>

Health Technical Memoranda are available from the same site at:

<https://www.gov.uk/government/collections/health-technical-memorandum-disinfection-and-sterilization>

Executive summary

Health Building Note (HBN) 00-07 provides guidance for NHS-funded providers on designing and planning for a resilient healthcare estate. It aims to help NHS-funded providers to determine appropriate levels of resilience for sites, buildings and installations against a wide range of emergencies, hazards and threats and their impacts and consequences including resilience to the impacts of climate change. This document focuses on:

- the strategic approach to resilience planning for healthcare estates;
- procuring resilient healthcare estates;
- design and planning considerations for a resilient healthcare estate;
- resilience of building services engineering.

It also embraces the move towards a whole-system approach to healthcare. The isolated approach of concentrating on the resilience of a single facility or organisation is no longer considered best practice. It is clear that this approach will affect building and services infrastructure requirements for the future and should be taken into account at the strategic planning stage for all new healthcare estates and facilities, and also when refurbishing or decommissioning the existing estate.

Relevance and audience

The guidance is relevant to the whole healthcare estate including private sector premises providing services to the NHS

(hereinafter referred to as “NHS-funded providers”); to those who advise and support them; and to associated supply chains.

It is applicable to new schemes, refurbishments, decommissioning and existing facilities. It takes into account the importance of resilience to ensure business continuity management (BCM) and aligns with the Integrated Emergency Management (IEM) model.

The HBN will be useful for a wide range of specialists, including (but not limited to):

- capital project teams;
- estates and facilities managers;
- healthcare engineers;
- architects and designers;
- healthcare planners;
- sustainability managers;
- IT and communication teams;
- local security management specialists (LSMS);
- accountable emergency officers (AEOs)/ head of resilience;
- emergency planning liaison officers and teams;
- clinician/medical teams involved with emergency planning;

- managers and directors including those executives with security and/or emergency planning portfolios.

It is essential that throughout the whole process of procuring and maintaining healthcare, the estates/facilities manager should communicate and work in close cooperation with the AEO (note: in some organisations this role may be carried out by the head of resilience). This will ensure that the resilience of the healthcare estate including climate change is integrated into the organisation's board-approved strategies, systems, training, policies and procedures.

Additional guidance for primary care and community care facilities is given in HBN 11-01 – 'Supplement A: resilience and emergency planning in primary and community care'.

The need for this guidance

This HBN has been revised to reflect the increasing long-term risks associated with climate change. HM Government's (2012) 'UK climate change risk assessment' (CCRA) shows that flooding is one of the largest risks for the UK. Therefore, this document has been updated to provide more guidance on adaptation measures to reflect this and other climate change impacts such as floods and heatwaves.

To assist in assuring compliance with relevant legislation and government policy, this HBN provides advice on the planning, design, construction, commissioning and operation of NHS-funded healthcare facilities. In particular, it has been developed to respond to the following key drivers:

- The CCRA identifies the key risks to the UK from climate change as being the first step towards development of the National Adaptation Programme (NAP) (HM Government, 2013). It acknowledges that building climate resilience is an ongoing investment and that a start needs to be made now, particularly for risks where

decisions have long-term consequences (for example, planning for a climate-resilient healthcare estate).

- The top risks for the UK identified in the CCRA are addressed in the 2013 NAP. This includes a health chapter for healthy and resilient communities, with this updated guidance specifically addressing health objective 12: "to promote climate resilience within the NHS, public health and care system to ensure continuity of services and resilient assets/estates, including the ability to deal with the increased demand for services associated with severe weather-related events".

Changes since the last edition

- This revision updates the HBN in line with new government policy, legislation and regulations and the reform of England's healthcare system including partnership working with Public Health England (PHE), NHS England and others.
- More guidance has been provided on the risks associated with climate change, and this is reflected in the specific advice given in the planning and design chapter.
- The resilience of engineering infrastructure has been expanded upon to reflect the critical nature of maintaining continuity of these services for healthcare delivery.
- The document still reflects the benefits of the IEM model, but the detail has been reduced and the reader has been signposted to other more relevant sources of information.
- It has revised, updated and incorporated the emergency planning and contingency sections that were in earlier editions of Health Technical Memorandum (HTM) 00 – 'Policies and principles of healthcare engineering'.

Definitions

For the purposes of this guidance the following definitions apply:

Adaptation – relates to changes made in readiness for, or in response to, the impacts of climate change.

Business continuity management – all activities undertaken to give NHS facilities the capacity to anticipate, prevent, prepare for, respond to and recover from disruptive challenges that would otherwise prevent the organisation from meeting its primary duties. The term subsumes resilience and resilience management.

Emergency – with regard to estates and facilities, this includes:

- a major incident;
- an unexpected event that gives rise to loss of, or damage to, facilities or services that may impact on the delivery of healthcare;
- an event or situation that threatens serious damage to the environment of a place in the UK, or war or terrorism which threatens serious damage to the security of the UK.

Hazards – non-malicious events including natural events, industrial accidents and industrial action.

Healthcare facility – all buildings, infrastructure, equipment, plant, embedded

systems and related items that support the delivery of healthcare and services of all types, irrespective of their ownership or operation by third parties.

Lockdown – lockdown refers to controlling the movement and access of people around a trust site or area in response to an identified risk, threat or hazard that might impact on the security of patients or assets.

Mitigation – relates to actions to limit the magnitude and/or rate of long-term climate change. Mitigation generally involves reductions in human-related emissions of greenhouse gases. Mitigation may be achieved by switching to low carbon energy sources such as renewable energy.

Recovery – the process of rebuilding, restoring or refurbishing a healthcare facility following an emergency, hazard or threat.

Resilience – the ability of an organisation to adapt and respond to disruptions, whether internal or external, to deliver organisationally agreed critical activities.

Surge capacity – the ability of a health service to expand beyond normal capacity to meet increased demand for clinical care. This is an important factor of resilience and emergency preparedness and should be addressed early in the planning process.

Threats – malicious attacks.

Whole system approach – any resilience planning should be integrated and take into account the whole healthcare system, including acute, community, primary and voluntary sectors. For example, not only do hospitals have to deal with the usual intake of patients during a severe event, but also with disaster-related patients and patients with chronic illnesses who are usually cared for at home, but who suddenly do not have access to the medical technologies they need.

1. Introduction

For the purpose of this document, resilience is defined as “the ability of an organisation to adapt and respond to disruptions, whether internal or external, to deliver organisationally agreed critical activities”. This builds on the definition of “resilience” in BS ISO 22301 and includes resilience to the impacts of climate change such as the increased extreme weather events of heatwaves and flooding.

Resilient facilities are those that have the following features:

- robustness – the system or facility should be able to absorb the effects of an event and continue to operate at the required level;
- redundancy – where robustness cannot be absolutely guaranteed, it is essential to provide more than one key facility or subsystem;
- reconfigurability – the unanticipated risk is often the most devastating. To be truly resilient, a system or facility should be adaptable to cope with the effects of an unexpected event, where practicable.

1.1 The resilience process aims to identify emergencies, hazards and threats, assess the associated risks, develop measures to mitigate those risks, and prepare plans for response to an emergency should it occur.

1.2 This document focuses on improving the resilience of the existing estate and its facilities management (FM) as well as new builds and refurbishments:

- For the existing estate and FM, resilience requires that plans are put in place to ensure that business continuity of healthcare is maintained no matter what the circumstances.
- Resilience should be considered early in the procurement/planning and design process/stages. Particular attention should be paid to flexibility in facility design in order to accommodate surge capacity and peaks in demand.

The whole system approach to healthcare estates resilience

1.3 Existing operational capability and resilience planning should take into account the whole healthcare system, including acute, community, primary and voluntary sectors. For example, hospitals have to deal not only with the usual intake of patients during a severe event, but also with the casualties caused by the disaster and those patients with chronic illnesses who are usually cared for at home but who suddenly do not have access to the medical technologies they need.

Purpose and scope

1.4 This document provides guidance on planning for a resilient healthcare estate. It aims to help NHS-funded providers to determine appropriate levels of resilience for sites, buildings and installations against a wide range of emergencies, hazards and threats and their impacts and consequences. The document provides guidance on:

- the strategic approach to resilience planning for healthcare estates;
- procuring resilient healthcare estates;
- design and planning considerations for a resilient healthcare estate;
- resilience of building services engineering.

1.5 This Health Building Note (HBN) is consistent with Department of Health (DH) policy and arrangements for planning for health emergencies. It complies with wider government plans for national and local emergencies as set out in the Cabinet Office's (2012) 'Emergency preparedness' and HM Government's 'Emergency response and recovery' guidance documents. It also embraces Public Health England (PHE) and NHS England's requirements for safeguarding healthcare services in England.

Relevant legislation that impacts on the resilience of the healthcare estate

1.6 The following main Acts and regulations are relevant to the resilience of the healthcare estate:

- The **Civil Contingencies Act 2004** requires NHS organisations, its subcontractors and providers of NHS-funded care to show that they can deal with such incidents and emergencies while maintaining services to patients.
- The **Climate Change Act 2008** established the target of reducing UK greenhouse gas emissions by at least 80% (from the 1990 baseline) by 2050. Reducing demand for energy, buildings and infrastructure will be more efficient and will reduce energy bills, but will also make organisations, and the country as a whole, more resilient through climate adaptation measures.
- The **Health and Social Care Act 2012** strengthens arrangements for emergency

response. It sets specific emergency duties for the Secretary of State for Health, NHS England and clinical commissioning groups.

Key drivers

1.7 To assist in assuring compliance with relevant legislation and government policy, this HBN is driven by:

- the National Adaptation Programme (NAP) health objective 12: “to promote climate resilience within the NHS, public health and care system to ensure continuity of services and resilient assets/ estates, including the ability to deal with severe weather-related events”;
- the UK climate change risk assessment (CCRA) (HM Government, 2012). This acknowledges that building resilience is an ongoing investment and that a start needs to be made now, particularly for those risks where decisions have long-term consequences (for example, planning for a resilient healthcare estate). The CCRA is the first step towards development of the NAP.

Assurance of the healthcare estate

1.8 Quality and fitness for purpose of the estate are assessed against a set of legal requirements and standards.

Regulatory requirements: essential standards of quality and safety for healthcare estates

1.9 The Care Quality Commission (CQC) regulates all providers of regulated health and adult social care activities in England. The CQC’s role is to make sure health and social care services provide people with safe, effective, compassionate, high-quality care that puts patients first, and to encourage care services to improve. The registration requirements are set out in the Care Quality Commission (Registration) Regulations 2009

(CQC Regulations) and include requirements relating to:

- safety and suitability of premises;
- safety, availability and suitability of equipment;
- cleanliness and infection control.

1.10 The CQC is responsible for assessing whether providers are meeting the registration requirements. Failure to comply with the CQC regulations is an offence and under the Health and Social Care Act 2008 (Regulated activities) Regulations 2010, CQC has a wide range of enforcement powers that it can use if the provider is not compliant. These include the issue of a warning notice that requires improvement within a specified time, prosecution and the power to cancel a provider’s registration, removing its ability to provide its regulated activities. The regulations stipulate that all premises and equipment used must be safe, clean, secure, suitable for the purpose for which they are being used, and properly used and maintained.

Note on amendment to the CQC Regulations

New regulations are due to come into effect during 2014 and will apply to all providers of health and social care that are required to register with the CQC.

The NHS Constitution

1.11 The NHS Constitution sets out the rights of patients, public and staff. It also outlines the pledges that the NHS is committed to achieve, together with responsibilities that the public, patients and staff owe to one another to ensure that the NHS operates fairly and effectively. All healthcare organisations are required by law to take account of the NHS Constitution in their decisions and actions. Healthcare organisations should “ensure that services are provided in a clean and safe environment that is fit for purpose, based on national best practice”.

In order to deliver this pledge, the NHS Constitution specifically advises NHS organisations to take account of:

- national best-practice guidance for the design and operation of healthcare facilities;
- the NHS Premises Assurance Model (NHS PAM).

1.12 The underlying principles of the NHS Constitution link to requirements for resilience in respect of the need to deliver a “positive experience of care and ensure that people are treated and cared for in a safe environment, protected from avoidable harm”.

The NHS Premises Assurance Model (NHS PAM)

1.13 With the support of DH, the NHS has developed the NHS Premises Assurance Model (NHS PAM). Its remit is to provide assurance for the healthcare environment and to ensure that

patients, staff and visitors are protected against risks associated with hazards such as unsafe premises.

1.14 Aimed at providing governance and assurance to boards of organisations, it allows organisations that provide NHS-funded care and services to better understand the effectiveness, quality and safety with which they manage their estate and facilities services and how that links to patient experience and patient safety.

1.15 Key questions are underpinned by prompt questions that require the gathering of evidence. Healthcare organisations should prepare and access this evidence to support their assessment of the NHS PAM.

1.16 The model also includes reference to evidence and guidance as a helpful aide-memoire to assist in deciding the level of NHS PAM assurance applicable to a particular healthcare organisation.

2. The strategic approach to resilience planning for healthcare estates

2.1 The healthcare sector's built environment and support services are the core element in an organisation's ability to maintain its business-prioritised activities.

2.2 Estates and facilities managers will need to consider a business continuity approach for buildings, infrastructure and services resilience, which needs to form part of the wider organisational approach to resilience. This is essential to maintain clinical services and should also take into account the need for surge capacity (that is, the ability of the health service to meet increased demand for clinical care).

2.3 Robust procedures should be prepared and tested for the following priority incidents as a minimum:

- unavailability of premises due to fire, flood, fuel shortages or other incidents;
- major problems relating to the transport infrastructure that affect access and

egress for healthcare professionals, patients and visitors;

- major electronic attacks or severe disruption to the IT network, systems and mobile telephony;
- loss of access to key resources, assets, utilities and fuel supply;
- theft or criminal damage that severely compromises the organisation's physical assets;
- significant chemical contamination of the working environment;
- loss of critical support services or the supply chain.

2.4 This support to business continuity is a key component towards compliance with the CQC's fundamental standards on cleanliness, safety and suitability of premises and equipment and good governance.

2.5 NHS-funded organisations will need to undertake regular risk assessment exercises appropriate to their facilities and services. For further guidance on business continuity management (BCM) and business continuity plans (BCPs), readers should refer to:

- chapter 6 of the Cabinet Office's (2012) 'Emergency preparedness';
- NHS England's:
 - 'Business continuity policy' (2013);
 - 'Business continuity management strategy' (2013); and
 - 'Business continuity management strategy toolkit' (2014).

2.6 BS ISO 22301 on BCM provides a generic framework that covers strategies in all phases before, during and after an incident.

Strategic planning tools and models supporting a resilient healthcare estate

2.7 Described below are a number of available tools and resources for use by NHS-funded providers as appropriate to their local needs and circumstances.

World Health Organization (WHO) tools and resources

Hospital emergency response checklist

2.8 WHO's (2011) 'Hospital emergency response checklist' is a tool for hospital administrators and emergency managers. The guidance and its checklists assist hospital-based emergency managers to respond effectively. The best practice guidance integrates priority actions required for rapid effective response to critical event-based all-hazard approaches.

2.9 It is structured according to a number of key components, each with a list of priority actions to support healthcare managers and

emergency planners in achieving the essentials for healthcare estates resilience:

- continuity of essential services;
- well-coordinated implementation of operations at every level;
- clear and accurate internal and external communication;
- swift adaptation to increased demands;
- the effective use of scarce resources;
- a safe environment for healthcare workers.

Hospital safety index

2.10 WHO's 'Hospital safety index' provides a rapid diagnosis of the safety, vulnerability and preparedness of hospitals. The results of the assessments inform decision makers about which hospitals could withstand the impact of hazards and deliver health services in emergency situations, and those which require remedial action to make them safe and operational in times of emergency.

The Strategic Health Asset Planning and Evaluation (SHAPE) tool

2.11 Produced by PHE, SHAPE is a web-enabled, evidence-based application that informs and supports the strategic planning of services and physical assets across a whole health economy. It links national datasets for clinical analysis, public health, primary care and demographic data with estate performance and facilities location and has a flood-mapping capability.

2.12 SHAPE enables interactive investigations by local area teams, clinical commissioning groups, GP practices and local authorities, and supports key policy initiatives such as the joint strategic needs assessment (JSNA).

2.13 Alongside SHAPE and in engagement with the Environment Agency (EA) locally, consideration should be given to using SMARTeST (Smart Resilient Technologies,

Systems and Tools) (www.floodresilience.eu). One of the key objectives of this is “climate proofing”, particularly of infrastructure.

The NHS Premises Assurance Model (PAM)

2.14 See paragraphs 1.13–1.16.

The Integrated Emergency Management (IEM) model

2.15 The IEM model is a holistic approach to preventing and managing emergencies that entails six key steps (see paragraph 2.16). Although there are other approaches to emergency management, the IEM model is adopted by this HBN not least because it:

- implements the common and consistent UK national model for the anticipation, assessment, mitigation and management of physical risks into the healthcare environment;
- defines a common set of words and processes, thereby minimising the risk of misunderstandings;
- facilitates the integration of site- and event-specific risk assessments and plans into the wider risk and emergency arrangements of other involved agencies;
- provides common ground for effective discourse between the organisations directly involved, the emergency services, and the many external agencies that may become engaged at different stages of any event or emergency and with varying degrees of intensity.

2.16 The IEM model describes a series of cyclical processes. It is essential to view the elements of the IEM as mutually-supporting processes and not as sequential steps, as the first four of the six are continuous, connected activities:

- a. anticipation;
- b. assessment;
- c. prevention;

- d. preparation;
- e. response;
- f. recovery.

2.17 For further details on the IEM model and these six steps, see the Cabinet Office’s (2012) ‘Emergency preparedness’ and HM Government’s ‘Emergency response and recovery’ guidance documents.

Risk assessment

2.18 For the estates and facilities manager, one of the main objectives of resilience is to undertake a risk assessment and to identify gaps in the overall capacity for managing the healthcare estate and to ensure the continued operation of its facilities, services and functions to maintain healthcare services during a crisis. The aim is to develop a plan of action to address those gaps and strengthen capacity. Follow-up assessments should be conducted at least every two years.

2.19 Every local situation will differ, but consideration should be given to how the building’s location, form and design could help in anticipating, preparing for, preventing, responding to, and recovering from disruptions whatever their source and whatever part of the business they affect.

2.20 Risk assessment plans should include a hazard-and-threat analysis as part of the decision-making process to take account of the issues addressed in Table 1.

2.21 Users will need to reference (among others):

- National Risk Register (<https://www.gov.uk/risk-assessment-how-the-risk-of-emergencies-in-the-uk-is-assessed>)
- Community Risk Register (<https://www.gov.uk/risk-assessment-how-the-risk-of-emergencies-in-the-uk-is-assessed>)

- UK Climate Impacts Programme (<http://www.ukcip.org.uk>).

See also the Cabinet Office's (2012) 'Emergency preparedness'.

risks/threats to allow for any changes that may take place (for example, over time, a low risk may become a high-risk event). The review frequency should be linked to an automated email system, calendar or other bespoke software.

2.22 The risk assessment should be periodically reviewed across the whole range of

Utility supplies, that is, electricity, gas, water – how would healthcare be delivered without heating, cooling, gas and air handling, washing linen and dishes, cooking, powering blood banks, maintaining radiology services etc?
Water, drainage – loss of pumping mechanisms to provide clean water for drinking/hydration; water for cleanliness and control of infection.
Sewage treatment failure could lead to untreated/undertreated sewage potentially contaminating local waterways leading to public health concerns and clean-up costs at a later date.
Accessibility/transport – what would happen without transport to the facility (for example contractors maintaining essential services; equipment/supplies that could not be delivered)? Engage with transport coordinators.
Flood plans – engage with the local environment agency and local planners to continually review the local flood model and ensure plans take account of adjacent or neighbouring developments that may affect surface water drainage.
Extreme weather events – for example heavy snowfall and ice or windstorms can be very disruptive – how can this be mitigated?
Heatwave plan – ensure the design and layout allows for shading, temperature control and cool rooms for heat-distressed patients.
Cold weather plan – to support improved building design and increased energy efficiency, which can reduce carbon emissions, and improve and protect health (thereby potentially reducing pressure on health provision).
Winter pressures – can place more pressure on clinical services such as A&E services and acute care.
Infection prevention and control – can room availability and layouts contain the spread of airborne and waterborne viruses? Is there sufficient storage for necessary supplies and disposal of increased clinical/hazardous waste?
Extreme medical conditions – could the building facilitate lockdown of sections or rooms for containment?
Resilience for essential services – telecommunications, IT systems, utility services, medical gases and heating.
Supplies and procurement – how long can the organisation cope if supplies of drugs, food, medical equipment etc could not be delivered? What are the contingency plans for partner organisations to respond in times of emergency?
Fire/bomb threat – can the building be evacuated while maintaining care of the most critical patients?
Fuel shortages – how long would the facility function if fuel were in short supply?
Arson attacks
Civil aviation issues – Is the building located in a flight path: what would this mean for major incident planning if a major air accident occurred? Does the building require an air ambulance facility?
Theft and vandalism
Location – is the facility sited near to a chemical plant or other facility at risk of explosion etc?

Table 1 Issues to consider in a risk assessment plan (in no order of priority)

3. Procuring resilient healthcare estates

Introduction

3.1 If the strategic planning phase reveals that the facility needs to be redeveloped or relocated, the options for procuring this development should be appraised before a specific scheme is identified. These options will usually involve:

- no building work at all (including the decommissioning and the potential lease/sale or demolition of existing buildings);
- relocating or reassigning functions within the existing fabric of the building;
- refurbishing existing buildings;

- new developments.

3.2 This chapter explains how emergencies, hazards and threats can be dealt with throughout the procurement process to ensure that resilience is achieved.

3.3 In procuring a regulated healthcare facility and the services/equipment that are required within it, designers, planners and clients will need to be assured of meeting the CQC's standards of care, which stipulate that all premises and equipment used must be safe, clean, secure, suitable for the purpose for which they are being used, and properly used and maintained.

3.4 Estates and facilities resilience should not be planned in isolation. For large projects (particularly new builds), the threat part of the assessment may be produced at regional or national level, and may include input from other sources. At a local level, advice should be sought from the local resilience forum (LRF), police architectural liaison officer or crime prevention design adviser, and local police counter-terrorist security advisers.

Incorporating resilience requirements into the project brief

3.5 The project brief should communicate the client's requirement for resilience to emergencies, hazards and threats to the design team. This is equally important when occupying and/or leasing premises that are not owned by the healthcare organisation. This is the start of the continuous process of assessment that should be undertaken as part of the facility's lifecycle.

3.6 Resilience measures should not be discounted or compromised on the basis of costs, as the NHS-funded provider is the ultimate bearer of any risk to service provision. Therefore, the delivery mechanisms proposed for resilience should be scrutinised very closely and gauged against the overall benefits in the longer term.

3.7 To ensure that resilience is considered as a factor in the estates strategy, the following questions should be posed:

- How resilient is our estate? (What risks exist in our assessment that need to be addressed in the design?)
- How resilient should it be? (What risks are unacceptably high?)
- How can we improve our resilience? (What building or engineering measures can we apply to mitigate risks?)

The design brief

3.8 The design for resilience in any facility will depend on the assessed risk for that scheme at the time. Applying the guidance in this HBN to a particular scheme for a particular locality will require skilful risk assessment due to the variability and likelihood of emergencies, hazards and threats in different parts of the country. A risk assessment will be required for each business case, and this will need to address the design brief, geographical location and any other mitigating local factors.

3.9 The design brief should take account of future-proofing, adaptability and flexibility of the building. Further advice on future-proofing of healthcare facilities is provided in chapter 8 of HTM 07-07 – 'Sustainable health and social care buildings'.

Review the design proposal

3.10 Design proposals should be reviewed to assess whether the level of resilience meets the requirements set out in the project brief. In a simple facility purchase, this can be a straightforward review of the physical design, but where some form of leasing arrangement is proposed, the review should also include an operational assessment.

3.11 In terms of the current requirements, BCM and the IEM model described in [Chapter 2](#) should be used to enhance the project proposal as this is the point at which emergencies, hazards and threats can be prevented or prepared for.

Controlling delivery of resilience

3.12 Measuring resilience need not be complicated. In fact, the system should be as simple and unequivocal as possible. In common with other requirements stated in the project brief, the requirements should be tested and measured in the delivered project against the original output specification.

3.13 In a facility where service provision has been outsourced, responsibilities need to be clear. A useful mechanism to control and monitor the delivery of resilience requirements is to incentivise the contract with the use of performance monitoring tools such as key performance indicators (KPIs). This mechanism is of particular value to identify the requirements, since they are not products that are delivered but capabilities that are expected to be available. When considering contracts,

see NHS England's 'NHS standard contracts' (updated each year to reflect the requirements of the NHS operating framework).

Measuring resilience – an example

3.14 The following is an example of one type of risk that could be considered as part of a local risk management process when service provision has been outsourced.

The requirement

"Provision is to be made for an electricity supply system that is capable, in the absence of mains electricity, of sustaining the essential load of the facility for a period of X hours."

Assessing whether the proposal satisfies the requirement

The measure is not just in the physical presence of a suitably-sized generator (or alternative), but also in the presence of:

- sufficient fuel for X hours' running;
- the necessary breakdown/maintenance cover;
- trained personnel to operate the generator system;
- proof that the system works in its design condition (that is, under continuous full load, not just that it starts).

Clarifying responsibilities

If the organisation owns the generator and the contractor is responsible for maintaining and operating it, where does responsibility lie for ensuring business continuity if it fails to start?

(Note: ultimately, no matter how the contract is written, the risk of loss of power lies with the NHS-funded provider; therefore, ownership of the risk has not been transferred.)

Where the entire supply mechanism (generator, maintenance, operation) is outsourced, responsibilities are easier to define and less likely to produce gaps from which failures tend to arise, although there is a need to clarify and be confident of contingency plans and arrangements with suppliers.

Using key performance indicators

Negative KPIs (penalty or reduced payments):

- number of days when the standby generator was unavailable due to maintenance failure;
- number of days when trained personnel were unavailable.

Positive KPIs (bonus payments):

- a successful periodic test run of the generator under load;
- successful completion of a periodic test exercise.

4. Design and planning considerations for a resilient healthcare estate

Introduction

4.1 Planning and designing for resilience whenever the opportunity arises – that is, when new sites/buildings or departments are being considered and when major refurbishments are taking place – is a key responsibility of the organisation or board of directors.

4.2 Clear requirements should be provided by the healthcare organisation at the planning and design stage to enable an appropriate level of resilience to be built in. For this purpose, close liaison should take place between the organisation's AEO and the estates and facilities professionals, local planning authorities, and police architectural liaison officers/crime prevention design advisers. LRFs and emergency preparedness, resilience and response (EPRR) teams may also be able to advise on specific cases.

4.3 Local plans should take account of climate change over the longer term, including factors such as flood risk, coastal change, water supply and changes to biodiversity and landscape. New developments should be planned to avoid increased vulnerability to the range of impacts

arising from climate change. When a new development is brought forward in vulnerable areas, care should be taken to ensure that risks can be managed through suitable adaptation measures, including the planning of green infrastructure.

Note on Building Information Modelling (BIM)

The government's mandate is that the public sector will deliver centrally procured projects using BIM by 2016. BIM can be used for effective management of information throughout a project's lifecycle – from earliest concept, design, build, operation and through to ultimate demolition. BIM also has the capability to accurately model the building and its energy performance. In addition, it can be applied in the design and analysis of a building in terms of resilience to climate change as different design parameters can be modelled and tested. It may be extremely valuable in the creation, storage and retrieval of data essential for resilience.

Site-wide design considerations for resilience

Site selection

4.4 Resilient design starts with the site option appraisal process as a means of selecting the most appropriate site. Adjacency to other buildings/types should also be considered as part of this process.

4.5 Site location, orientation and accessibility issues are also paramount. Project teams will need to engage with the EA, local authority and local highway authority to assess local conditions, for example:

- the likelihood of flood risk in the area whether due to the proximity of a floodplain or increased impact from neighbouring developments;
- proximity and potential for impact from COMAH (Control of Major Accident Hazards) sites.

Engagement through the wider community LRF will also be key.

4.6 Although hospitals and medical facilities are not often targets for terrorist attacks, other neighbouring facilities may be. Therefore, siting a prospective new-build near to a potential terrorist target (government, commercial or domestic building) may increase the risk of becoming involved in an incident. (Note that city centres themselves, because of their symbolic nature or the potentially large number of people, have also been attacked.)

4.7 It may also be beneficial to consider the resilience of key utilities where an adjacent incident may impact on the proposed site. Designers should look at the wider national infrastructure from which a proposed development will draw services to evaluate any additional need for on-site resilience. SHAPE may be useful here (see [paragraphs 2.11–2.13](#)).

Grounds and site layout

4.8 Having selected a site, the nature of the grounds and the layout of the facility should be considered to take advantage of natural geographical features or to determine how best to enhance them to withstand natural hazards (for example, by providing better drainage, such as sustainable drainage systems (SuDS), to avoid disruption caused by floods etc). Boundary fencing to control the flow of foot and vehicle traffic should also be considered.

Radon controls

4.9 Designers need to consider the implications of radon contamination within buildings. This is determined by various factors including the geology of the ground, construction details and factors such as the methods of heating and ventilation.

4.10 In outline, basic radon protective measures involve the fitting of a gas-tight ground barrier to protect against radon ingress. This, which also acts as a damp-proof membrane, should cover the whole building footprint and be lapped to the damp-proof course in the walls and sealed around service penetrations. Full radon protective measures require the radon-proof ground barrier, together with a sump in the foundation, to be designed and constructed such that a suitable extraction system can be installed if high levels of radon are detected after occupancy. See also the Department for Communities and Local Government's (DCLG) (2013) 'Revision of building regulation policy on radon: impact assessment'.

Road and vehicular accessibility

4.11 For resilience and to maintain business continuity, it is essential to ensure adequate access and egress routes to healthcare facilities are kept open and functional.

4.12 Depending on location and likelihood of emergencies, hazards and threats, the following will need to be taken into consideration:

- **Roads:** balance the need for easy access for emergency vehicles against the perceived need for access. Limit the maximum possible approach speeds of vehicles by implementing traffic calming measures such as bends, humps and chicanes and consider the use of barriers as a final line of defence.
- **Accessibility in adverse weather:** consider the cost benefits of having access to a snow plough, de-icing vehicles or vehicles capable of transporting key personnel in a snowstorm to maintain business continuity at a time when there is increased need for healthcare facilities due to slips, trips, falls, accidents and injury.
- **Car parking:** careful management of the car park will be required to reduce any risk. Siting car parks in basements beneath tall buildings, where the effects of a flood, fire or a confined explosion would be much greater, will require significant additional structural engineering effort (and hence expense) to ensure that the building would safely withstand the impacts.
- **Vehicle bomb:** the best defence against such devices is distance; therefore, where such a threat is considered credible, precautions should be designed to maintain a stand-off distance by controlling vehicular approaches.
- **Loading bays:** these present a particular vulnerability to the structure since trucks need to approach right up to the building to deliver supplies. The risk can be minimised by siting them away from high-occupancy areas such as wards, canteens or sensitive areas such as laboratories. Access to the loading bays should be controlled; where the threat is deemed high enough, barriers covered by a CCTV and intercom arrangement should be considered, to deny entry until the validity of the delivery is assured.

4.13 Unexpected changes in risk and threat may mean that additional measures will need to be imposed to control vehicular access. Having a flexible management strategy in place will help to deal with new risks and threats as they become known.

4.14 The design team should consider provision of space for eventual introduction of further restrictions on vehicular access, denial of access to certain areas altogether and the introduction of enhanced parking restrictions.

Space for additional facilities

4.15 Space may need to be allocated on the proposed site for additional emergency facilities to deal with specific eventualities. Facilities such as chemical, biological, radiological and nuclear (CBRN) decontamination units, temporary water and/or fuel tanks and logistic stockpiles may be included in the project brief, and need space to be allocated to them. If the public parking area is designated for this, an alternative plan will be needed to allow visitors access to the site, and perhaps a shuttle bus-service could be considered.

4.16 If an emergency occurs, it may not be possible for waste disposal vehicles to come to site to remove healthcare waste. Most healthcare sites do not have the space to store waste for more than 24 hours. If this happens, for example, at a time of pandemic influenza, clinical/hazardous waste will build up more rapidly. Steps will need to be taken in discussion with the EA and infection prevention and control teams to avoid problems that could result. Consideration should also be given to the build-up of combustible materials which create a fire hazard. See HTM 07-01 – ‘Safe management of healthcare waste’. See also [paragraphs 5.64–5.67](#).

Control of pedestrians

4.17 Within the grounds, hard landscaping features such as footpaths and planted areas can be used to mark areas that are part of the design requirements for resilience. Smooth

building lines and well-designed, well-maintained footpaths/grounds will improve pedestrian flow while minimising the effects of weather events.

Pedestrian entrances

4.18 Designers should consider:

- limiting the number of entrances into a building or facility to the smallest number commensurate with the anticipated (and desired) flow of patients, staff and visitors;
- including space at the entrance to incorporate an influx of patients/personnel seeking aid or a personnel search facility if required;
- ensuring that access can be further restricted as necessary without excess impact on operational efficiency;
- access control (for example, swipe-card access and other controls), separating staff and visitor entrances and incorporating positive access control on using keys or electronic pass systems;
- allowing space for a decontamination area to be set up to receive contaminated casualties. External or adjacent land – car parks, playing fields, open areas etc – should be considered as potential decontamination locations using tents for cover. The draught lobby space or commercial areas could also be used for this;
- making the entrance robust against potential civil disturbances, if required, by selecting suitable street furniture and landscaping materials to ensure that the opportunity for aggravated disturbance is minimised.

Separation of patient access areas from other parts of healthcare premises

4.19 HTM 05-02 (Firecode) – ‘Guidance in support of functional provisions for healthcare premises’ provides guidance on the separation of patient access areas from areas considered

to be a fire hazard or risk and the development of appropriate evacuation strategies. In most healthcare buildings that provide in-patient accommodation, the fire evacuation strategy is based on progressive horizontal evacuation, where people are moved progressively away from a fire through fire-resisting walls. This approach may not be appropriate for non-fire emergencies. Therefore, alternative strategies may need to be developed through the normal user group consultation.

4.20 The ‘Heatwave plan for England’ (PHE, 2013) includes the requirement for internal room temperatures to be monitored and to ensure sufficient flexibility of room design and function such that vulnerable patients/people can be relocated to cool areas or zones within facilities when necessary.

High-density sites

4.21 In city-centre or other high-density sites, where pressure for space will always be high, designers should consider potentially radical options for reusing space to ensure that the impact of an event is reduced to an acceptable level (for example, adapting office accommodation or non-clinical areas for use as treatment areas). This should be done in consultation with key advisers such as local fire officers and AEOs.

Redundancy

4.22 Depending on the risk or threat level, organisations should consider whether any of the site-wide design considerations listed above should exist in duplicate or have an alternative. For example, access roads and entrances from the public highway may need an additional temporary route.

Protective security

4.23 Security covers many areas, most of which are described as robustness measures throughout this document. Additionally, the hazard and threat assessment may indicate that the areas described below are also examined.

4.24 Perimeter controls, such as fencing, while not popular, do offer the ability to control foot and vehicle traffic and enable accurate surveillance by channelling visitors into areas covered by CCTV and making a suspicious intent more obvious earlier. This can improve the general security of the facility as well as improving resilience by reducing the likelihood of a threat materialising.

4.25 When considering general security and crime prevention, see also the Association of Chief Police Officers' (2005) 'Secured by design' for additional guidance.

Lockdown

4.26 The need to seal off a facility from the outside or to isolate it internally may arise as a result of an intrusion, civil disturbance, terrorist attack or outbreak of an infectious disease. Selection of appropriate doors, barriers and locks as well as the use of electronic locks and identity/authority verification systems such as card readers, PIN codes and biometrics can then be used to enforce a policy. Appropriate signage and wayfinding strategies may also be used to support the enforcement of lockdown (see NHS Protect's (2009) 'Lockdown guidance').

4.27 Lockdown may be imposed from either an internal or an external authority, and may have as its role either the prevention of entry or the prevention of exit. The precise form the lockdown takes will depend on a number of variables, including:

- duration;
- reason;
- direction of movement to be controlled;
- local circumstances;
- availability of personnel to administer;
- suitability of facility to be locked down;
- physical environment and orientation of the site;

- lockdown zoning.

4.28 Design teams should consider the necessary architectural elements which make the implementation of lockdown easier to perform – in essence, those elements which define discrete zones within a facility and which limit access to those zones, with particular reference to external interfaces and interfaces to areas of high sensitivity or threat potential. This should be carried out in consultation with the local security management specialist (LSMS).

4.29 With regard to the measures for managing threats, project teams should read the Cabinet Office's (2013) 'HMG security policy framework' and bear in mind the advice in the Association of Chief Police Officers' (2005) 'Secured by design', which defines a series of baseline measures for security-conscious design.

Detection systems

4.30 There are a number of electronic options to assist security staff in detecting intruders and managing incidents. These may include:

- intruder detection systems (burglar alarms), which provide an excellent method of backing up an access control system by guarding entrances that are not normally in use (fire escape doors, windows etc); and
- CCTV, which allows more efficient deployment of security manpower and allows verification of alarm incidents remotely. CCTV may prove particularly useful in isolation units as it will allow staff to maintain protection around an area without needing to enter it. CCTV would also assist where buildings have a period of low occupancy or use.

4.31 In a new project, access control, intruder detection, CCTV (high definition and low light) and audio capability could be integrated into a security management system.

Note

See also the Centre for the Protection of National Infrastructure's website (www.cpni.gov.uk).

Screening

4.32 Where there is a particularly high risk to a facility, permanent installation of screening equipment to examine incoming goods and mail may be indicated. Even where it is not, it may be prudent to allow space and services for its installation in the future.

Mail rooms

4.33 Mail rooms should be sited to minimise the distance that unchecked mail has to travel through a building. Rooms should have at least one outside wall to allow a blast to vent, and should be robust enough not to pose a threat to the remainder of the structure.

Personnel screening

4.34 The precise screening measures required will depend on the risk assessment and may include the provision of security staff at entry and exit points on a part- or full-time basis.

4.35 Additional detection/search facilities may be required in high-risk areas at times of heightened alert. Where required, these should take place outside of a protected space. Consideration should be given to the space required not only to carry out the searches but also for queues of waiting people. If the threat is one of explosives, physical protection of the rest of the facility from the screening area should be addressed. Thought should also be given to how persons screened but found unsuitable for access should be directed away from site in a secure manner.

4.36 It should be noted that any imposition of an airport-style regime would severely impact on the functionality of the building and how this eases or impedes the flow of people in and out of any facility. Each line would require at least

three persons to administer it – one screening, one searching and one keeping oversight of all activity.

Designing for resilience to the impacts of climate change

Introduction

4.37 The built environment's response to climate change is organised around two main types of intervention:

- **adaptation** – the need for climate resilience in building type, form and layout needs to be planned and designed appropriately to meet projected healthcare demands and to protect the health of the patients, staff and visitors within these buildings (paragraphs 4.38–4.63 focus on this type of intervention);
- **mitigation** – the amount of energy generated (carbon footprint) which contributes to climate change, requiring buildings to be energy-efficient in design, location and service function (see HTM 07-02 – 'Encode').

4.38 The impact of climate change on a building will depend on how early and well organisations have planned for, and adapted their facilities to cope with, the impacts of climate change. For example, health impacts during heatwaves can be reduced by the effective planning and provision of appropriate temperature controls such as using green roofs and planting trees and zoning of healthcare buildings. The earlier adaptation measures are introduced, the lower the overall financial impact is likely to be on an organisation in the longer term and the better equipped they will be to deal with the predicted changes in climatic conditions.

4.39 Generic adaptation measures appropriate for healthcare infrastructure could include the following:

- The increased use of SuDS to provide a more sustainable approach to draining

Summary of specific responsibilities related to climate change

- The Climate Change Act 2008 requires a quinquennial CCRA – first published in 2012 – to identify the risks and opportunities related to climate change (HM Government, 2102). The Act also sets a framework for dealing with the top risks identified in the CCRA through the UK NAP (HM Government, 2013).
- The UK NAP (also a requirement of the Climate Change Act 2008) provides a framework for action. Adaptation planning is an opportunity to ensure a cohesive approach to current and future planning. The process of developing these plans should integrate with the development and refinement of emergency preparedness and BCPs to prepare for the current and future impacts of climate change.
- The EA's "climate ready service" provides tools and information to help businesses and other organisations live with the changing climate, now and in the future.
- The 'National flood emergency framework for England' (Department for Environment, Food & Rural Affairs, 2013) sets out the Government's strategic approach against flooding and is intended for use by all those involved in planning for and responding to flooding from the sea, rivers, surface water, groundwater and reservoirs.
- The Natural Hazards Partnership (NHP) (<https://www.gov.uk/government/policies/improving-the-uks-ability-to-absorb-respond-to-and-recover-from-emergencies>) brings together expertise from across the UK's leading public sector agencies with the aim of drawing on scientific advice in the preparation, response and review of natural hazards. Partners include the EA and PHE. Among its activities, the NHP publishes a daily hazard summary assessment, which is issued to stakeholders and currently covers some of the following hazards:
 - flooding;
 - geological hazards, such as landslides;
 - weather;
 - wildfires;
 - windstorms.

surface water (for example, a forecourt made from permeable material will allow water to drain away easily). Drainage systems need to be able to cope with the predicted increased frequency of heavy bursts of rainfall.

- Raising flooring in new-build properties to guard against flooding due to increased heavy downpours. Repositioning of power points further up the wall to guard against flood damage.

- Well-designed green spaces to help reduce the urban heat island effect, protect against flooding, promote healthy lifestyles and provide health co-benefits. Plants can be selected for resistance to drought. Trees can provide natural shading and their transpiration helps to mitigate the urban heat island effect.
- Double-glazed windows provide both insulation and natural ventilation, while screens protect against biting insects and vector-borne diseases.

- Roofs could be “green” (to help with the urban heat island effect, reduce water run-off and help biodiversity) or “white” (to reflect heat from the sun) or fitted with solar panels or micro wind turbines to generate electricity.

Note

Load-bearing properties of the roof will need to be carefully calculated to safeguard against potential overloading at times of heavy or prolonged rainfall when the green roof will absorb and retain moisture.

- Innovative building designs will be needed to ensure buildings remain resilient and fit for purpose over time.
- Heat pumps are able to extract heat from the air, ground or water sources (such as rivers or lakes) within the curtilage of a healthcare building and are an energy-efficient way to replace or supplement heating provided by fossil fuels or conventional electric heating methods. They can also be reversed to extract heat from the building when internal cooling is required.
- Road surfaces can be made from materials that are able to cope with hotter temperatures and more intense rainfall.

Floods

4.40 This document incorporates an increased focus on flood risk because the CCRA shows this is one of the largest increasing risks for the UK. ‘Report on the lessons learned from the summer 2007 flooding experiences from an estates and facilities perspective’ (DH, 2007) demonstrates the importance of being resilient to floods and the consequences of not being resilient.

4.41 Developments should be located outside areas of flood risk. Where this is not feasible, DCLG’s ‘National planning policy framework for England and planning practice guidance’

website contains useful guidance (<http://planningguidance.planningportal.gov.uk>).

Important flood risk factors to consider which will influence the design include:

- flood mechanisms (how the site would flood);
- predicted flood level;
- duration;
- frequency;
- velocity of flood water;
- depth; and
- amount of warning time before flooding.

4.42 Where assessment shows that there are no suitable alternative sites available in lower flood-risk areas and development is required, a detailed site-specific flood risk assessment (FRA) should be carried out.

4.43 A range of construction measures can be used to reduce the flooding risk at a site:

- **Flood avoidance:** where it is not possible to locate a building in an area of lower flood risk, constructing a building and its surrounds (at site level) to avoid it being flooded (for example, by raising it above flood level).
- **Flood resistance:** constructing a building to prevent floodwater entering the building and damaging its fabric.
- **Flood resilience:** constructing a building to reduce the impact of floodwater entering the building (so that no permanent damage is caused, structural integrity is maintained and drying and cleaning are facilitated).
- **Flood repairable:** constructing a building so that elements that are damaged by floodwater can be easily repaired or replaced.

4.44 Residential areas may contain a variety of land uses, including dwellings, vehicle and pedestrian access, parking areas, shops,

schools, healthcare and other community facilities. Layout should be designed so that the most vulnerable uses are restricted to higher ground at lower risk of flooding, with more flood-compatible development (parking, open space etc) in the highest-risk areas.

4.45 In designing site layout, the use of low-lying ground in waterside areas for recreation, amenity and environmental purposes can provide important flood conveyance and storage as well as providing connected green spaces with consequent social and environmental benefits. This green infrastructure has the potential to raise the profile and profitability of a development and contribute to other sustainability objectives.

4.46 Landscaping of public access areas subject to flooding should allow for easy access to higher land as flood waters rise and should avoid local features that could become isolated islands. Fences, hedges and walls should be designed and implemented so that they do not cause obstructions to escape routes.

4.47 Any essential structures, such as shelters and seats, should be designed to be flood resilient and firmly attached to the ground. The planning permission should make provision for future management of such areas through planning conditions or Section 106 agreements, with particular regard to safety signing, permitted and prohibited structures and the management of vegetation.

4.48 Buildings should be designed to withstand the effects of flooding. In areas of high velocity water, buildings should be structurally designed to withstand the expected water pressures, potential debris impacts, erosion and undercutting that may occur during a flood event. Particular care should be taken in the design of any building located in a rapid inundation zone. This should also apply to any architectural features within the grounds.

4.49 The final step in the flood risk management hierarchy is to mitigate through building design. This represents the least-

preferred option for new development as although buildings can be designed for reducing the impacts of flooding, hazards still remain, particularly for access and utility supply (see also DCLG's (2007) 'Improving the flood performance of new buildings: flood resilient construction').

Flood risk assessment (FRA) and consequence reports

4.50 FRA and consequence reports should be commissioned to address local authority planning requirements and the need to understand the nature of potential flood risks. Reports should include consideration of the likely effects of climate change (such as increased rainfall). For new developments, areas of permeable and impermeable ground cover should be pre-calculated. All possible relevant flood sources should be covered, including rivers, coastal inundation, surface water, groundwater, sewers and reservoir failure.

4.51 Consultation should be undertaken with regulators, including local authority drainage engineers where appropriate. Risk assessment and consequence reports can be used to meet the requirements of the following guidance by DCLG:

- 'National planning policy framework for England and planning practice guidance' (<http://planningguidance.planningportal.gov.uk>), when considering a planning application or for a healthcare provider to influence an emerging local plan;
- 'Code for sustainable homes' (particularly the environmental issues "Sur 1: management of surface water run-off from developments" and "Sur 2: Flood risk").

4.52 For properties located close to, or within, an EA fluvial or tidal flood risk zone, it is recommended that reports include EA data on flood levels; a data request will provide modelled flood elevations. The SHAPE tool also

has flood-mapping capability (see [paragraphs 2.11–2.13](#)).

4.53 Reports should clearly identify who or what is at risk and may include solutions to limit such risk. They are based on factual interpretation, addressing areas of concern and assessing flood risks to the site from rivers, run-off and groundwater, and also consider potential issues from the regulatory perspective. They can include traffic-light risk ratings and preliminary risk assessment in line with best practice and regulatory guidance such as DCLG's 'National planning policy framework for England and planning practice guidance' (<http://planningguidance.planningportal.gov.uk>).

4.54 Reports should be obtained:

- for the clarification of risk for insurance purposes;
- when validating planning requirements when submitting a planning application;
- to meet planning conditions;
- for land and property purchase;
- for the sale or divestment of a site;
- for due diligence purposes;
- as required for external organisations when new facilities are procured from non-NHS organisations (for example, the requirement of a bank or other funding institution financing the project);
- as part of the business risk assessment.

4.55 Reports should reference:

- customer-supplied information (for example, site location plans, proposed development plans, walkover surveys and recent site photographs);
- the local strategic FRA;
- preliminary risk assessment of flood to the site from all potential sources;

- assessment of flood risks off-site due to new developments and the latest UK environmental datasets:

- flood risks from rivers, surface water run-off and groundwater;
- sewer flood risk if the site is in a built-in area;
- historic flood maps;
- solid and drift geology;
- rainfall assessment.

4.56 When commissioning FRA and consequence reports from specialists, it is prudent and cost-effective to consider obtaining additional reports to assess other environmental matters such as SuDS (identifying site constraints and potential sustainable drainage solutions including run-off and storage volumes), geo-hazards and contaminated land (which may include landfill sites and burial grounds).

Note

The Floods and Water Management Act 2010 establishes a Sustainable Drainage Systems Approving Body in unitary or county councils. This body must approve drainage systems in new developments and redevelopments before construction begins.

Heatwave risks/drought: specific adaptation measures

4.57 Extended periods of dry weather leading to drought could:

- cause increased levels of dust, haze and fog;
- lead to land instability; and
- cause wildfires, which can culminate in one or more of the following:
 - loss or significant reduction in water supplies;

- slowed rate of sewage flow through the system, leading to public health concerns;
- increased risk of vermin above ground;
- reduction in water quality;
- loss or reduction of capacity in the electrical supply network;
- potential impact/closure of primary transport routes;
- possible closure of some businesses;
- increased demand for water supplies from all infrastructure sectors including health, agriculture, energy and emergency services;
- increased demand for emergency power;
- increased demand for health and emergency services.

The dynamics and implications on the built environment and its resilience are illustrated in research by Short et al (2012). The challenge of reducing carbon emissions and energy demand is amplified by the health implications of a changing climate.

The 2003 heatwave led to 15,000 excess deaths in Northern France. The UK heatwave of June/July 2006 is thought to have led to an increase in deaths over baseline mortality of 4%, and there were approximately 300 excess summer deaths after the 2009 heatwave between 30 June and 2 July.

Individuals sensitive to high temperatures are likely to be present at all times in hospitals, including those with compromised thermoregulatory systems (older people, the chronically and severely ill and those on certain medications that impair perspiration) as well as those who cannot take action in the face of high temperatures (small children, those patients who are confined to bed and

patients with mental health problems). However, very few existing buildings within the NHS estate were designed to be air-conditioned; indeed, many are poorly insulated and often over-glazed, leading to increased risk of summertime overheating, even in recently completed buildings.

The paper concludes that refurbishment, in particular to curb the heat lost through uncontrolled leakage of ventilation air from the building, could reduce energy demands and maintain or even improve the internal environment in the current climate. The five refurbishment options researched also offer the opportunity to increase the resilience of the building in a warming climate while saving energy. It concludes that relatively modest interventions could achieve substantial savings while achieving future resilience.

Excessive cold – snow and ice

4.58 PHE's 'Cold weather plan for England' builds on existing measures taken by DH, the NHS and local authorities to protect individuals and communities from the effects of cold weather and to encourage community resilience.

4.59 Coordinated multi-agency long-term planning and commissioning for cold weather is essential to:

- protect people and infrastructure from the effects of cold weather and thus reduce excess winter illness and death and the burden on health and social care sectors;
- support improved building design and increased energy efficiency which can improve and protect health (thereby potentially reducing pressure on health provision) and reduce carbon emissions;
- improve insulation properties of buildings in order to retain heat and minimise energy usage (note: insulation values need to be evaluated along with temperature controls).

Case study: Winter freeze/thaw, December 2010

This case study details a review undertaken by the Sustainable Development and Engineering Branch of the Health Estates Investment Group (Northern Ireland) into the resilience of the Health and Social Care estate in Northern Ireland subsequent to the extreme cold weather events of December 2010 and thaw of January 2011.

The main problems encountered by the trusts during the extreme cold weather event of December 2010 and January 2011 included:

- Buildings were designed to a standard and performed to that standard, but were unable to cope with prolonged temperatures of -10°C .
- Failure of frost coils in air handling units (AHUs). The short-term solution was to divert warm plantroom air into the AHU inlets. The reduction of air flow, where possible, also helped.
- An excess of natural ventilation in newer buildings gave problems in lifting air temperatures.
- In fully air-conditioned buildings, the AHUs were the only source of heating. This gave rise to a single point of failure.
- Pipes that were stressed by being frozen burst under pressure.
- Reverse osmosis plant in some instances could not operate due to being in an unheated space.
- In multi-storey facilities, loss of water pressure caused problems.
- Contingency plans did not cover a complete loss of both electricity and water supply.
- Lack of a dedicated point of contact within Northern Ireland Water (the water supplier).
- Lack of a formal structure for emergency contacts with Northern Ireland Water.

The full report of the investigations into the freeze/thaw incident can be found on the Northern Ireland Executive website (http://www.northernireland.gov.uk/consolidated_report_-_freezethaw_2010-11_incident.pdf).

Wildfires

4.60 The CCRA (HM Government, 2012) identified an increase in the incidence of wildfires as an emerging risk associated with climate change. Severe wildfire is included in the 'National risk register of civil emergencies' (Cabinet Office, 2013). It is anticipated that LRFs will review and consider the severe wildfire risks, as will the fire and rescue service, through their integrated risk management plan process. The Forestry Commission and the UK Forestry Standard should be consulted as part of the

contingency planning for any development whose location may be prone to such risks.

Windstorms (storms and gales)

4.61 Severe windstorms around the UK have become more frequent in the past few decades. The vulnerability of healthcare buildings in windstorms is a function of the strength of the building envelope components and their connections. Designers should use wind damage and impact prediction models to

take account of the increase in the frequency of windstorms and in average wind speeds.

See also HTM 07-04 – ‘Water management and water efficiency’.

Case study

In 2013 a storm brought disruption to the whole of South Yorkshire, and gale-force conditions cut off the power supply to Barnsley District General Hospital, which was obliged to cancel out-patient appointments while operating on emergency standby generators. The hospital issued a statement to reassure people that patients in the hospital were safe. Power was recovered and normal service resumed later that same day. The incident demonstrates the need to maintain business continuity through implementation of contingency plans and concomitantly the importance of good strategic communications – reassuring the public and mitigating risk.

Water resources

4.62 Increasing pressure on water resources is a growing risk. Buildings will need to become more water-efficient due to the predicted changes in water availability. Climate change and population growth may ultimately lead to less reliable supply conditions or restrictions on abstraction licences for those healthcare organisations with their own borehole supplies.

4.63 Adaptation and mitigation measures would include:

- close cooperation and communication with local water companies to conserve water;
- water conservation measures to collect and store water for non-patient use;
- installing water monitoring systems and water management plans for early detection and repair of leaks;
- checking and regular monitoring of water-pipe capacity and capability at planning/design stage and regularly thereafter.

Blast-resistant building design considerations

4.64 If a risk assessment (see [paragraphs 2.18–2.22](#)) identifies a high likelihood of threat from terrorism or a bomb, the following will need to be considered to maintain the structural design of buildings to resist blast effects caused by explosions:

- Use a framed construction in either structural steel or reinforced concrete that has the “degree of robustness” required by the relevant British Standards, whatever the number of storeys (that is, all buildings less than five storeys high should be designed as a five-storey building for robustness only).
- Provide “protected spaces” (previously known as bomb-shelter areas). This may be achieved by careful planning of the internal building (not necessarily reinforced concrete) or by the provision of a robust basement construction. In a healthcare environment these areas may need to be extended to wards if patients cannot be evacuated.
- Have ground- and first-floor slabs constructed of in-situ reinforced concrete, with slabs designed as suspended so that they can withstand the removal of one or more structural columns beneath them.
- Have floor slabs tied down to their structural supports to allow for the load reversal that occurs in an upward blast.
- Have a roof slab that is of similar construction to that of a typical floor.
- Have a cladding system that will not become an additional shrapnel hazard if separated from its supports and that can be repaired without removing undamaged panels.

Access to documentation

4.65 During an extreme event, the emergency services may request to see up-to-date electronic and paper copies of site plans, engineering services diagrams and other relevant documents. Senior managers should ensure that these are readily available and accessible.

5. Resilience of building services engineering

Resilient infrastructure and supply

5.1 Many medical technologies and modern communications are reliant on a reliable energy source. Therefore, in planning and designing any healthcare facility, the energy supply not only has to be adequate, but also robust and resilient. Single points of failure should be eliminated.

5.2 The location of hospitals requires careful consideration to ensure that they are built within low-risk areas so that disruption of infrastructure, including energy supplies, is minimised or prevented (see [Chapter 4](#)). Once operational, the systems and equipment providing the source of energy require regular maintenance with the prioritisation of the replacement of old equipment and the use of new and emerging technologies to mitigate the effects of age-related failure of systems and equipment (Klinger et al, 2014).

Electricity

5.3 Electricity is probably the most vital of all infrastructure services; without it, most of the other services will not function. The entire electricity distribution system, both within the facility and the external provision from the supply network, should therefore be designed to be as resilient as possible. This can be achieved by applying the principles of robustness, redundancy and reconfigurability to the system as the design progresses in accordance with HTM 06-01 – 'Electrical services: supply and distribution'. See also 'Report on the lessons learned from the summer 2007 flooding experiences from an estates and facilities perspective' (DH, 2007).

Mains electricity supplies

5.4 Designers should consider how a secure electricity supply can be ensured. Priority allocation of the site should be carried out with the network supplier for the site. Where

practical, consideration should be given to having two or more sources of supply from the supplier. A supply at high voltage (HV) from one or more primary network substations may have a higher initial cost, but will be more resilient against load-shedding in times of high demand or extreme events.

5.5 It is important that NHS-funded providers establish a formal working relationship with the electricity supplier. This may mean registering as a priority user. Normally this will be with a nominated client manager.

Robustness

5.6 The distribution system, including all of the non-electrical components such as substation buildings, emergency fuel supplies, cable ducts and other containment, should be robust enough to survive design hazards and threats. Where facilities are not duplicated, or where potential for a single point of failure exists (for example, where the standby generator is in the same building as the intake substation), robustness is doubly vital as the last line of defence. Consideration should be given to designing such facilities as protected spaces. Action should also be taken to eliminate the single point of failure as a matter of good practice and to ensure maximum robustness.

Redundancy

5.7 The electricity distribution system within the facility is best protected by having multiple sources of supply at all levels. Normal electrical system design, including the requirements and recommendations made in HTM 06-01 – ‘Electrical services: supply and distribution’, recommends the degree of redundancy in an electrical system which may need to be enhanced once credible threats are included in the risk management process.

Control

5.8 Building management (or other control) systems need to give an indication as to the state of the electricity supply. When the mains

supply fails or is subjected to cyber attack, actions need to be triggered such as:

- the preparation of maintenance responses;
- automated responses such as the shutting down of a computer server on activation of a UPS;
- isolation of non-essential loads;
- the ability to initiate manual overrides.

Reconfigurability

5.9 The ability to reconfigure a faulty or failed electricity supply system, or to reconfigure it should demand increase, can be designed into a system at the outset:

- Ring circuits rather than radial feeders provide two possible sources of supply and therefore provide a degree of resilience against damage and failure. Critical ring mains in HV networks can be made “closed” rather than “open” for maximum security of supply, albeit at greater expense, provided that adequate protection arrangements are installed.
- Interconnectors between node points on the network can be positioned to increase options for supply and to allow for bypass of damaged areas or failed components.
- Spare capacity in switchrooms and substations is essential to allow on-site engineering staff options to re-establish supplies after a failure. If access to the busbar is available (for example, by installing sockets and suitable interlock systems), a portable generator can be coupled to the system to replace a failed mains supply, or a new cable can be run out to a temporary facility. When refurbishment projects are being designed in existing facilities, it is good engineering practice to ensure spare capacity remains and, if necessary, install new switchgear.

- Sensing and control: developments in building management and automatic control systems are making it increasingly possible to design-in the ability to automatically sense failures and reconfigure the network accordingly. Business-critical facilities should consider using this technology.

Standby generation

5.10 Generators will provide an additional level of redundancy for essential loads. HTM 06-01 – ‘Electrical services: supply and distribution’ gives guidance on the number of generators that may be appropriate; the hazards and threats identified in the design brief will indicate whether it is appropriate to site standby generation in the same physical location as the power supply it replaces.

5.11 Standby generators should not be sited in basement areas or low-lying areas that are at risk of flooding.

5.12 Standby generators should be subjected to regular full-load testing. This will also ensure that the automated changeover from the mains supply to the standby generator functions correctly. Full-load testing can be achieved using load banks if required, but this on its own will not replicate the correct operation at a time of full mains failure.

Combined heat and power (CHP)

5.13 Where a CHP system is being considered, there is scope to consider this as a secondary form of standby generation provided that its other operating capabilities will be met. If the CHP system is provided on a leased arrangement, the maintenance and emergency repair response times should be considered and stated as contractual requirements, as should regular testing and availability criteria.

Uninterruptible power supplies (UPS)

5.14 Critical loads may require a UPS (static or rotary) to be installed. Currently, battery technology and space requirements generally

limit these devices to providing power for a short period or to a controlled closedown rather than to continue operating indefinitely. An exception to this is where a UPS is used to cover the break in supply while a standby generator starts or to support critical care and essential supplies while alternative supplies are made available.

5.15 For more information regarding management and operation of electrical systems, see the HTM 06 series of guidance, in particular HTM 06-02 – ‘Electrical safety guidance for low voltage systems’ and HTM 06-03 – ‘Electrical safety guidance for high voltage systems’.

Lighting

5.16 Consideration should be given to robust exterior lighting systems for all public access. These systems need to be suitable for extreme weather events (for example, high winds and flooding). External lighting may need to be fixed to the building structure in key locations.

5.17 LED lighting technology is increasingly being used in healthcare settings, principally because of their efficiency and low power consumption. It is possible to supply LED lighting via a dc power source so in an extreme power loss situation it is possible to supply LED lighting systems via battery banks.

Water

5.18 The continued availability of clean and safe hot and cold water supply is vital for healthcare premises, which are dependent on water to maintain hygiene, hydration and a comfortable environment for patients and staff.

5.19 Interruptions in mains water supply – whether planned or unplanned (such as a burst water main, low mains pressure, electrical supply failure, pump failure or concerns relating to water quality) – can disrupt healthcare activities. The design of systems must ensure that sufficient reserve water storage is available to minimise the consequence of disruption, while at the same time ensuring an adequate

turnover of water to prevent stagnation in storage vessels and distribution systems.

5.20 Mitigating the risk of having a single source of supply should be considered, and the possibility of acquiring a second source should be investigated. This could take the form of a second mains water supply, fed from a separate network to reduce reliance on a single network, or alternatively the utilisation of a private borehole or other alternative source. Should the private borehole be identified as being specifically for emergencies, obtaining or retaining an abstraction licence may be easier.

Note

It is important that NHS-funded providers establish a formal working relationship with the water supplier. This may mean registering as a priority user. Normally this will be with a nominated client manager. The two parties should work together to establish, as a minimum:

- potential mains water supply risks and how these risks can be mitigated;
- provision of water supply in the event of mains water failure (for example, provision of water tankers/bowsers, bulk bottled water);
- leakage prevention strategies to prevent contamination of the water distribution system within the healthcare provider's estate from lack of integrity of the on-site potable water distribution system.

5.21 Designers should consider not only how a secure supply can be guaranteed but also how its potable quality can be assured. Client organisations should advise the designer on whether the risk of using non-potable supplies for certain tasks (such as laundry services and cleaning) is acceptable.

5.22 Where potable water is required from secondary or alternative sources, on-site water treatment options (see paragraphs 5.26–5.31)

can help mitigate the loss of mains potable water.

5.23 The designer should consider the integration of bowser/tanker connections so that tankered water supplies can be efficiently discharged into the healthcare building's water storage system. The local water supplier should be able to assist in the provision of tankered water supplies and this will help ensure that the quality of the water delivered in this manner is through an appropriate quality control system.

5.24 HTM 04-01 – 'The control of *Legionella*, hygiene, "safe" hot water, cold water and drinking water systems' and its addendum give comprehensive advice and guidance to healthcare management, design engineers, estate managers and operations managers on the legal requirements, design applications, maintenance and operation of hot and cold water supply, storage and distribution systems in all types of healthcare premises. It is equally applicable to both new and existing sites.

5.25 With respect to risks associated with flood and fire, designers should also refer to:

- Chapter 8 on flood risk in HTM 07-04 – 'Water management and water efficiency';
- 'Report on the lessons learned from the summer 2007 flooding experiences from an estates and facilities perspective' (DH, 2007);
- HTM 05-02 (Firecode) – 'Guidance in support of functional provisions for healthcare premises' (so that requirements for fire-fighting are also met).

Water treatment

5.26 Where a need for on-site water treatment is identified, the required final water quality will determine the treatment required.

5.27 Where the healthcare provider has its own on-site borehole, if this is already being used for the provision of potable water, it should already

be registered with the local authority and compliant with the Private Water Supplies Regulations 2009. Depending on the borehole's characteristics, filtration and disinfection may be required, but in most cases the borehole supply is solely subjected to disinfection.

5.28 Where the on-site borehole is suspected of being contaminated by floodwater or other contaminants, the borehole should be removed from service and expert advice sought before it is returned to service.

5.29 Where it is identified that treatment of alternative water sources is required, packaged potable water treatment plants are available. These are likely to be either reverse osmosis plants or filtration plants. Both require a disinfection process before the water enters the healthcare building's water distribution system and will need to be compliant with the Private Water Supplies Regulations 2009.

5.30 Disinfection may take the form of chlorine-based chemical disinfection, ozone disinfection (via an ozone generator) or ultraviolet disinfection using specialist lamps. As properly controlled chemical dosing with chlorine-based compounds can maintain a residual disinfectant level in the treated water, it is the preferred solution.

Note

There may be the need to consider remineralisation following treatment.

All chemicals used in the disinfection process should be BS/EN accredited.

5.31 For further guidance on water treatment, see HTM 04-01 – 'The control of *Legionella*, hygiene, "safe" hot water, cold water and drinking water systems'.

Bulk stocks

5.32 The quantity of water that is held in storage on-site should be decided. The key factor affecting the decision will be the

anticipated length of time that the mains water supply may fail and the time that would be required to establish an alternative (for example bowser/tanker delivery) supply route. This should also be balanced against the costs associated with maintaining the stock in a potable condition.

5.33 When bulk supply of bottled water is carried out, the pallets of bottled water should be suitably stored to prevent external contamination of the bottles. They should also be stored at room temperature and away from direct sunlight.

5.34 A suitable arrangement for the supply of bottled water should be in place with the healthcare provider's water supplier or other suitable organisation that is able to respond accordingly.

Sewage

5.35 Although certain healthcare premises may have their own sewage treatment facilities, most will dispose of their sewage and trade effluent through the municipal sewerage network. However there are instances where this normally reliable disposal route may break down. A combination of aging sewer networks and the restriction of sewers due to the build-up of fat deposits and other media can lead to capacity problems within the network. In certain instances this will manifest itself as a complete blockage of the network.

5.36 Owing to the increased use of macerators to dispose of bedpan waste and food waste, this effect can also occur within a healthcare organisation's own sewage disposal network if care is not exercised in the correct risk assessment, selection and monitoring of macerators and the on-site sewage disposal network.

5.37 The lack of capacity within the sewer network can be exacerbated during times of heavy or prolonged rainfall, a particular concern during extreme weather events, leading to the backing up of the sewage within the network

and/or surface water flooding. Both can result in flooding of premises or land with water contaminated to a greater or lesser degree with sewage effluent.

5.38 Consideration of the age and condition of the local sewage and surface water disposal networks should form part of the decision-making process when:

- selecting a site for a new facility;
- planning construction of additional buildings on an existing site.

5.39 This is particularly pertinent for facilities built in flood-prone areas, where the risk of sewage inundation as well as flooding should be assessed.

Note

As with water, it is important that NHS-funded providers establish a formal working relationship with the water company that provides their sewage and trade effluent services. This will normally be with a nominated client manager and may be the same person/team providing the point of contact for water services. The two parties should work together to establish, as a minimum:

- potential sewage and trade effluent disposal risks and how these risks can be mitigated or removed;
- provision of waste water tankering services or temporary sewage treatment facilities in the event of sewer collapse, sewerage system failure etc;
- remediation services to assist with promptly returning services to normal following contamination due to sewage or sewage-contaminated flood water.

5.40 The loss of the ability to dispose of sewage and trade effluent is a critical infrastructure vulnerability, and due attention

should be paid to close liaison with local providers at the design stage to ensure that the relevant local sewerage infrastructure is fully understood in terms of its resilience and reliability. As part of risk mitigation, NHS-funded providers may need to consider provision of alternative disposal facilities, perhaps at a far lower flow rate, to allow continued operation of at least part of the facility under condition of failed sewerage arrangements.

5.41 Healthcare organisations that have their own on-site sewage treatment facilities should ensure they have robust plans in place that outline how they will continue to ensure the safe treatment and disposal of sewage during adverse conditions, including returning the treatment facility to correct operation after inundation during flooding events.

5.42 Water UK's (2011) 'National guidance for healthcare waste water discharges' strongly recommends that NHS-funded providers prepare an emergency plan that includes:

- spillages;
- loss of water supply; and
- drainage plans on which drains are suitably marked (for example, "red for foul water sewer" and "blue for surface water sewer").

Fuel

5.43 Fuels should be selected to ensure continuity of supply as well as to satisfy economic and environmental concerns. Primary and secondary fuel arrangements (for example natural gas/diesel dual-fuel options for boilers) are necessary to reduce reliance on sole suppliers and to improve resilience of the supply chain in the event of disruption. Prior engagement and communication with the supplier will:

- better ensure supply in case of emergency; and

- reduce the need for high volume local storage (which mitigates possible theft, contamination and degradation).

5.44 Bulk stocks of fuel should be held to span gaps in supply, but these bulk stocks may also present an attractive target to potential thieves or attackers and should be physically protected. Redundancy can be achieved by ensuring that a number of smaller tanks are held in more than one location, but the fuel, generator and mains transformer should not be aggregated into the same space. Security is important, including the use of lock and key.

5.45 Piped supplies of gas should be discussed with the regional gas transporter to ensure that they are noted as “priority user” and will be maintained/restored as priorities in the event of network difficulties.

5.46 Where off-site fuel storage is considered (oil, solid fuel etc), plans should be made for alternative routes of access in case of blocked roads.

Critical cooling

5.47 Cooling is a particular concern during periods of high temperature. A number of areas and equipment within healthcare facilities have a critical requirement for cooling. These include drug and blood banks, mortuaries, food and prepared meal stores, critical care areas, theatres and diagnostic imaging equipment. Related facilities include business-critical server data centres and high-powered diagnostic equipment.

5.48 In addition to ensuring that the cooling systems have adequate arrangements to power them, adequate redundancy within the system should be provided. This could be achieved by installing a common type of plant across a site to enable cannibalisation of equipment if required.

5.49 Monitoring systems to provide warning of cooling or power failures should be provided, and arrangements or plans made such as:

- data centres being able to hand over to a third party’s backup facility;
- high-priority items such as drugs and blood stocks being moved to other temperature-controlled stores;
- letting enabling contracts for the provision of temporary facilities such as refrigerated ISO containers (that is, shipping containers compliant with ISO standards);
- provision of temporary refrigeration units (if refrigerated mortuary facilities are required).

Piped medical gases

5.50 Healthcare facilities that have a significant requirement for medical gases may consider the benefits of providing a vacuum-insulated evaporator (VIE) and a piped distribution system rather than individual bottles an economically attractive option. In such circumstances, the following factors should also be considered alongside the guidance given in HTM 02-01 – ‘Medical gas pipeline systems’:

- A single VIE for each nature of gas presents a vulnerability to interruption of supply. Provision of two smaller (and physically separated) tanks may not be as economic but will improve resilience with respect to supply chain and deliveries. Monitoring of stock levels within the storage vessels via telemetry to the supplier will also provide additional resilience in supply chain management.
- Regardless of the storage method selected, cylinder storage facilities should be available as a last resort, since the supply of these can be assured from a number of sources (see [paragraphs 5.53–5.54](#)).
- The location of storage tanks should be very carefully considered as they represent a significant hazard in their own right, regardless of any additional threats. The tanks should have good physical protection from unauthorised access and

be sited away from high-occupancy areas. Where space considerations prevent a reasonable separation, a protective wall or bund should be considered.

- The engineering infrastructure to generate medical air and vacuum should be as resilient as the supply of other gases. Compressors and vacuum pumps require a source of electrical power to operate, and standby vacuum devices that operate on the venturi principle need a working supply of medical air.

5.51 Additionally, the piped medical gas distribution systems should include features to prevent gases such as oxygen contributing to a fire or explosion in the event that they become damaged (for example, numerous and easily accessible isolation valves should be provided).

5.52 NHS-funded providers should ensure that continuous access to reliable oxygen supplies (be they via bulk storage systems or individual cylinder provision) is available at all times. This is particularly pertinent during the winter period when pressures on the healthcare system may coincide with extreme wintry weather and associated logistics issues.

Cylinder gases

5.53 Healthcare facilities will need to ensure safe and secure storage for bottled and cylinder gases. In the event of a fire, this can lead to an exclusion zone being set up around the site by the fire and rescue service. This can seriously disrupt services and access, and should be taken on board when choosing a site.

5.54 For both piped and cylinder gases, ensuring priority user status with the supplier will:

- better ensure supply in case of emergency; and
- reduce problems of storage and fire safety.

Ventilation systems

5.55 Ventilation systems are installed throughout healthcare premises to fulfil a number of purposes, some of which have resilience implications. Factors such as smoke clearance for fire protection are already well understood and documented.

5.56 Hazards and threats that may be considered credible in a healthcare facility might include the spread of:

- airborne infections;
- waterborne infections;
- chemical or biological contaminants brought in on casualties;
- a contaminant deliberately released in a healthcare facility. Such a contaminant need not be in itself dangerous – but the impact of a cloud of coloured vapour in a crowded reception may be significant.

5.57 Designers should be briefed that as well as the guidance in HTM 03-01 – ‘Specialised ventilation for healthcare premises’, they should consider ventilation schemes across the entire facility and make an assessment of the flow of air based on developed pressure differentials. This is already commonplace in smaller areas of hospitals such as operating suites, but holistic consideration of the ventilation profile will enable better assessment of likely contamination routes and – if properly designed and commissioned – will provide an additional obstacle to the spread of contamination.

5.58 Good practice dictates the positioning of air intakes out of easy reach and the provision of facilities for immediate shut-down and isolation of discrete zones within the healthcare facility from a central location.

5.59 HTM 03-01 stresses the importance of ensuring that systems are correctly designed, installed, commissioned and maintained. Resilience requirements do not detract from these, but do reinforce the need for stringent maintenance including regular testing,

inspection and cleaning to ensure that systems are operating as designed and will deliver the required function in the event of an incident.

5.60 Owing to the higher running costs associated with generating the pressure differentials, it may be felt appropriate that systems have a “normal” (low-pressure) mode and an “isolation” (high-pressure) mode. If such a method is chosen, the control of how the modes are changed should be carefully designed – both in engineering and management terms – to ensure that it is activated at the appropriate times and remains active until no longer required. Both engineering and clinical staff need to be aware of the modes and the consequences of operation.

5.61 Risk assessment may indicate the filtration of supply air either full-time or temporarily in times of heightened threat. Consideration should be given to the development of safe changing routines in the event that contamination has occurred.

5.62 The three resilience principles (robustness, redundancy and reconfigurability) should be applied to designs to ensure that the ventilation system is:

- **robust** enough to withstand hazards and threats;
- **redundant** in order to allow continued operation in the event of component failure; and
- **reconfigurable** in the event of damage – although in such a case, this may be limited to the provision of dampers to ensure that damaged areas are isolated and that pressure gradients can be maintained.

5.63 Due consideration should be given to whether ventilation systems should be kept on or turned off during incidents (see also HTM 03-01 – ‘Specialised ventilation for healthcare premises’ and HTM 05-02 (Firecode) – ‘Guidance in support of functional provisions for healthcare premises’).

Note

Sealing buildings to increase energy efficiency may lead to a decrease in indoor air quality and/or overheating (unless suitable ventilation is maintained).

Waste disposal

5.64 The ability to remove waste from a facility is a critical logistical concern. Site restrictions and hygiene requirements will preclude the storage of waste for any significant length of time. Healthcare facilities typically require a means to dispose of three separate types of waste (see paragraph 5.65). The area where waste is stored should be secure and well-lit. It should also be sited away from flood risk and contamination sources.

Infectious/clinical/hazardous waste

5.65 When deciding how infectious/clinical waste will be disposed of, consideration should be given to emergency arrangements. Where it is proposed that disposal be outsourced, the issue becomes one of supply chain resilience, but the consequences of this failure may be such that contingency arrangements over the normal contractual arrangements will be required (for example, the provision of a temporary refrigerated store (including body store) or facility). Note that any such temporary arrangements should only be undertaken in full consultation with the EA. See also HTM 07-01 – ‘Safe management of healthcare waste’.

Refuse/recyclables

5.66 Refuse removal is traditionally outsourced to a municipal or other contractor, thus requiring an assessment of supply chain resilience that may indicate that an area for refuse storage needs to be set aside or an alternative standby arrangement made, which may include an alternative supply chain.

5.67 For further guidance on waste disposal, see HTM 07-01 – ‘Safe management of healthcare waste’.

IT and communication systems

5.68 Particular care needs to be considered for the electricity supply and cooling systems needed to support IT systems and communication systems/networks (including wireless systems) as these may be critical during an emergency. For example, if the electricity supply should fail, what impact would this have on:

- access to patients' records, patient data and telemedicine;
- electronically held policy and procedure manuals;
- telephones (including voice over internet protocol (VOIP) systems);
- pagers/cardiac pagers;
- printing;
- building management systems (BMS)/site alarms;
- pneumatic tube systems;
- internal communications (for example, email);
- or other essential systems (that is, those used for the ordering of supplies and medications)?

IT systems

5.69 IT resilience should ensure that suppliers plan, deliver and have the capacity to continually improve IT services aligned to business requirements and industry-standard best practice. Suppliers need to have a monitoring procedure to reduce risks of adverse impact on the business through system failures (for example, cyber attacks). Back-up systems and procedures need to be planned and periodically tested to ensure that essential records (such as patient care records) and data are not lost and to ensure that the building management system (or other systems) are not compromised.

IT service continuity management

5.70 Suppliers should communicate their own resilience plans to NHS-funded providers to enable integration into BCPs and to ensure system resilience is able to meet the level of service availability and business requirements. This should include mitigating any risks accordingly and supporting service improvements. NHS-funded providers should ensure appropriate monitoring of service availability is deployed by suppliers.

Telecommunications

5.71 In designing new, or proposing changes to existing, systems, designers should ensure that consideration is given to the requirements of emergency plans and communication-service resilience before decisions are taken.

5.72 Telecommunications systems should be considered from two perspectives:

- the systems themselves may be business-critical (for example in an IT data centre); or
- they may provide a vital function in managing an emergency (for example public address, telephone and paging systems, the Airwave mobile telecommunication system).

5.73 Where the system is business-critical, the resilience principles should be applied to it and any supporting subsystems.

5.74 For both business-critical and emergency situations, designers of telecommunications systems should consider:

- emergency switching of telephones: fall-back telephones should be sited to guarantee the availability of internal communications to all planned refuges and control centres. The public mobile telephone networks should not be relied on in any emergency communications plan, since extreme external events may overload them or force them to be shut down. Unless specific provision has been

made for availability of a reduced mobile telephone service for specific individuals and handsets, this service should not be solely relied upon in emergency planning;

- public address (PA) and alarm systems: PA and alarm systems provide the primary means to communicate with service users. In addition to providing systems throughout a facility, consider extending the system (or making provision for extension) into the car park or other waiting areas. PA systems should be on the essential services power supply and should also allow input into the system from multiple locations;
- use of dedicated two-way radios as back-up system (as networks are not always reliable during some incidents (for example, suspected terrorism) when networks may be switched off or lost);
- use of corporate screensavers for post-incident bulletin updates;
- paging and wireless data systems: similarly, these systems may need to be receivable in spaces adjacent to the site that are designated for emergency use;
- in an emergency, the media will be extremely keen to gather information. The security of data links, including audio, should be considered. Some form of encryption may be prudent to enable positive control of information release and protect personal or sensitive information;
- automated meter reading of bulk oxygen or fuel supplies via telemetry systems to the supplier (failure in the system will require manual intervention).

5.75 Digital communication and information is vital to business continuity, and specific plans need to be in place to mitigate any loss of service (see the Cabinet Office's (2011) 'UK cyber security strategy – protecting and promoting the UK in a digital world'). Where the system is business-critical, the resilience

principles should be applied to it and any supporting subsystems.

5.76 Home/mobile communication systems will be needed for key staff with whom contact will be required in the event of an emergency or adverse incident.

5.77 Special note should be taken of the need to ensure that batteries of all essential communications equipment are serviceable and fully charged to meet the needs of a prolonged power failure.

Emergency plans for engineering services

5.78 To be resilient, healthcare organisations should be able to restore engineering systems to normal as soon as practicable after an emergency. This will take the form of an emergency plan that will need to be regularly tested and updated, internally as well as with suppliers, to meet changing circumstances.

Note

In all aspects of emergency and resilience planning, NHS-funded providers should ensure engagement with the AEO, LSMS and emergency planning liaison officer (EPLO).

5.79 Healthcare organisations may encounter such scenarios as:

- unplanned interruption to a utility supply (gas, water, electricity, telecommunications etc);
- unexpected equipment and service distribution failures (telephones, water pipework, medical gases etc);
- a civil incident (act of terrorism, civil disturbance etc);
- an environmental incident (floods, storm damage, overheating or other extreme weather event);

- failure of transport infrastructure leading to the loss of external supplies or facilities that support the healthcare organisation.

5.80 Emergency and resilience planning cannot be carried out in isolation; all arrangements should be agreed through consultation and dialogue (internally and externally).

5.81 Individual services or departments should be encouraged to accept responsibility for contingency arrangements. This is particularly important for services provided through associated contracts (via PFI partners, commercial businesses, service level agreements etc).

Creating an emergency plan supported by resilience capability

5.82 It is important to define the area to which the plan will apply. This may be by site rather than individual buildings to avoid repetition and to embrace the wider service issues. All the estates services and facilities that exist in the range of buildings on-site should be considered. This plan should be considered in conjunction with the risk assessment described in [paragraphs 2.18–2.22](#).

5.83 [Table 2](#) gives a broad list of suggested topics for consideration. It is not a comprehensive list and may not be applicable to all sites, but it should act as a prompt to establish the “services list” for a particular healthcare organisation.

5.84 All plans should be documented and supported by relevant information. This should be kept up-to-date and under constant review. See NHS PAM for further assistance ([paragraphs 1.13–1.16](#)).

Testing the plan

5.85 Plans should be exercised in order to familiarise staff and to test procedures. Duty to exercise plans is contained in ‘NHS Commissioning Board core standards for emergency preparedness, resilience and response (EPRR)’ from NHS England (2013).

5.86 Larger and more wide-ranging exercises should be carefully planned and coordinated through the AEO or the EPLO.

5.87 These approaches should engage all staff involved in resilience planning for the healthcare organisation so that all lessons learned can be shared across all services and used to update the plans.

5.88 Maintaining services is an essential function of the emergency plan. Alternative sources of catering, laundry, waste disposal, transport, energy etc need to be confirmed, and all lines of communication and supply chains regularly tested and reviewed.

5.89 It is also necessary to discuss and establish the priorities of clinical services within the plan. These will include life-critical functions (operating theatres, critical and special care areas, neonatal intensive care units, emergency care etc); diagnostic services (imaging, laboratories etc); and clinical support functions (blood, sterile services, pharmaceutical supplies, medical gases, transport etc).

5.90 Particular consideration needs to be given to the services supporting critical and special patient requirements. This could include, for example, positive/negative ventilation for immuno-suppressed/infectious patients, intensive care, patient mobility and community care. These examples are not exhaustive, and a comprehensive assessment undertaken by a multidisciplinary group should take place and be maintained, to inform the emergency plan.

5.91 Prioritised but flexible, estate and facilities services which underpin clinical priorities will provide a good platform for the organisation to cope with the impact of emergencies, hazards and threats and speed up recovery to provide normal business continuity.

External impact

5.92 External influences are perhaps the most difficult element to incorporate into emergency plans due to the wide range of scenarios that could be presented. Consequently, scenario

System	Services	External influence
Mains electricity supply Standby generators CHPs UPS + other batteries Emergency lighting Mains water Hot water Treated water (renal etc) Heating, ventilation and air-conditioning Steam Pneumatic air tube systems Building management system Drainage Surface/foul/waste Fuel supplies Gas/oil/other fuels Communications, including wireless systems: • telephones (fixed) • mobile • paging CCTV Burglar alarms Door interlocks (access and ingress) IT and patient information systems Nurse call systems Lifts Sterilization and decontamination Piped and cylinder medical gases Fire alarms Refrigeration (food, mortuary, blood supplies, pharmacy equipment etc) Medical equipment Building structure Architectural design features	Catering – patients and staff Key clinical departments (A&E, theatres, critical care etc) Clinical support (pathology/radiology etc) Estates & facilities management (including engineering staff such as Authorised Persons and Competent Persons) Transport Portering Administration support Patient information Cleaning Waste disposal Laundry Medical supplies Fuel supplies Water drainage Security Parking	Mains water contamination Air pollution/quality Flooding Mains sewage treatment failure Transport routes and infrastructure Infestation Civil disturbance Explosion Excavation Terrorism incidents Communications Other severe/extreme weather conditions: • high temperatures/heatwaves • extreme cold weather/ice and snow • high winds (windstorms) Fires from adjacent properties Fauna and flora damage

Table 2 Suggested systems and services and building for consideration when creating an emergency plan

planning for every eventuality is very unlikely and unnecessary; a generic response framework can address most scenarios.

5.93 However, some of the most likely scenarios and the key issues arising should be examined, evaluated and tested to ensure that some form of response is in place for that eventuality (for example, loss of a major utility or external communication links).

Staff functions

5.94 The structure of different organisations will mean that staff with varying levels of experience and expertise could be called on to deal with estates and facilities emergencies; hence, there is a need to ensure that regular training and exercises take place involving all staff groups that may be called upon.

5.95 Written emergency operational procedures should be easily understood by those people expected to use them. For example, emergencies associated with engineering services should always be handled by qualified, competent and experienced engineers, as the emergency operational procedure may be highly technical.

5.96 In many cases, however, standby staff who may be the first to attend an emergency will not have the technical knowledge to make appropriate decisions. If this is the case, emergency operational procedures should be detailed and specific, and should include instruction on where and how to seek assistance from a more experienced colleague at any stage. This instruction should normally include more than one route and more than one level of management (that is, it should have some communication resilience).

Appendix 1: Design proposal review

Impacts of loss of power, water, drainage, sewage and transport – giving example questions to mitigate the impacts on healthcare organisations

This appendix gives examples of the questions that should be asked by the reviewers of a design proposal.

The list of questions given should not be taken as exhaustive; it is intended as a guide to show how to gauge the level of resilience in a proposal.

Understanding the impacts outlined in [Table A1](#) on the ability to deliver healthcare will inform the design team and direct the questions to ask during the planning process.

Scenario 1 – Mains water supply fails for three days

When considering safe water supplies, consideration needs to be given to:

- the Health and Safety Executive's 'Legionnaires' disease: the control of legionella bacteria in water systems – Approved Code of Practice and guidance on regulations' (commonly known as L8); and
- HTM 04-01 – 'The control of *Legionella*, hygiene, "safe" hot water, cold water and drinking water systems'.

- 1 What arrangements exist in the design for supplying water?
- 2 How will a failure in the supply be detected?
- 3 Are emergency stocks held in tanks?
 - 3a How much stock?
 - 3b How was this figure arrived at?
 - 3c Is this based on normal rates of consumption or rationed?
 - 3d How will the water in these tanks be kept potable so that it is ready for use immediately?
 - 3e What arrangements exist for turning over the stock?
- 4 Is there space in the grounds for collapsible temporary tanks?
 - 4a How long will it take to provide this capability (that is, how much notice is required)?
 - 4b Does the volume of tank stock allow sufficient time to construct these temporary tanks?
 - 4c Will they require pumping arrangements to feed into the existing distribution system?

Power outage	Results in reduced ability or inability to maintain critical care which may result in patients being either transferred to unaffected areas or evacuated to other designated facilities. Lifts, hoists and pneumatic air tube systems not working – severely restricting access to full healthcare facilities. Fire safety alarms, CCTV, burglar alarms and associated equipment not working – extreme risk of patient safety and safeguarding the infrastructure. IT, internet and computers going down, therefore limiting access to medical records – can have severe repercussions on patient care. Refrigeration – some medication needs temperature-controlled storage in a medical refrigerator. Impact on continuing patient treatment. Also, if food refrigeration is not available, food will be spoiled; this may affect patients' dietary requirements. Communication systems – patients unable to contact emergency services; impact on mobile phone networks; inability to recharge mobile phones or portable/cordless phones and two-way radios. No electricity to recharge essential equipment. Lighting inadequate or in some instances not provided – inability to deliver patient care (for example operating theatre lists); safety and security issues; impact on patients with visual impairment; impact on people with mental health problems or those with dementia. The ability to maintain essential equipment in limited lighting. Emergency lighting – (as above). Heating, cooling and ventilation – loss of any of these systems creates a poor care environment with patients too cold in winter or suffering heat exhaustion in summer or respiratory conditions through poor ventilation. Washing machines, dishwashers and catering equipment cannot be used – adequacy of linen supplies and availability of disposable paper plates/plastic utensils etc. Impact on increased waste, storage and cost of disposal. Pumping stations, booster pumps and monitoring mechanisms may not work at their optimum level, causing disruption to water, drainage and sewage – hydration, cleanliness, hygiene, contamination issues (see below).
Water, drainage, sewage	Power is necessary for pumping and booster pumps and monitoring mechanisms – loss of clean drinking water, hot water for bathing, washing, cleaning and hygiene. Poor drainage leads to back-up water in the pipes – contamination and potential public health issues. Sewage treatment failure – could lead to untreated/undertreated sewage being added directly to streams and water courses, leading to contamination, public health issues and clean-up measures and costs in the future.
Transport	Transport is dependent on fuel and reliant on electricity – that is, fuel pumps. If transport cannot get to and from the site, it is likely to result in issues around: • patients' inability to get to hospital for healthcare • patients calling emergency services for help • staff accessing patients in the community • staff ability to get to hospital to provide an adequate care service • staff on duty not able to go home, leading to stress and exhaustion.
Community health effects	Loss of home care, that is, oxygen or dialysis units. Lack of home care because staff not able to deliver community service. Loss of power in the community impacts on loss of lighting and therefore increase in accidents; loss of cooking and refrigeration affecting ability to have wholesome nutritional meals, hot drinks etc. Adverse mental health reactions to loss of services, that is, trauma, anxiety, depression. The impact means a greater demand on hospital healthcare services.

Table A1 Impacts of power outages and their implications on water, drainage, sewage, IT and transport and the ability of NHS-funded providers to maintain healthcare

- 5 Could a borehole and private supply be provided (that is, one procured outwith that supplied by the local water vendor)?
- 5a Will this be for emergency use only (may be easier to get an abstraction licence)?
- 6 What engineering controls will be in place if water rationing is part of the response plan?
- 7 Will non-essential supplies be shut off? Manually or automatically (by the BMS)?
- 8 What impact will the loss of water or imposition of rationing have on other services?
 - steam boiler/generator plant;
 - centralised sterile services department, operating theatre air-conditioning plant and other medical users;
 - catering, cleaning and other support users.
- 9 What will be the effect of reduced flow on the sewerage system?
 - simple trap-water seals may evaporate and allow gases/airborne bacteria to backflow;
 - reduced effectiveness in clearing pipework, build-up of sludge, blockages.
- 10 What is the possibility of using non-potable water from borehole or other source to flush systems?
- 2 What external services require mains electricity for delivery?
- 3 Will the local water undertaking be able to deliver water (pump failure?)
- 4 Outsourced suppliers, for example sterile supplies: is there sufficient space allocated within the facility to hold stocks for the anticipated duration of the failure? Will the provider be prepared to invest sufficient capital to hold these stocks?
- 5 What arrangements exist for emergency supply of electricity (that is, temporary generators, quick connections)?

Standby generator

- 6 Is the engine rated for continuous running? (Certain generators are only rated for non-continuous operation, for example 8 hours in a 24-hour period.)
- 7 How much fuel is held? Is there a need for a fuel bowser?
- 8 Is there adequate cooling for the generator to operate for extended periods in midsummer?
- 9 What if the generator is down for servicing on the day?
- 10 Has provision been made in the design for connection of another generator during maintenance?
- 11 Who will provide this additional generator and where will it be sourced from?
- 11a Is there an additional competent person available to supervise the running of the generator while under load?
- 12 Who owns the standby generator: the provider or a subcontractor?
- 12a If it is a subcontractor, how quickly are emergency repairs carried out?

Scenario 2 – Mains electricity fails for 24 hours

When considering this scenario, consideration will need to be given to prioritisation strategies with suppliers.

- 1 Is the normal supply at HV or LV?

- 12b** Consider the implications of a wide-scale incident on this subcontractor's ability to deliver.

Combined heat and power (CHP) plant used as a standby generator

When considering this aspect, refer to HTM 06-01 – 'Electrical services: supply and distribution'.

- 13** What arrangements exist for dumping excess heat in case of low demand? (If this needs water, consider a cascade failure.)
- 14** Does the design use the hospital heating system? (Consider the effect of possibly having to turn on the heating in midsummer to allow the generator to operate.)
- 15** What is the impact of internal failure, for example if a substation or distribution board fails?
- 15a** Can supply be re-routed from somewhere else?
- 15b** Is it possible to attach a portable generator?
- 15c** Who will provide the generator, service it etc?
- 16** What impact will the loss of the non-essential supply have on facility operations?
- 17** How long will it take to recover and clear any backlog of non-essential work?

Scenario 3 – Loss of telephone communications for up to five days

- 1** Which systems use the telephone network?

Internet connection and data centres

When considering this aspect, undertaking a cost/benefit analysis would be necessary to

determine the best options to realistically pursue.

- 2** Can supplier orders and deliveries still be tracked?
- 3** Are stock levels of critical supplies sufficient to last for the loss of service, or will manual monitoring of stock levels be required?
- 4** Where will the manpower for manual monitoring come from?

Building management system

- 5** Are satellite sites controlled and monitored from a remote location?
- 6** Could loss of the telephone network and data centres make remote operation impossible?
- 6a** Will systems have to be manually operated (manpower provision, costs)?
- 6b** Will systems/plant and equipment operate in less economical modes (increased running costs)?

Plant monitoring systems

- 7** Leased/hired generators and CHP plant often have a telephone connection to the manufacturer to report faults, allow for remote fault-finding, and identify routine maintenance requirements.
- 7a** How will a fault be reported if found?
- 7b** Will the estates department be aware?

CCTV and security systems

- 8** Remote monitoring of CCTV at an off-site security centre may be a financially viable option for a provider to consider.
- 8a** Will this system continue to operate if the telephone network and data centres fail?
- 8b** What vulnerabilities would be exposed by this failure?

Appendix 2: Case study. Ysbyty Ystrad Fawr local general hospital

The site for the new 276-bed Ysbyty Ystrad Fawr local general hospital is located on a floodplain. During the various stages of design, proposals were developed to ensure that the hospital remains in operation during any extreme flood event. Thus, the main hospital concourse is located one floor above the floodplain with parking arranged at the lower ground level. Patient and staff areas are sited around a series of enclosed and semi-enclosed

courtyards at both the lower ground and upper ground levels.

Extensive flood modelling was undertaken to understand the impact of a flood with regard to the hospital site. In addition, the flood-modelling exercise determined the broader impacts of flooding and displacement on the wider community.

APPENDIX A – SCHEDULE OF VENTILATION SYSTEMS.....	10
APPENDIX B – 40 POINT CHECK SHEET	11

1.0 Introduction

- Ventilation is used extensively in healthcare premises to closely control the environment and air movement of the space that it serves. This is for both the comfort of occupants in buildings and to contain, control and reduce hazards to patients, staff and visitors from airborne contaminants including, dust and harmful micro-organisms.
- This Policy sets out the detailed requirements for the maintenance and safe operation of all air conditioning and ventilation plant as stated in SHTM 03-01 Parts A & B. These will be maintained so that they do not present a risk to persons either in the vicinity of the plant, in areas served by the plant, or a statutory compliance risk to NHS Greater Glasgow & Clyde.
- This Policy requires that all ventilation and air conditioning equipment is installed, inspected, serviced and maintained in accordance with all Statutory Instruments, NHS Guidelines and Scottish Health Technical Memorandums (SHTM's) to ensure that such equipment does not pose a health or operational risk to either, staff, patients or visitors

2.0 Scope

- This Policy applies to all staff, service users and contractors associated with the NHS Greater Glasgow & Clyde. Those persons with defined responsibilities should read this policy, and where applicable, read and understand the ventilation procedures manual.
- This Policy covers all maintenance activities on ventilation and air conditioning plant within NHS Greater Glasgow & Clyde, and any sites which NHS Greater Glasgow & Clyde is responsible for the maintenance of ventilation equipment. This will include, but not limited to, local room extraction plants up to full air handling and conditioning systems.
- The Ventilation policy makes reference to SHTM 00 Best Practice Guidance for HealthCare Engineering with regards to dealing with emergencies e.g. Loss of utilities, failure of a main component and storm damage (relevant if AHU's and chillers are located on roofs).
- This policy will need to be reviewed annually or subject to and industry or government guidance, SHTM `s and best practice updates.

3.0 Duties and responsibilities

3.1 Clear lines of managerial responsibility should be in place so that no doubt exists as to who is responsible for the safe operation and maintenance of the equipment.

3.2 A periodic review of management systems should take place in order to ensure that the agreed standards are being maintained.

3.3 Persons required for inspecting, verifying or maintaining ventilation equipment will need to show that they are competent to do so. As a minimum they should have sufficient knowledge of its correct operation to be able to recognise faults. They should have attended CP (V) training.

3.4 Designated staff functions

A person intending to fulfil any of the staff functions specified below should be able to prove that they possess sufficient skills, knowledge and experience to be able to perform safely the designated tasks.

3.5 Management

Management is defined as the owner, occupier, employer, chief executive, general manager or other person who is ultimately accountable for the safe operation of premises.

3.6 Chief Executive

The Chief Executive has the overall authority and responsibility for ensuring ventilation services and systems are properly operated, maintained and repaired throughout NHS GG&C in line with SHTM 03-01. The Chief Executive's specific responsibilities are to ensure that NHS GG&C appoint the Designated Person in writing.

3.7 Designated Person (DP)

This person provides the essential senior management link between the organisation and professional support. The Designated Person should also provide an informed position at board level. They are also responsible for ensuring that there are sufficient and suitable resources available to enable all systems associated with ventilation systems are operated, maintained and repaired safely and effectively.

3.8 Authorising Engineer (Ventilation), AE(V)

The AE (V) is defined as a person designated by Management to provide independent auditing and advice on ventilation systems and to review and witness documentation on validation.

The AE will act as an independent, professional advisor to the healthcare organisation. The AE should be appointed by the organisation with a brief to provide services in accordance with the SHTM guidance.

The AE will act as an assessor and make recommendations for the appointment of AP's, monitor the performance of the service and provide an annual audit to the DP. To carry out this effectively, particularly with regard to audit, it is preferable that the AE remains independent of the operational structure of the NHS board.

3.9 The Compliance Manager

Has an administrative role in ensuring compliance for Ventilation systems across NHS GG&C is managed effectively.

3.10 Authorised Person – Lead (Ventilation), AP (V/L)

The Lead Authorised Person is a site specific role, they will direct all other AP's in their daily duties and control and manage the Ventilation systems on the site. They will be responsible for the practical implementation and operation of Management's safety policy and procedures relating to the engineering aspects of ventilation systems.

3.11 Authorised Person (Ventilation) AP (V)

The AP(V) will be an individual possessing adequate technical knowledge and having received appropriate training, appointed in writing by the Designated Person (in conjunction with the advice provided by the AE(V)), who is responsible for the practical implementation and operation of Management's safety policy and procedures relating to the engineering aspects of ventilation systems. There is currently no requirement for AP refresher training however there is a requirement for an AE (V) to interview AP (V) every 3 years.

3.12 Competent Person (Ventilation) CP (V)

The CP (V) is defined as a person designated by Management to carry out maintenance, validation and periodic testing of ventilation systems. Who, further to CP Ventilation training and assessment by their AP (V) , should be appointment as a CP (V) in writing.

3.13 Competent Person with limitations (Ventilation) CP (V*)

All persons carrying out work on ventilation systems are to be appointed as a CP (V) in writing by the AP (V) for the level and complexity of work undertaken.

3.14 Infection Control Officer

The Infection Control Officer (or consultant microbiologist if not the same person) is the person nominated by management to advise on monitoring the infection control policy and microbiological performance of the systems.

Major policy decisions should be made through an infection control committee. The infection control committee should include representatives of the user department and estates and facilities or their nominated representative (that is, the AP (V)).

4.0 Records

A record should be kept of those appointed to carry out the functions listed above. The record should clearly state the extent of the post holder's duties and responsibilities, and to who they are to report.

5.0 Training

Routine inspection and maintenance procedures can cause risks to the health of staff carrying out the work and those receiving air from the plant. All those involved should be made aware of the risks, and safe systems of work should be agreed. Suitable safety equipment should be provided as necessary, and training in its use should be given.

Any training given should be recorded, together with the date of delivery and topics covered.

Training in the use of safety equipment and a safe system of work will need to be repeated periodically in order to cater for changes in staff

6.0 Ventilation Systems

6.1 All ventilation systems should be subject to but not limited to one visual inspection annually.

6.2 The purpose of the inspection is to establish that:

- The system is still required; the AHU conforms to the minimum standard set out in (SHTM 03-01 part B Section 3);
- The fire containment has not been breached;
- The general condition of the system is adequate for purpose;
- The system overall is operating in a satisfactory manner.

6.3 The 40 point check sheet (Appendix B) should be used to record the result of the inspection.

- 6.4 All critical ventilation systems should be inspected quarterly and verified at least annually. In some circumstances the verification may need to be carried out more frequently.
- 6.5 The quarterly inspection should be as detailed in paragraphs 6.1 – 6.3.
- 6.6 The purpose of the annual verification will be to ensure additionally that the system:
- Unless otherwise specified below, the ventilation system should achieve not less than 75% of the design air-change rate given in SHTM03-01 Part A Appendix 1, or its original design parameters.
 - The pressure regime should achieve not less than 75% of the design value given in SHTM03-01 Part A Appendix 1, or its original design parameters; and the pressure gradient relationships with regards to surrounding areas must be maintained.;
 - Is operating to an acceptable performance level;
 - Remains fit for purpose.

Definition of a critical system

- 6.7 Ventilation systems serving the following are considered critical:
- Operating theatres of any type, including rooms used for investigations (for example catheter laboratories);
 - Patient isolation facility of any type;
 - Critical care, intensive treatment or high-dependency unit;
 - Neonatal unit; SHTM 03-01: Part B: Operational management and performance verification Version 1: October 2011 Page 26 © Health Facilities Scotland, a Division of NHS National Services Scotland
 - Category 3 or 4 laboratory or room;
 - Pharmacy aseptic suite;
 - Inspection and packing room in a sterile services department;
 - MRI, CAT and other types of emerging imaging technologies that require particularly stable environmental conditions to remain within calibration;
 - Any system classified as an LEV system under the COSHH Regulations;
 - Any other system that clearly meets the definition.

7.0 Estates alerts and operational restrictions

Estates alerts and operational restrictions related to ventilation systems on site(s) may be issued by various means, such as

- Health and Safety Alerts
- NHS Estates
- Health Facilities Scotland (HFS)
- Competent Persons reports
- Safety Information Bulletins issued by NHS
- Manufactureres of ventilation installation equipment and components
- Asbestos Register (Shine). The Board has ducting with asbestos mastic and rope seals throughout its estate.

8.0 Equipment Release Certificate

8.1 This is a safety document, for use in Critical Ventilation plant, which is a form signed by the user, countersigned signed and issued by an AP (V) to the CP (V) in charge of work to be carried out. It defines the scope of the work to be undertaken and makes known exactly what areas are affected.

8.2 The AP (V) will ensure all CP(V)`s and Test Specialists working on ventilation systems carry out their duties in a safe and efficient manner in accordance with SHTM 03-01 and best practice. All work will be conducted in accordance with written instructions.

9.0 Emergency Procedures

In the event of System failure the AP (V) will notify the User (Critical System) and the site infection control team, who shall collectively consider the implications of the failure and the continued use of the Area served by the Critical System, to decide whether or not to recommend closure of the facility to the respective Management Team. All decisions should be formally recorded and issued to the General Managers for their records.

10.0 Business Continuity Plans

Departments and users should develop business continuity plans for loss of critical ventilation services in the event of system failure or conditions outside of the systems operating envelope.

11.0 Monitor & Review

The ventilation services policy shall be reviewed annually with regards to procedures, incidents and the competence of staff for their assigned duties by the DP. An agreed minute of the review meeting shall be presented by the DP to the Chief executive for their consideration before being passed to the relevant persons and line managers for action, thereafter the document is to be placed in the operational procedures manual / file.

APPENDIX A – SCHEDULE OF VENTILATION SYSTEMS

Ventilation systems include (but are not restricted to) the following summary:

System / Type	Typical Area of Use
General (Extract)	Operating theatres Hospital wards and departments Toilets Bathrooms Kitchens Mortuary
General (Supply)	Operating theatres Hospital wards and departments
Ultra Clean Ventilation Systems	Operating theatres
Local Cooling / Refrigeration Units	Laboratories Clinical areas Specialist areas
Local Exhaust Ventilation (LEV)	Operating theatres (exhaled gas) Laboratories Dental Mortuary Workshops Specialist areas
Fume Cupboards	Pharmacy Laboratories
Microbiological Safety Cabinets	Pharmacy Laboratories

APPENDIX B – 40 Point Check Sheet

Competent Person (Ventilation) Air Handling Unit (AHU) Routine Inspection

Note: Critical ventilation systems should be inspected quarterly. Non-critical ventilation systems should be inspected annually.

GENERAL CONDITION

End of useful life. This should be clear from the condition of the AHU and its associated services and plant. **Action: Urgent replacement indicated.** The main indicators will be:

1. Extensive internal and/or external corrosion of the AHU casing.
2. Failure of filter housings to prevent air bypass.
3. General corrosion of heater and cooling battery fins, attenuator surfaces etc.
4. Significant failure to meet minimum standards.
5. Associated plant services and controls in poor condition or not able to fulfil their purpose.
6. AHU aged 20 years or more.

Poor. Should be fairly apparent but would include an assessment of the degree of corrosion; cleanliness of coils and batteries; quality of filter mountings and their ability to prevent air bypass; fan and drive train condition; the control system elements' ability to fulfil their function; condition of the access doors and inspection covers. The age of the AHU is generally less important. **Action: Extensive refurbishment or programmed replacement indicated.**

Average. Some faults but generally free of significant corrosion, clean internally and conforming to minimum standards. **Action: Faults capable of correction at next maintenance period.**

Good. Conforming to the minimum standards, obviously cared for and subject to routine maintenance. **Action: Routine maintenance will preserve standard of the equipment.**

COMPLIANCE WITH MINIMUM STANDARDS (questions 2 to 23, 32 and 33)

Poor. More than three answers are negative. **Action: Management action required by estates/facilities department.**

Average. No more than three answers are negative. **Action: Maintenance action required.**

Good. No answers are negative, full compliance. **Action: None.**

MAINTENANCE QUALITY (questions 5, 12, 26 to 31 and 34 to 40)

Poor. More than three answers are negative. **Action: Management action required by estates/facilities department.**

Average. No more than three answers are negative. **Action: Maintenance action required.**

Good. No answers are negative. **Action: None.**

General condition: End of useful life Poor Average Good

Compliance with minimum standards Poor Average Good
(Questions 2 to 23, 32 and 33)

Maintenance quality Poor Average Good
(Questions 5, 12, 26 to 31 and 34 to 40)

Serial	Survey Question	Yes	No	Comments
1	Plant running?			
2	Is the unit and its associated plant secure from unauthorised access?			
3	Is the unit safely accessible for inspection and maintenance?			
4	Is the air intake positioned to avoid short circuiting with extract or foul air from other sources such as gas scavenging outlets?			
5	Are all inspection lights operating?			

6	Are motorised dampers fitted to the intake and discharge?			
7	Are fan motor(s) outside of the air stream?			
8	Is the fan drive train visible without removing covers?			
9	Is the cooling coil located on the discharge side of the fan?			
10	Is an energy-recovery system fitted (state type)?			
11	Are condensate drainage systems fitted to all energy recovery systems, cooling coils and humidifiers in accordance with Chapter 3 of Health Technical Memorandum 03-01, Part B?			
12	Are drainage traps clean and filled with water? (see Table 3 in Health Technical Memorandum 03-01, Part B)			
13	Is the drain trap air break at least 15 mm?			
14	If a humidifier is fitted, state the type			
15	Is the humidifier capable of operation?			
16	Is there space to safely change the filters?			
17	Are there test holes in the principal ducts?			
18	Are the test holes capped?			
19	What is the general condition of the exterior of the AHU?			
20	Are the principal ducts lagged?			
21	What is the general condition of the associated control valves and pipework?			
22	Is the pipework adequately lagged?			
23	Is the system clearly labelled?			
24	Record prefilter differential pressure			

25	Record main filter differential pressure			
SWITCH PLANT OFF. FIT PADLOCK AND CAUTION SIGN TO ISOLATOR				
26	Did the motorised dampers close on plant shut-down?			
27	Is the vermin/insect screen clean?			
28	Is the intake section including the fog coil clean?			
29	Are the prefilters correctly fitted with no air bypass?			
30	Are all drive belts correctly aligned and tensioned?			
31	Is the cooling-coil matrix clean?			
32	Are all drip-trays fully accessible or capable of being removed for cleaning and have a fall to drain?			
33	Are the drainage trays stainless?			
34	Are the drainage trays clean?			
35	Are there any signs of water ponding in the AHU?			
36	Is the matrix clean for each heater-battery?			
37	Have the main filters been correctly fitted with no air bypass?			
38	Is AHU and its associated main ductwork clean internally?			
ENERGISE PLANT				
39	Did unit restart satisfactorily?			
Test automatic fan-motor change-over, if fitted				
40	Did automatic change-over operate satisfactorily?

1. Terms of Reference

1.1 This audit was conducted in accordance with the following current reference documents:

- Scottish Health Technical Memorandum 00: Policies and principles of healthcare engineering.
- Scottish Health Technical Memorandum 03-01: Specialised ventilation for healthcare premises.

2. Executive Summary

2.1 Introduction. The purpose of this audit was to assess the compliance, operation and maintenance of the Safe System of Work at the Hospital(s) in accordance with the discipline specific Health Technical Memoranda, Acts, Regulations and HSE Guidance documents. The resulting Action Plan will be reviewed periodically. The appointments of the discipline specific Authorised Persons were also assessed during the audit.

2.2 Report Summary

- The Lead AP should review the action plan at the end of this report and produce his own action plan.
- A draft ventilation Standard Operating Procedure (SOP) was held on StaffNet. In addition to the SOP, a ventilation safety policy should be produced and ratified by the board.
- Due to the size and ongoing change at the hospital the APs were not always able to find the time to carry out their duties. The provision of APs (V) should be reviewed by senior management taking into consideration other duties the APs are liable for. Cyril Dowson is scheduled for his AP assessment in December 2016. Jim Guthrie and David Bratney should attend training before being assessed.
- CPs should be trained, assessed and appointed. Evidence of competency was held for two contractor CPs, letters of competency should be held for all contractor CPs.
- Task risk assessments were not held for in-house tasks. These must be produced and communicated to the in-house CPs.
- Permits to work were in use for the Lab Block but they were not in use across the rest of the estate. There were some minor errors on some of the permits to work issued which all APs should note.
- The Document Register was populated for the Lab Block. This should be extended to include the Adult & Children's and the retained estate. The Document Register should include a list of all ventilation assets.
- Planned maintenance was not carried out on the retained estate. The AHUs should be subject to planned maintenance, cleaning, quarterly inspections and annual inspections.
- Chilled beams should be cleaned 6 monthly and split air condition systems should be cleaned 3 monthly.
- The Lab Block AHUs were cleaned periodically but records were not retained. Cleaning records should be retained.

9. Not all critical systems were subject to annual verifications. Adult & Children's isolation rooms, critical care areas and MRI/CT suites should be verified annually. Retained estate neonatal and MRI/CT suites should be verified annually. When a critical system fails to meet the performance criteria set out in SHTM 03-01, Part B, the AP should notify the User (V)/Responsible Person and infection control in writing.
10. Most but not all LEVs had been subject to 14 monthly examinations under the COSHH Regulations. The mortuary dissection tables had not been examined and performance tested. Some MGPS AGSS had been tested but records had not been retained. The test reports for the Lab Block LEV systems were retained by individual departments. The AP should check that all LEVs in the Lab Block have been examined and tested at least every 14 months.

3. Conclusion

ASSESSMENT OF SAFE SYSTEM OF WORK	CONCLUSION
1. Assessment of the Management Policy.	Medium
2. Assessment of the Authorised Persons.	Medium
3. Assessment of the Competent Persons.	High
4. Assessment of Incidents, Accidents and Dangerous Occurrences.	Very Low
5. Assessment of the Safety Documentation.	Low
6. Assessment of the Operating Records.	Medium
7. Assessment of the Safety equipment & Access Control.	Low
8. Assessment of the Engineering Systems.	Medium
9. Assessment of the Engineering Work Spaces.	Medium

Is the system safe to continue?	Yes, under the supervision of the AE
---------------------------------	--------------------------------------

4. Next Audit Date

The next audit visit is planned to take place in

November 2017

PREVIOUS ACTION PLAN

Serial	Rating	Reference	Action Required	Remarks
1	3	141208/1	The Ventilation Services Policy should be reviewed.	Ongoing, review at next audit.
2	3	141208/4	CPs should be occasionally monitored when carrying out works and a record of monitoring activities retained in the Documents Register.	Ongoing, review at next audit.
3	5	141208/6	In-house CPs should be trained, assessed and appointed. Certificates of appointment and evidence of training should be retained in the Documents Register.	Ongoing, review at next audit.
4	5	141208/7	Letters of competency should be obtained from the employers of contractor CPs and retained in the Documents Register.	Ongoing, review at next audit.
5	3	141208/8	A CP Register should be produced listing the contractor CPs and should be retained in the Documents Register.	Ongoing, review at next audit.
6	5	141208/9	Plant shutdown/make-safe risk assessments should be produced to identify the hazards associated with taking critical ventilation systems out of use and for work on LEVs that present a hazard to the maintainer. The risk assessments should be retained in the Documents Register.	Ongoing, review at next audit.
7	5	141208/10	Ensure task risk assessments are held for all works on ventilation systems. This documentation should be retained or referenced in the Documents Register.	Ongoing, review at next audit.
8	5	141208/12	Produce a schedule of ventilation systems to identify all systems as critical, non-critical or LEV in accordance with SHTM 03-01, Part B, Para 4.7. Retain the schedule in the Documents Register.	Ongoing, review at next audit.
9	3	141208/18	Display safety signs at the entrance to all plantrooms.	Ongoing, review at next audit.
10	3	141208/19	Display unique plantroom identity signs at the entrance to all plantrooms.	Ongoing, review at next audit.
11	3	141208/21	Repair/replace the dilapidated Neurosurgery external plant area access door.	Completed.
12	3	141208/22	Install task lighting and emergency lighting for the Neurosurgery external plant area.	Ongoing, review at next audit.

SHTM 03-01 SPECIALISED VENTILATION FOR HEALTHCARE PREMISES

Page 98

13	5	141208/23	Implement a planned maintenance regime for emergency lights fitted in plantrooms.	Action updated, review at next audit.
14	3	141208/27	Monitor the condition of the corroded intake louvres on the Neurosurgery external AHUs.	Completed.
15	3	141208/31	Repair the inspection lights on Neonatal AHU 3 and Neurosurgery AHU 5.	Completed.
16	5	141208/33	Investigate and repair the Magnehelic gauges on the Old Maternity AHU and Neurosurgery AHU 5.	Action updated, review at next audit.
17	3	141208/34	Fit direction of flow labels to the discharge ductwork on the Old Maternity AHU.	Asbestos hazard prevents access. Action withdrawn.
18	5	141208/36	Carry out quarterly inspections on all critical ventilation systems in accordance with SHTM 03-01, Part B, Appendix 1.	Progress made, action updated and review at next audit.
19	5	141208/37	Carry out annual inspections on all non-critical ventilation systems in accordance with SHTM 03-01, Part B, Appendix 1.	Progress made, action updated and review at next audit.
20	2	141208/39	Reference the location of inspection reports and verification reports in the Document Register.	Completed.
21	5	141208/40	Test fire dampers in accordance with SHTM 03-01, Part B, Para 4.13.	Ongoing, review at next audit.
22	5	141208/41	Carry out a 14 monthly thorough examination and test of all AGSS in accordance with the COSHH Regulations requirement for LEVs.	Action updated, review at next audit.
23	2	141208/42	Oversee the 14 monthly examinations of LEVs to ensure all the LEVs listed in the schedule of ventilation systems are examined.	Ongoing, review at next audit.
24	3	151209/1	Assess and appoint Mr Cyril Dowson as an AP (V).	Ongoing, review at next audit.
25	3	151209/2	Assess and appoint David Bratney as an AP (V) when he has completed AP (V) training.	Ongoing, review at next audit.
26	3	151209/3	Arrange for David Bratney to attend AP (V) training and forward a copy of his training certificate to the AE on completion.	Ongoing, review at next audit.
27	3	151209/4	Forward a copy of David Bratney's first aid training certificate to the AE.	Ongoing, review at next audit.
28	3	151209/5	Forward a copy of Cyril Dowson's first aid training certificate to the AE.	Completed.
29	3	151209/6	Arrange for Paul Allan to attend first aid training by 30 Jun 16 and forward a copy of his training certificate to the AE on completion.	Action updated, review at next audit.
30	4	151209/7	Use permits to work when taking critical systems out of service and when carrying out intrusive maintenance on hazardous LEVs.	Ongoing, review at next audit.

SHTM 03-01 SPECIALISED VENTILATION FOR HEALTHCARE PREMISES

Page 90

31	3	151209/8	Take remedial action to prevent the uncommanded shutdown of the AHU serving Theatre 8.	Completed.
32	3	151209/9	Only issue permits to work to appointed NHS CPs or contractor CPs listed in the CP Register.	Ongoing, review at next audit.
33	3	151209/10	Catalogue the ventilation system drawings for the Lab Block and Adults & Children's so they are readily available to the APs.	Completed.
34	5	151209/11	Populate the CAFM system (FM First) with planned maintenance tasks for all ventilation systems and retain records of all planned maintenance tasks carried out.	Ongoing, review at next audit.
35	3	151209/12	Calibrate the micro manometer and hand held anemometers annually and retain copies of calibration certificates in the document register.	Completed.
36	3	151209/13	Obtain copies of instrument calibration certificates used by all contractor CPs.	Completed.
37	5	151209/14	Rectify the unserviceable lighting on the Old Maternity 4th floor plantroom and install emergency lighting.	Ongoing, review at next audit.
38	3	151209/15	Fit identify signs or labels to the HEPA filter enclosures in the Adult and Children's Plantroom 21.	Ongoing, review at next audit.
39	5	151209/16	Provide a standby air handling unit for Ward 4b Haemato-oncology to allow for proper maintenance & verification and to provide redundancy in the system.	Action withdrawn.
40	3	151209/17	Fit access hatches to all AHU intake ductwork sections to allow inspections.	Ongoing, review at next audit.
41	3	151209/18	Fit glass drain traps to all Neurosurgery AHUs on the retained estate.	Progress made, action updated and review at next audit.
42	4	151209/19	Modify the drain trap arrangement on all AHUs in the Lab Block and Adult & Children's to ensure there is a 15mm air gap between the trap outlet and the drainage pipework.	Ongoing, review at next audit.
44	2	151209/21	Consider fitting inspection windows and internal lighting on all Lab Block AHU's.	Ongoing, review at next audit.
45	3	151209/22	Rectify the unserviceable lighting on retained estate Neonatal AHUs 1, 3 and 4.	Completed.
46	3	151209/23	Investigate and rectify the spurious bag filter readings on retained estate Neonatal AHUs 1, 3 and 4.	Ongoing, review at next audit.
47	4	151209/24	Rectify the collapsing pre-filters on the Old Maternity level 4 plantroom intake plenum and fit a pressure differential gauge/manometer.	Ongoing, review at next audit.

SHTM 03-01 SPECIALISED VENTILATION FOR HEALTHCARE PREMISES

Page 100

48	3	151209/25	Fit direction of flow labels to the isolation room extract ductwork in the Adult & Children's Plantroom 21.	Ongoing, review at next audit.
49	5	151209/26	Carry out annual verifications on the retained estate Neonatal and SCBU ventilation systems.	Action updated, review at next audit.
50	3	151209/27	Carry out and record annual cleaning on all AHUs.	Action updated, review at next audit.
51	3	151209/28	Ensure verification reports for critical ventilation systems include a summary clearly stating whether a pass or a fail was achieved and that the reports also record noise levels.	Completed.
52	5	151209/29	Ensure that LEV examinations and tests are carried out on the Mortuary dissection tables every 14 months in accordance with the COSHH Regulations.	Ongoing, review at next audit.
53	5	151209/30	Obtain confirmation from Pharmacy that the Aseptic suite containment cabinets are subject to LEV examinations and tests every 14 months in accordance with the COSHH Regulations.	Completed.
54	5	151209/31	Survey the Clinical Research department to identify any LEVs. Subject all identified LEVs to examinations and tests every 14 months in accordance with the COSHH Regulations.	Ongoing, review at next audit.
55	3	151209/32	Critical ventilation systems that do not meet the performance criteria specified in SHTM 03-01 should be taken out of service. If the clinical requirement prevents this the User and infection control should be notified in writing by the AP.	Ongoing, review at next audit.

Additional Comments

Nil.

Comments

Paul Allan should attend emergency first aid training by 12 Dec 16 as planned. He should forward a copy of his training certificate to the AE .

Jim Guthrie should attend AP (V) training and forward a copy of his training certificate to the AE on completion.

David Bratney should attend AP (V) training and forward a copy of his training certificate to the AE on completion. He should also attend emergency first aid training forwarding a copy of his certificate to the AE.

REPORT

Personnel

Duty Holder	Robert Calderwood	1
Designated Person	Mary-Anne Kane	1
Authorising Engineer	Duncan Machell	1
Authorised Persons	Paul Allan	2
	Cyril Dowson (Designate)	1
	Jim Guthrie (Designate)	3
	David Bratley (Designate)	4

1. Management Policy	Y/N	Comments	
Is there a Board Ventilation Safety Policy In place?	Y	NHS GG&C Ventilation Safety Policy.	1
Is the Ventilation Safety Policy approved at Board level?	Y	The policy was approved by Alex McIntyre (Director of Facilities).	1
Is the Board Ventilation Safety Policy reviewed periodically?	Y	The policy was first issued in October 2011 and reviewed in August 2012. The policy had been withdrawn from StaffNet for a review.	3
Is the Board Ventilation Safety Policy a controlled Document?	Y	The policy is a controlled document. A copy was held in the Document Register.	1
Are the Duty Holder (V) responsibilities clearly defined in the Policy?	Y	The policy states that the Duty Holder is responsible for ensuring the ventilation systems are operated, maintained and repaired in accordance with SHTM 03-01.	1
Is the Designated Person appointed in writing?	N	The Designated Person is shown as the Director of Facilities in the structure chart.	2
Does the Board Ventilation Safety Policy include emergency procedures?	N	Emergency procedures were not included in the policy.	3
Have the emergency procedures been validated or tested during the current audit period?	N/A	Not applicable.	
Has the Authorising Engineer (AE) (V) appointment been correctly made and is it in date?	Y	The AE's appointment expires on 31 Aug 17.	1

2. Authorised Persons (V)	Y/N	Comments	
Are all APs (V) currently certified?	N	Jim Guthrie, David Bratley and Cyril Dowson had not been appointed. Cyril Dowson will be assessed in December 2016.	4
Are the APs (V) due for refresher training in SHTM 03-01?	Y	Jim Guthrie and David Bratley should attend AP (V) training and forward copies of their training certificate to the AE on completion.	3
Are the APs (V) due for training in emergency first-aid?	Y	Paul Allan and David Bratley should attend emergency first aid training by 14 Feb 17 and should forward a copy of their training certificates to the AE on completion.	3

Are the APs (V) carrying out AP (V) duties on a regular basis?	N	Paul Allan and David Bratney were not using permits to work to control maintenance activities.	4
Are the APs (V) formally monitoring the work-in-progress and are they recording their observations?	N	CP Monitoring had not been carried out. Identified in previous audit.	3
Is the provision of APs (V) adequate?	N	When Jim Guthrie, David Bratney and Cyril Dowson are appointed this will provide four APs (V) for the campus. Comments were made by some APs that they struggled to find the time to carry out AP (V) duties on top of their other commitments.	3

3. Competent Persons (V)			
	Y/N	Comments	
Have the NHS CPs (V) been formally assessed and appointed by an AP (V)?	N	In-house CPs had not been assessed and appointed. Training certificates were held for two NHS CPs and a third was thought to have been trained but a certificate was not available. The remaining NHS CPs had not been trained.	4
Is evidence of the competency of Contractor CPs (V) held in the Document Register?	N	Evidence of competency was held for A Laughland and R Peel of Atlas Clean Air Ltd who carry out performance verifications on safety cabinets in the Laboratory building. Letters of competency or training certificates were not held for the CPs employed by H&V Commissioning Services Ltd and MAT Ltd.	3
Are the roles and responsibilities of Contractor CPs (V) defined in writing?	N/A	Not checked.	
Are records held in the Document Register of the site induction for the Contractor CPs (V)?	Y	The GG&C Contractor Control & Permit Register includes the issue of an identity card that listed the fundamental site rules and procedures.	1
Is there an up to date Register of CPs (V) appointed for the Trust included in the Document Register?	N	A CP Register was not held. Identified in previous audit.	3
Are the NHS CPs (V) carrying out their duties on a regular basis?	Y	In-house CPs and contractor CPs had been carrying out duties on a regular basis.	1

4. Incidents, Accidents and Dangerous Occurrences			
	Y/N	Comments	
Have there been any accidents, incidents, dangerous occurrences or "near misses" in connection with the ventilation systems?	Y	None reported.	1
Have the details of incidents, accidents or dangerous occurrences been properly recorded and reported?	N/A	Not applicable.	

5. Safety Documentation

Job Number:	Permit to work 81	Originating AP (V):	C Dowson
		Y/N	Comments
Was there a suitable & sufficient Risk Assessment to cover the work undertaken?	Y	23 May 16. Annual service of Labcaire PCR by Atlas Clean Air Ltd. Two risk assessments were held in the Document Register.	1
Was the permit-to-work completed by the AP (V) specifying the work to be carried out?	Y	The Hazardous/Not Hazardous option was not struck through at Part 1 of the permit to work.	3
Was the permit-to-work signed by the User (V) to allow the work to proceed?	N	The permit to work was not signed by the User (V).	3
Was the permit-to-work issued to a CP (V)?	Y	The permit to work was issued to A Laughland.	1
Was the permit-to-work cleared by a CP (V) and did they state that system was fit or unfit for use?	Y	No issues found.	1
Was the permit-to-work cancelled by an AP (V) and did they acknowledge that the system was fit or unfit for use?	Y	No issues found.	1
Did the User (V) acknowledge that the system should or should not be brought back into use?	Y	No issues found.	1
Were the site records up-dated on completion of the work?	Y	No issues found.	1

6. Operating Records

General	Y/N	Comments
Are the ventilation operating record documents kept in a secure location?	N	The ventilation documents were held in a secure office.
Do the APs (V) have access to copies of relevant SHTMs and other reference documents?	Y	An electronic copy was held.
Does the Document Register index include all of the subjects required by SHTM 03-01?	N	The Document Register was populated for the Laboratory Block only. The APs should either populate the Document Register with information for The Adult & Children's and the retained estates or populate individual document registers.
Is the working Ventilation Document Register periodically reviewed and out-of-date information transferred to the archive Ventilation Document Register?	N/A	The Document Register was in the process of being populated. Not assessed.
Is there a schedule of ventilations systems detailing which are critical, non-critical or LEVs?	N	Asset lists were held electronically covering the retained estate and Adult & Children's. The Lab Block asset list was held in the Document Register. A consolidated schedule of ventilation plant should be produced stating the classification (non-critical, critical or LEV) of the plant.

Are adequate technical drawings available to the APs?	Y	Drawings were held electronically (Zutec) for the Adult & Children's and the Lab Block. The drawings were well managed. Drawing ME/ZA/00/PL/524/518/21 dated 14 Jan 14 was checked with no issues found. Adequate drawings were not held for the retained estate neurosurgery theatres but these are due for refurbishment/replacement from mid 2017. Original drawings for the retained estate maternity theatres were reported to be held.	2
Are adequate O&M manuals available to the APs?	Y	O&M information was held electronically (Zutec) and on the shared drive for the Adult & Children's and the Lab Block. Original O&M information for the retained estate maternity theatres was reported to be held and was scheduled to be organised into a useable pack in 2017.	2
Are all of the ventilation systems included in the Trust's planned maintenance programme?	N	The Adult & Children's ventilation systems and the Lab Block ventilation systems were subject to planned maintenance. Good. Planned maintenance was not being carried out on the retained estate ventilation systems. Chilled/active beams were not subject to 6 monthly inspection & cleaning but this was being planned by the APs. Split air conditioning systems were not subject to quarterly hygiene inspections.	4
Are the planned maintenance records suitable, sufficient and accessible to the APs?	N	In-house maintenance was documented manually on check sheets. Service sheets were held for work carried out by contractor CPs. None of the maintenance was scheduled on FM First.	3
Are the results of the Trust's planned maintenance programme formally reviewed annually to establish trends and gaps? Are these reviews recorded?	N/A	Not checked.	
Inspection and Verification			
	Y/N	Comments	
Are critical ventilation systems being inspected quarterly?	N	The Adult & Children's critical systems were subject to quarterly inspections. Good. The retained estate critical systems were not subject to quarterly inspections.	3
Are non-critical systems being inspected annually?	N	Retained estate non-critical ventilation systems were not subject to annual inspections.	3

Are critical ventilation systems being verified annually?	N	All theatres were subject to a rolling programme of annual verifications. Good. Other critical systems in the Adult & Children's (isolation rooms, critical care and MRI) were not being verified annually but this requirement was under consideration by the APs. The retained estate ventilations systems serving Neonatal and MRI/CT were not subject to annual verifications.	3
Are the inspections and verifications being recorded as per SHTM 03-01, Part B, Appendices 1 & 2 and the records retained in the Ventilation Documents Register?	Y	Verification reports produced by H&V Commissioning Services Ltd provided an executive summary, air change rates, pressure differentials and noise levels. The quarterly inspections carried out on the Adult & Children's isolation rooms, MRI/CT and critical care areas did not conform fully to Appendix 1.	2
Are the main components in AHUs serving critical and non-critical areas being cleaned annually?	N	Annual cleaning of the AHUs in the Adult & Children's was being carried out. Good. The cleaning of Lab Block AHUs was not recorded. Retained estate non-critical AHUs had not been cleaned within the previous year.	3
Are the fire dampers being tested annually?	N	Fire dampers were not subject to annual testing. A list of the fire dampers in the Lab Block had begun to be populated.	5
Are the LEV systems being examined and tested by a competent person at least every 14 months?	N	All Lab Block safety cabinets and fume cupboards were reported to have had COSHH LEV performance tests carried out in the past 14 months. Records were held by individual departments. The Mortuary dissection table had not been subjected to a COSHH LEV test in the past 14 months. Some but not all Anaesthetic Gas Scavenging Systems (AGSS) had been re-commissioned annually. Adequate test records were not held for those systems that had been recommissioned. It was reported that the Clinical Research department may contain LEVs.	3
Are critical systems that are unable to meet the required standards being taken out of service after receipt of condemnatory reports?	N	The annual verification report produced by H&V Commissioning Services Ltd dated 5 May 16 recorded non-compliant air change rates and pressure differentials in Neuro Sciences Theatres 6 & 7 dirty utility. The User (V) had not been notified of the non-compliance.	3

7. Safety Equipment & Access Control		Y/N	Comments	
Do the APs (V) have sufficient isolation safety devices for the likely number of concurrent jobs?	Y	Adequate safety devices were held at the hospital.	1	
Do the APs (V) have sufficient safety signage for the likely number of concurrent jobs?	Y	Adequate safety signs were held at the hospital.	1	
Do the NHS CPs (V) have sufficient safety devices and signs for their routine work?	N/A	Not checked.		
Are records available of annual NHS safety and protective equipment inspections by an AP (V)?	N	The half masks issued to the CPs should be visually inspected annually by an AP and a record kept of the inspections.	3	
Do all NHS test instruments have in date calibration certificates?	Y	Micro Manometer 4902159510 and Anememomter13450118 were calibrated on 24 Feb 16. Good.	1	
Have contractors provided in-date calibration certificates for all of their test instruments and safety equipment?	Y	Copies of calibration certificates were provided for the test instruments used by H&V Commissioning Services Ltd who carry out annual verifications.	1	
Is there an effective and auditable system for the control of plantroom access in use?	Y	An access control procedure was held in the document register.	1	

8. Engineering Systems

Air Handling Units (AHUs)	Y/N	Comments	
Is each AHU clearly and uniquely labelled and does this label exactly correspond to the AHU Register?	N	The isolation room HEPA filter extract cabinets in Adult & Children's Plantroom 21 were not labelled.	3
Is the general condition of each AHU satisfactory?	Y	Those checked.	1
Is the AHU constructed according to the principles in SHTM 03-01, Part A, Figure 1?	Y	Those checked.	1
Are the automatic controls fitted to critical systems capable of being overridden in the event of a software failure?	Y	Those checked.	1
Are fresh air intakes sited correctly, constructed correctly and are access hatches or hinged louvres installed?	N	AHUs in the Adult & Children's Plantrooms 21 & 22 and in the Lab Block Cat 2 and Cat 3 plantrooms did not have access hatches fitted to the intake ducts to allow for inspection.	3
Are drainage systems installed for wet components and are the drainage systems properly constructed?	N	The traps fitted to the retained estate neurosurgery AHUs had no drainage pipework fitted. Drain traps on the AHUs in the Adult & Children's Plantrooms 21 & 22 were connected directly to drainage pipework with no air gap. Some drain traps were visibly dirty. The drain traps on the Lab Block AHUs were connected directly to drain with no air gap.	3

Are belt driven fan drives situated outside of the air stream?	N	Some fan drives were internal to the AHUs. No action required.	2
Is there adequate access around the AHU and are access doors provided for all major components?	Y	The Lab Block Cat AHUs had no inspection windows fitted.	2
Are inspection windows and internal lights provided for cooling coils and filters?	Y	Those checked.	1
Are the filters the correct grade and correctly fitted to minimise bypass?	N	Pre-filters were fitted to a walk-in plenum in the Old Maternity Level 4 plantroom. Several filters were not secure in the frame and the access door was open allowing complete bypass of the filters.	3
Are the filters provided with a means of checking the differential pressure across them?	N	Retained estate Neonatal AHUs 1, 3 and 4 bag filter Minihelic gauges were reading 0 Pascal's. There was no means of checking pressure differential on the pre filters fitted to the walk-in plenum in the retained estate Old Maternity Level 4 plantroom.	3
Is the direction of air flow clearly marked on all main and branch ducts?	N	The extract ductwork serving the isolation rooms in Adult & Children's Plantroom 21 did not have direction of flow labels fitted.	3
Are all air flow test-points properly located, clearly identified and is the size of the duct provided at each point?	Y	No issues found.	1

9. Engineering work spaces

Plantroom externals	Y/N	Comments	
Is there a legible and secure safety sign displayed at the entrance to the plantroom?	N	Adult & Children Plantrooms 21 & 22 and the Old Maternity 4th floor plantroom did not have warning signs displayed at the entrance doors.	3
Is the name of the plantroom exactly the same as the AHU Register?	N	Adult & Children Plantrooms 21 & 22 and the Old Maternity 4th floor plantroom did not have unique name signs displayed at the entrance doors.	3
Is the correct contact telephone number shown?	N/A	Not applicable.	
Plantroom security	Y/N	Comments	
Is the door soundly made and kept secure?	Y	No issues found.	1
Is there an emergency escape door and can it be opened from the inside?	N/A	Not checked.	
Is there a clear escape route outside the plantroom?	Y	No issues found.	1
Are adequate emergency communications systems available?	Y	Staff entering plantrooms carry either a mobile telephone or PDA.	1
Are there any unauthorised items stored in the plantroom?	N	No issues found.	1
If so, are the access arrangements to the plantroom adequately controlled?	N/A	Not applicable.	

Plantroom structure

Is the plantroom structure and condition satisfactory?	N	The Old Maternity 4th floor plantroom general lighting was unserviceable. Emergency lighting was not installed in the Old Maternity 4th floor plantroom.	3
Are posters and drawings displayed as required?	N/A	Not checked.	

Fire Precautions

	Y/N	Comments	
Is combustion equipment located in the plantroom?	Y	No issues found.	1
Are any rubbish or fire hazardous materials stored immediately outside the plantroom?	Y	No issues found.	1
Is there at least one suitable fire extinguisher provided in the plantroom and has it been inspected in the last 12 months?	Y	All fire extinguishers checked were serviced in April 2016.	1

I confirm that, where actions are required, a report has been submitted to the Designated Person

Duncan G Machell

UPDATED ACTION PLAN

Serial	Rating	Reference	Action Required	Responsible Person	Date due
Action points carried forward from previous audit					
1	3	141208/1	The Ventilation Services Policy should be reviewed.	DP	08-Mar-15
2	3	141208/4	CPs should be occasionally monitored when carrying out works and a record of monitoring activities retained in the Documents Register.	All APs	08-Mar-15
3	5	141208/6	In-house CPs should be trained, assessed and appointed. Certificates of appointment and evidence of training should be retained in the Documents Register.	Lead AP	08-Jun-15
4	5	141208/7	Letters of competency should be obtained from the employers of contractor CPs and retained in the Documents Register.	Lead AP	08-Mar-15
5	3	141208/8	A CP Register should be produced listing the contractor CPs and should be retained in the Documents Register.	Lead AP	08-Mar-15
6	5	141208/9	Plant shutdown/make-safe risk assessments should be produced to identify the hazards associated with taking critical ventilation systems out of use and for work on LEVs that present a hazard to the maintainer. The risk assessments should be retained in the Documents Register.	Lead AP	08-Jan-15
7	5	141208/10	Ensure task risk assessments are held for all works on ventilation systems. This documentation should be retained or referenced in the Documents Register.	Lead AP	08-Jan-15
8	5	141208/12	Produce a schedule of ventilation systems to identify all systems as critical, non-critical or LEV in accordance with SHTM 03-01, Part B, Para 4.7. Retain the schedule in the Documents Register.	Lead AP	08-Jan-15
9	3	141208/18	Display safety signs at the entrance to all plantrooms.	Lead AP	08-Mar-15
10	3	141208/19	Display unique plantroom identity signs at the entrance to all plantrooms.	Lead AP	08-Mar-15
11	3	141208/22	Install task lighting and emergency lighting for the Neurosurgery external plant area.	Lead AP	08-Dec-15

SHTM 03-01 SPECIALISED VENTILATION FOR HEALTHCARE PREMISES

Page 111

12	5	141208/23	Implement a planned maintenance regime for emergency lights fitted in plantrooms. Where DALI systems are installed a formal check of the automatic test results should be carried out.	Lead AP	08-Jan-15
13	5	141208/33	Investigate and repair the Magnehelic gauge on Neurosurgery AHU 5.	Lead AP	08-Dec-14
14	5	141208/36	Carry out quarterly inspections on the retained estate critical ventilation systems. Record all critical system quarterly inspections in accordance with SHTM 03-01, Part B, Appendix 1.	Lead AP	08-Mar-15
15	5	141208/37	Carry out annual inspections on the retained estate non-critical ventilation systems in accordance with SHTM 03-01, Part B, Appendix 1.	Lead AP	08-Mar-15
16	5	141208/40	Test fire dampers in accordance with SHTM 03-01, Part B, Para 4.13.	Designated Person	08-Mar-15
17	5	141208/41	At least every 14 months carry out a thorough examination and test (recommission) of all AGSS. Record the test results and a sketch of the systems.	Lead AP	08-Jan-15
18	2	141208/42	Oversee the 14 monthly examinations of LEVs to ensure all the LEVs listed in the schedule of ventilation systems are examined.	Lead AP	08-Mar-15
19	3	151209/1	Assess and appoint Cyril Dowson as an AP (V).	AE/DP	12-Mar-16
20	3	151209/2	Assess and appoint David Bratney as an AP (V) when he has completed AP (V) training.	AE/DP	12-Jun-16
21	3	151209/3	Arrange for David Bratney to attend AP (V) training and forward a copy of his training certificate to the AE on completion.	DP	12-Jun-16
22	3	151209/4	Forward a copy of David Bratney's first aid training certificate to the AE.	Lead AP	12-Jan-16
23	3	151209/6	Arrange for Paul Allan to attend first aid training by 14 Feb 17 and forward a copy of his training certificate to the AE on completion.	DP	30-Jun-16
24	4	151209/7	Use permits to work when taking critical systems out of service and when carrying out intrusive maintenance on hazardous LEVs.	D Bratney and P Allan	12-Jan-16
25	3	151209/9	Only issue permits to work to appointed NHS CPs or contractor CPs listed in the CP Register.	All APs	12-Jan-16
26	5	151209/11	Populate the CAFM system (FM First) with planned maintenance tasks for all ventilation systems and retain records of all planned maintenance tasks carried out.	DP	12-Jun-16
27	5	151209/14	Rectify the unserviceable lighting on the Old Maternity 4th floor plantroom and install emergency lighting.	Lead AP	12-Mar-16

SHTM 03-01 SPECIALISED VENTILATION FOR HEALTHCARE PREMISES

Page 112

28	3	151209/15	Fit identify signs or labels to the HEPA filter enclosures in the Adult and Children's Plantroom 21.	Lead AP	12-Mar-16
29	3	151209/17	Fit access hatches to all AHU intake ductwork sections to allow inspections.	Lead AP	12-Dec-16
30	3	151209/18	Fit drainage pipework to the glass drain traps on the retained estate Neurosurgery AHUs.	Lead AP	12-Mar-16
31	4	151209/19	Modify the drain trap arrangement on all AHUs in the Lab Block and Adult & Children's to ensure there is a 15mm air gap between the trap outlet and the drainage pipework.	Lead AP	12-Jun-16
32	2	151209/21	Consider fitting inspection windows and internal lighting on all Lab Block AHU's.	Lead AP	12-Jun-16
33	3	151209/23	Investigate and rectify the spurious bag filter readings on retained estate Neonatal AHUs 1, 3 and 4.	Lead AP	12-Mar-16
34	4	151209/24	Rectify the collapsing pre-filters on the Old Maternity level 4 plantroom intake plenum and fit a pressure differential gauge/manometer.	Lead AP	12-Jun-16
35	3	151209/25	Fit direction of flow labels to the isolation room extract ductwork in the Adult & Children's Plantroom 21.	Lead AP	12-Mar-16
36	5	151209/26	Carry out annual verifications on the Adult & Children's isolation rooms, critical care and MRI ventilation systems. Carry out annual verifications on the retained estate Neonatal and MRI/CT ventilation systems.	Lead AP	12-Mar-16
37	3	151209/27	Record annual the annual cleaning of AHUs in the Lab Block. Carry out and record the annual cleaning of all AHUs in the retained estate.	Lead AP	12-Dec-16
38	5	151209/29	Ensure that LEV examinations and tests are carried out on the Mortuary dissection tables every 14 months in accordance with the COSHH Regulations.	Lead AP	12-Jan-16
39	5	151209/31	Survey the Clinical Research department to identify any LEVs. Subject all identified LEVs to examinations and tests every 14 months in accordance with the COSHH Regulations.	Lead AP	12-Mar-16
40	3	151209/32	Critical ventilation systems that do not meet the performance criteria specified in SHTM 03-01 should be taken out of service. If the clinical requirement prevents this the User and infection control should be notified in writing by the AP.	Lead AP	13-Mar-16
Action points from this audit					
41	3	161114/1	Produce a local action plan to address the actions raised in this report.	Lead AP	14-Dec-16

42	3	161114/2	Review the time available for APs to carry out AP (V) duties taking into consideration other disciplines they are responsible for.	DP	14-Feb-17
43	3	161114/3	Train, assess and appoint Jim Guthrie as an AP (V).	DP/AE	14-May-17
44	3	161114/4	Ensure all options are struck through on all permits to work	All APs	14-Dec-16
45	3	161114/5	Ensure the User (V) signs Part 2 of all permits to work.	All APs	14-Dec-16
46	3	161114/6	Populate the existing Document Register with information relating to the retained estate and Adult & Children's, or setup and populate individual document registers.	All APs	14-Feb-17
47	4	161114/7	Carry out planned maintenance on the retained estate AHUs. Carry out quarterly hygiene checks on split air conditioning units. Carry out 6 monthly chilled beam cleaning.	Lead AP	14-May-17
48	3	161114/8	Inspect the half masks issued to the CPs annually and retain a record of the inspections.	Lead AP	14-May-17

DP-Designated Person : AE- Authorising Engineer : AP- Authorised Person with Line Management Support

The **Designated Person** should sign this Action Plan to acknowledge the contents. The original copy should then be filed in the Document Register.

Date(s) of Audit 07 & 10 Nov 17

Date(s) of Previous Audit 14-15 Nov 2016

Site Address

1345 Govan Road,
Glasgow
G51 4TF

Reference 20171113-250-QEUH-V-JM-001

1. Terms of Reference

1.1 This audit was conducted in accordance with the following current reference documents:

- a. Scottish Health Technical Memorandum 00: Policies and principles of healthcare engineering.
- b. Scottish Health Technical Memorandum 03-01: Specialised ventilation for healthcare premises.

2. Executive Summary

2.1 Introduction. The purpose of this audit was to assess the compliance, operation and maintenance of the Safe System of Work at the Hospital(s) in accordance with the discipline specific Health Technical Memoranda, Acts, Regulations and HSE Guidance documents. The resulting Action Plan will be reviewed periodically. The appointments of the discipline specific Authorised Persons were also assessed during the audit.

2.2 Report Summary

1. The Lead AP should review the action plan at the end of this report and produce his own action plan.
2. Due to the size and on-going change at the hospital the APs were not always able to find the time to carry out their duties. The provision of APs (V) should be reviewed by senior management taking into consideration other duties the APs are liable for.
3. CPs should be trained, assessed and appointed. Evidence of competency was held for two contractor CPs, letters of competency should be held for all contractor CPs.
4. Task risk assessments were not held for in-house tasks. These must be produced and communicated to the in-house CPs.
5. The Document Register was populated for the Lab Block. This should be extended to include the Adult & Children's and the retained estate. The Document Register should include a list of all ventilation assets.
6. Chilled beams should be cleaned 6 monthly and split air condition systems should be cleaned 3 monthly.
7. The Lab Block AHUs were cleaned periodically but records were not retained. Cleaning records should be retained.
8. Work should continue to verify all critical systems. When a critical system fails to meet the performance criteria set out in SHTM 03-01, Part B, the AP should notify the User (V)/Responsible Person and infection control in writing before it is brought back into service.
9. Most but not all LEVs had been subject to 14 monthly examinations under the COSHH Regulations. The mortuary dissection tables had not been examined and performance tested.
10. Oil and combustible material should be removed from the Neonatal plant room ASAP.
11. Fire dampers must be tested for correct operation annually.

12. The use of authority for disconnection (permit to work) should be reintroduced to prevent unintentional loss of supplies to the theatres and critical equipment.

3. Conclusion

ASSESSMENT OF SAFE SYSTEM OF WORK	CONCLUSION
1. Assessment of the Management Policy.	4
2. Assessment of the Authorised Persons.	8
3. Assessment of the Competent Persons.	16
4. Assessment of Incidents, Accidents and Dangerous Occurrences.	1
5. Assessment of the Safety Documentation.	20
6. Assessment of the Operating Records.	16
7. Assessment of the Safety equipment & Access Control.	8
8. Assessment of the Engineering Systems.	20
9. Assessment of the Engineering Work Spaces.	20

Is the system safe to continue?	Yes, under the supervision of the AE
---------------------------------	--------------------------------------

4. Next Audit Date

The next audit visit is planned to take place in

PREVIOUS ACTION PLAN

Serial	Rating	Reference	Action Required	Remarks
1	12	141208/1	The Ventilation Services Policy should be reviewed.	Reviewed Dec 16. Closed
2	8	141208/4	CPs should be occasionally monitored when carrying out works and a record of monitoring activities retained in the Documents Register.	On-going, review at next audit.
3	20	141208/6	In-house CPs should be trained, assessed and appointed. Certificates of appointment and evidence of training should be retained in the Documents Register.	On-going, review at next audit.
4	20	141208/7	Letters of competency should be obtained from the employers of contractor CPs and retained in the Documents Register.	On-going, review at next audit.
5	12	141208/8	A CP Register should be produced listing the contractor CPs and should be retained in the Documents Register.	On-going, review at next audit.
6	20	141208/9	Plant shutdown/make-safe risk assessments should be produced to identify the hazards associated with taking critical ventilation systems out of use and for work on LEVs that present a hazard to the maintainer. The risk assessments should be retained in the Documents Register.	On-going, review at next audit.
7	20	141208/10	Ensure task risk assessments are held for all works on ventilation systems. This documentation should be retained or referenced in the Documents Register.	On-going, review at next audit.
8	20	141208/12	Produce a schedule of ventilation systems to identify all systems as critical, non-critical or LEV in accordance with SHTM 03-01, Part B, Para 4.7. Retain the schedule in the Documents Register.	On-going, review at next audit.
9	8	141208/18	Display safety signs at the entrance to all plant rooms.	On-going, review at next audit.
10	8	141208/19	Display unique plant room identity signs at the entrance to all plant rooms.	On-going, review at next audit.
11	12	141208/22	Install task lighting and emergency lighting for the Neurosurgery external plant area.	Completed, closed.

12	16	141208/23	Implement a planned maintenance regime for emergency lights fitted in plant rooms. Where DALI systems are installed a formal check of the automatic test results should be carried out.	On-going, review at next audit.
13	20	141208/33	Investigate and repair the Magnehelic gauge on Neurosurgery AHU 5.	Completed, closed.
14	20	141208/36	Carry out quarterly inspections on the retained estate critical ventilation systems. Record all critical system quarterly inspections in accordance with SHTM 03-01, Part B, Appendix 1.	Completed, closed.
15	20	141208/37	Carry out annual inspections on the retained estate non-critical ventilation systems in accordance with SHTM 03-01, Part B, Appendix 1.	On-going, review at next audit.
16	25	141208/40	Test fire dampers in accordance with SHTM 03-01, Part B, Para 4.13.	On-going, review at next audit.
17	20	141208/41	At least every 14 months carry out a thorough examination and test (recommission) of all AGSS. Record the test results and a sketch of the systems.	Completed, closed.
18	8	141208/42	Oversee the 14 monthly examinations of LEVs to ensure all the LEVs listed in the schedule of ventilation systems are examined.	On-going, review at next audit.
19	8	151209/1	Assess and appoint Cyril Dowson as an AP (V).	Completed, closed.
20	8	151209/2	Assess and appoint David Bratney as an AP (V) when he has completed AP (V) training.	Overtaken by events. Closed.
21	8	151209/3	Arrange for David Bratney to attend AP (V) training and forward a copy of his training certificate to the AE on completion.	Overtaken by events. Closed.
22	8	151209/4	Forward a copy of David Bratney's first aid training certificate to the AE.	Overtaken by events. Closed.
23	8	151209/6	Arrange for Paul Allan to attend first aid training and forward a copy of his training certificate to the AE on completion.	Completed, closed.
24	20	151209/7	Use permits to work when taking critical systems out of service and when carrying out intrusive maintenance on hazardous LEVs.	On-going, review at next audit.
25	12	151209/9	Only issue permits to work to appointed NHS CPs or contractor CPs listed in the CP Register.	On-going, review at next audit.

26	20	151209/11	Populate the CAFM system (FM First) with planned maintenance tasks for all ventilation systems and retain records of all planned maintenance tasks carried out.	On-going, review at next audit.
27	20	151209/14	Rectify the unserviceable lighting on the Old Maternity 4th floor plant room and install emergency lighting.	On-going, review at next audit. Asbestos?
28	12	151209/15	Fit identify signs or labels to the HEPA filter enclosures in the Adult and Children's Plant room 21.	On-going, review at next audit.
29	8	151209/17	Fit access hatches to all AHU intake ductwork sections to allow inspections.	On-going, review at next audit.
30	4	151209/18	Fit drainage pipework to the glass drain traps on the retained estate Neurosurgery AHUs.	On-going, review at next audit.
31	16	151209/19	Modify the drain trap arrangement on all AHUs in the Lab Block and Adult & Children's to ensure there is a 15mm air gap between the trap outlet and the drainage pipework.	Completed, closed.
32	4	151209/21	Consider fitting inspection windows and internal lighting on all Lab Block AHU's.	On-going, review at next audit.
33	12	151209/23	Investigate and rectify the spurious bag filter readings on retained estate Neonatal AHUs 1, 3 and 4.	Completed, closed.
34	12	151209/24	Rectify the collapsing pre-filters on the Old Maternity level 4 plant room intake plenum and fit a pressure differential gauge/manometer.	On-going, review at next audit.
35	8	151209/25	Fit direction of flow labels to the isolation room extract ductwork in the Adult & Children's Plant room 21.	On-going, review at next audit.
36	20	151209/26	Carry out annual verifications on the Adult & Children's isolation rooms, critical care and MRI ventilation systems. Carry out annual verifications on the retained estate Neonatal and MRI/CT ventilation systems.	MRI is difficult to access, Isolations rooms 50% complete. On-going review at next audit.
37	12	151209/27	Record the annual cleaning of AHUs in the Lab Block. Carry out and record the annual cleaning of all AHUs in the retained estate.	On-going, review at next audit.
38	20	151209/29	Ensure that LEV examinations and tests are carried out on the Mortuary dissection tables every 14 months in accordance with the COSHH Regulations.	On-going, review at next audit.

39	20	151209/31	Survey the Clinical Research department to identify any LEVs. Subject all identified LEVs to examinations and tests every 14 months in accordance with the COSHH Regulations.	Completed, closed.
40	12	151209/32	Critical ventilation systems that do not meet the performance criteria specified in SHTM 03-01 should be taken out of service. If the clinical requirement prevents this the User and infection control should be notified in writing by the AP.	Theatres are taken out of service for 1 week. Any failures are rectified before recommission. Closed.
41	8	161114/1	Produce a local action plan to address the actions raised in this report.	Gary Cullen has taken this on.
42	12	161114/2	Review the time available for APs to carry out AP (V) duties taking into consideration other disciplines they are responsible for.	On-going, review at next audit.
43	12	161114/3	Train, assess and appoint Jim Guthrie as an AP (V).	Overtaken by events. Closed.
44	12	161114/4	Ensure all options are struck through on all permits to work	Overtaken by events. Closed.
45	12	161114/5	Ensure the User (V) signs Part 2 of all permits to work.	Overtaken by events. Closed.
46	12	161114/6	Populate the existing Document Register with information relating to the retained estate and Adult & Children's, or setup and populate individual document registers.	On-going, review at next audit.
47	16	161114/7	Carry out planned maintenance on the retained estate AHUs. Carry out quarterly hygiene checks on split air conditioning units. Carry out 6 monthly chilled beam cleaning.	On-going, review at next audit.
48	12	161114/8	Inspect the half masks issued to the CPs annually and retain a record of the inspections.	On-going, review at next audit.

Additional Comments

AP Training and Appointments Matrix

AP Name	Paul Allan	Cyril Dowson			
Status	AP (V)	AP (V)			
Based at	QEUH	QEUH			
Appointment Certificate	GG&C V 07	GG&C V 16			
Issue Date	05-Jan-15	12-Dec-16			
Expiry Date	04-Jan-18	11-Dec-19			
Sites covered	QEUH	QEUH			
Ventilation Training Expiry Date	30-Oct-17	27-Apr-18			
First Aid Expiry Date	11-Dec-19	22-Jun-18			
Permit-to-work	0	0			
Number checked by AE	0	0			

Comments

Paul Allan should attend an AP refresher course.

Another AP (V) should be nominated to carry out training.

One of the AP (V) should be designated the lead AP.

REPORT

Personnel

Duty Holder	Robert Calderwood	1
Designated Person	Mary-Anne Kane	1
Authorising Engineer	Jamie Minhinick	1
Authorised Persons	Paul Allan	5
	Cyril Dowson	1

1. Management Policy	Y/N	Comments	
Is there a Board Ventilation Safety Policy In place?	Y	NHS GG&C Ventilation Safety Policy.	1
Is the Ventilation Safety Policy approved at Board level?	Y	The policy was approved by Alex McIntyre (Director of Facilities).	1
Is the Board Ventilation Safety Policy reviewed periodically?	Y	The policy was reviewed in Dec 16 and will be reviewed annually.	1
Is the Board Ventilation Safety Policy a controlled Document?	Y	The policy is a controlled document. A copy was held in the Document Register.	1
Are the Duty Holder (V) responsibilities clearly defined in the Policy?	Y	The policy states that the Duty Holder is responsible for ensuring the ventilation systems are operated, maintained and repaired in accordance with SHTM 03-01.	1
Is the Designated Person appointed in writing?	N	The Designated Person is shown as the Director of Facilities in the structure chart.	5
Does the Board Ventilation Safety Policy include emergency procedures?	N	Emergency procedures were not included in the policy.	8
Have the emergency procedures been validated or tested during the current audit period?	N/A	Not applicable.	
Has the Authorising Engineer (AE) (V) appointment been correctly made and is it in date?	Y	No issues found.	1

2. Authorised Persons (V)	Y/N	Comments	
Are all APs (V) currently certified?	Y	Jim Guthrie has left the hospital and David Bratney is due to retire. Another 2 AP V should be nominated and trained.	8
Are the APs (V) due for refresher training in SHTM 03-01?	Y	Paul Allan should attend AP (V) training and forward copies of his training certificate to the AE on completion.	8
Are the APs (V) due for training in emergency first-aid?	Y	No issues found.	1
Are the APs (V) carrying out AP (V) duties on a regular basis?	N	The APs are not using permits to control maintenance activities.	8

Are the APs (V) formally monitoring the work-in-progress and are they recording their observations?	N	CP Monitoring had not been carried out. Identified in previous audit.	12
Is the provision of APs (V) adequate?	N	Jim Guthrie has left and David Bratney is due to retire. Comments were made by some APs in previous audits that they struggled to find the time to carry out AP (V) duties on top of their other commitments. A further 2 APs (V) should be identified and trained.	16

3. Competent Persons (V)			
	Y/N	Comments	
Have the NHS CPs (V) been formally assessed and appointed by an AP (V)?	N	In-house CPs had not been assessed and appointed. Training certificates were held for two NHS CPs and a third was thought to have been trained but a certificate was not available. The remaining NHS CPs had not been trained.	16
Is evidence of the competency of Contractor CPs (V) held in the Document Register?	Y	Evidence of competency was held for A Laughland and R Peel of Atlas Clean Air Ltd who carry out performance verifications on safety cabinets in the Laboratory building. Letters of competency or training certificates were not held for the CPs employed by H&V Commissioning Services Ltd and MAT Ltd.	8
Are the roles and responsibilities of Contractor CPs (V) defined in writing?	N/A	Not checked.	
Are records held in the Document Register of the site induction for the Contractor CPs (V)?	Y	The GG&C Contractor Control & Permit Register includes the issue of an identity card that listed the fundamental site rules and procedures.	1
Is there an up to date Register of CPs (V) appointed for the Trust included in the Document Register?	N	A CP Register was not held. Identified in previous audit.	12
Are the NHS CPs (V) carrying out their duties on a regular basis?	Y	In-house CPs and contractor CPs had been carrying out duties on a regular basis.	1

4. Incidents, Accidents and Dangerous Occurrences			
	Y/N	Comments	
Sine the last audit has the site been free from any accidents, incidents, dangerous occurrences or "near misses" in connection with the ventilation systems?	Y	None reported.	1
Have the details of incidents, accidents or dangerous occurrences been properly recorded and reported?	N/A	Not applicable.	

5. Safety Documentation

Job Number:	Originating AP (V):	Y/N	Comments
Was there a suitable & sufficient Risk Assessment to cover the work undertaken?	n/a	No permits issued since last audit.	
Was the permit-to-work completed by the AP (V) specifying the work to be carried out?	n/a	No permits issued since last audit.	
Was the permit-to-work signed by the User (V) to allow the work to proceed?	n/a	No permits issued since last audit.	
Was the permit-to-work issued to a CP (V)?	n/a	No permits issued since last audit.	
Was the permit-to-work cleared by a CP (V) and did they state that system was fit or unfit for use?	n/a	No permits issued since last audit.	
Was the permit-to-work cancelled by an AP (V) and did they acknowledge that the system was fit or unfit for use?	n/a	No permits issued since last audit.	
Did the User (V) acknowledge that the system should or should not be brought back into use?	n/a	No permits issued since last audit.	
Were the site records up-dated on completion of the work?	n/a	No permits issued since last audit.	

6. Operating Records

General	Y/N	Comments
Are the ventilation operating record documents kept in a secure location?	Y	Gary Cullen is setting up an electronic ventilation operating record on Smart Sheet. As compliance officer ventilation, once proved this will roll out across to board.
Do the APs (V) have access to copies of relevant SHTMs and other reference documents?	Y	An electronic copy was held.
Does the Document Register index include all of the subjects required by SHTM 03-01?	N	This is a work in progress on Smart Sheet by Gary Cullen. This will be used in conjunction with a hard copy held by retained estates and be expanded to include all areas.
Is the working Ventilation Document Register periodically reviewed and out-of-date information transferred to the archive Ventilation Document Register?	N/A	The Document Register was in the process of being populated. Not assessed.

Is there a schedule of ventilations systems detailing which are critical, non-critical or LEVs?	N	Asset lists were held electronically covering the retained estate and Adult & Children's. The Lab Block asset list was held in the Document Register. A consolidated schedule of ventilation plant should be produced stating the classification (non-critical, critical or LEV) of the plant.	20
Are adequate technical drawings available to the APs?	Y	Technical drawings are held on Zutec. Can be difficult to navigate.	4
Are adequate O&M manuals available to the APs?	Y	O&M information was held electronically (Zutec) and on the shared drive for the Adult & Children's and the Lab Block. Original O&M information for the retained estate maternity theatres was reported to be held.	4
Are all of the ventilation systems included in the Trust's planned maintenance programme?	N	The Adult & Children's ventilation systems and the Lab Block ventilation systems were subject to planned maintenance. Chilled/active beams were not subject to 6 monthly inspection & cleaning but this was being planned by the APs. Split air conditioning systems were not subject to quarterly hygiene inspections.	12
Are the planned maintenance records suitable, sufficient and accessible to the APs?	N	In-house maintenance was documented manually on check sheets. Service sheets were held for work carried out by contractor CPs. None of the maintenance was scheduled on FM First.	12
Are the results of the Trust's planned maintenance programme formally reviewed annually to establish trends and gaps? Are these reviews recorded?	N/A	Not checked.	

Inspection and Verification		Y/N	Comments	
Are critical ventilation systems being inspected quarterly?	Y	PPM files were held for all critical AHU. Monthly and quarterly checks were retained.	1	
Are non-critical systems being inspected annually?	Y	PPM files were held for all non critical AHU. Monthly and quarterly checks were retained.	1	
Are critical ventilation systems being verified annually?	Y	All theatres were subject to a rolling programme of annual verifications. Other critical systems in the Adult & Children's such as isolation wards are in the process of being verified with 50% complete. The retained estate ventilations systems for MRI/CT were not subject to annual verifications.	8	
Are the inspections and verifications being recorded as per SHTM 03-01, Part B, Appendices 1 & 2 and the records retained in the Ventilation Documents Register?	Y	Verification reports produced by H&V Commissioning Services Ltd provided an executive summary, air change rates, pressure differentials and noise levels. The quarterly inspections carried out on the Adult & Children's isolation rooms, MRI/CT and critical care areas did not conform fully to Appendix 1.	5	
Are the main components in AHUs serving critical and non-critical areas being cleaned annually?	Y	Annual cleaning of the AHUs is now being carried out.	1	
Are the fire dampers being tested annually?	N	Fire dampers were not subject to annual testing. A list of the fire dampers in the Lab Block had begun to be populated.	25	
Are the LEV systems being examined and tested by a competent person at least every 14 months?	N	All Lab Block safety cabinets and fume cupboards have had COSHH LEV performance tests carried out in the past 14 months. Records were held by Estates. The Mortuary dissection table had not been subjected to a COSHH LEV test in the past 14 months.	8	
Are critical systems that are unable to meet the required standards being taken out of service after receipt of condemnatory reports?	Y	All critical AHU's verified in the last 12 months are performing to the required standard. Immediate reports are given to estates before H&V leave site allowing problems to be rectified in the shut down period.	1	

7. Safety Equipment & Access Control			
	Y/N	Comments	
Do the APs (V) have sufficient isolation safety devices for the likely number of concurrent jobs?	Y	Adequate safety devices were held at the hospital.	1
Do the APs (V) have sufficient safety signage for the likely number of concurrent jobs?	Y	Adequate safety signs were held at the hospital.	1
Do the NHS CPs (V) have sufficient safety devices and signs for their routine work?	N/A	Not checked.	
Are records available of annual NHS safety and protective equipment inspections by an AP (V)?	N	The half masks issued to the CPs should be visually inspected annually by an AP and a record kept of the inspections.	8
Do all NHS test instruments have in date calibration certificates?	N	Micro Manometer 4902159510 and Anemometer 13450118 were calibrated on 24 Feb 16. Certificates could not be located during this audit.	5
Have contractors provided in-date calibration certificates for all of their test instruments and safety equipment?	Y	Copies of calibration certificates were provided for the test instruments used by H&V Commissioning Services Ltd who carry out annual verifications.	1
Is there an effective and auditable system for the control of plant room access in use?	Y	An access control procedure was held in the document register.	1

8. Engineering Systems

Air Handling Units (AHUs)			
	Y/N	Comments	
Is each AHU clearly and uniquely labelled and does this label exactly correspond to the AHU Register?	N	The isolation room HEPA filter extract cabinets in Adult & Children's Plant room 21 were not labelled.	8
Is the general condition of each AHU satisfactory?	Y	Those checked.	1
Is the AHU constructed according to the principles in SHTM 03-01, Part A, Figure 1?	Y	Those checked.	1
Are the automatic controls fitted to critical systems capable of being overridden in the event of a software failure?	Y	Those checked.	1
Are fresh air intakes sited correctly, constructed correctly and are access hatches or hinged louvres installed?	N	AHUs in the Adult & Children's Plant rooms 21 & 22 and in the Lab Block Cat 2 and Cat 3 plant rooms did not have access hatches fitted to the intake ducts to allow for inspection.	8
Are drainage systems installed for wet components and are the drainage systems properly constructed?	N	Some of the traps fitted to the retained estate neurosurgery AHUs had no drainage pipework fitted. Some drain traps were visibly dirty. The drain traps on the Lab Block AHUs were connected directly to drain with no air gap.	8
Are belt driven fan drives situated outside of the air stream?	N	Some fan drives were internal to the AHUs. No action required.	4

Is there adequate access around the AHU and are access doors provided for all major components?	Y	The Lab Block Cat AHUs had no inspection windows fitted.	5
Are inspection windows and internal lights provided for cooling coils and filters?	Y	Those checked.	1
Are the filters the correct grade and correctly fitted to minimise bypass?	N	Pre-filters were fitted to a walk-in plenum in the Old Maternity Level 4 plant room. A number of pre-filters in plant room 21 had collapsed allowing bypass.	16
Are the filters provided with a means of checking the differential pressure across them?	Y	There was no means of checking pressure differential on the pre filters fitted to the walk-in plenum in the retained estate Old Maternity Level 4 plant room.	8
Is the direction of air flow clearly marked on all main and branch ducts?	N	The extract ductwork serving the isolation rooms in Adult & Children's Plant room 21 did not have direction of flow labels fitted.	8
Are all air flow test-points properly located, clearly identified and is the size of the duct provided at each point?	Y	No issues found.	1

9. Engineering work spaces

Plant room externals	Y/N	Comments	
Is there a legible and secure safety sign displayed at the entrance to the plant room?	N	Adult & Children Plant rooms 21 & 22 and the Old Maternity 4th floor plant room did not have warning signs displayed at the entrance doors.	8
Is the name of the plant room exactly the same as the AHU Register?	N	Adult & Children Plant rooms 21 & 22 and the Old Maternity 4th floor plant room did not have unique name signs displayed at the entrance doors.	8
Is the correct contact telephone number shown?	N/A	Not applicable.	
Plant room security	Y/N	Comments	
Is the door soundly made and kept secure?	Y	No issues found.	1
Is there an emergency escape door and can it be opened from the inside?	N/A	Not checked.	
Is there a clear escape route outside the plant room?	Y	No issues found.	1
Are adequate emergency communications systems available?	Y	Staff entering plant rooms carry either a mobile telephone or PDA.	1
Is the plant room free from any unauthorised items stored within?	N	Oil stored on top of and wood / cardboard leaning against the plant in the Neonatal Theatre No 2 plant room.	25
If so, are the access arrangements to the plant room adequately controlled?	N/A	Not applicable.	

Plant room structure			
Is the plant room structure and condition satisfactory?	N	The Old Maternity 4th floor plant room general lighting was unserviceable. Emergency lighting was not installed in the Old Maternity 4th floor plant room.	8
Are posters and drawings displayed as required?	N/A	Not checked.	
Fire Precautions		Y/N	Comments
Is the plant room free from combustion equipment?	Y	No issues found.	1
Is the plant room free from rubbish or fire hazardous materials stored inside or immediately outside the plant room?	N	An open bottle of lubricating oil and drip tray was observed on the top of Theatre No 2 AHU in the Neonatal plant room. Various wood and materials were leaning against the AHU.	25
Is there at least one suitable fire extinguisher provided in the plant room and has it been inspected in the last 12 months?	Y	All fire extinguishers checked were serviced in April 2017.	1

I confirm that, where actions are required, a report has been submitted to the Designated Person

UPDATED ACTION PLAN

Serial	Rating	Reference	Action Required	Responsible Person	Date due
Action points carried forward from previous audit					
1	8	141208/4	CPs should be occasionally monitored when carrying out works and a record of monitoring activities retained in the Documents Register.	All APs	08-Mar-15
2	20	141208/6	In-house CPs should be trained, assessed and appointed. Certificates of appointment and evidence of training should be retained in the Documents Register.	Lead AP	08-Jun-15
3	20	141208/7	Letters of competency should be obtained from the employers of contractor CPs and retained in the Documents Register.	Lead AP	08-Mar-15
4	12	141208/8	A CP Register should be produced listing the contractor CPs and should be retained in the Documents Register.	Lead AP	08-Mar-15
5	20	141208/9	Plant shutdown/make-safe risk assessments should be produced to identify the hazards associated with taking critical ventilation systems out of use and for work on LEVs that present a hazard to the maintainer. The risk assessments should be retained in the Documents Register.	Lead AP	08-Jan-15
6	20	141208/10	Ensure task risk assessments are held for all works on ventilation systems. This documentation should be retained or referenced in the Documents Register.	Lead AP	08-Jan-15
7	20	141208/12	Produce a schedule of ventilation systems to identify all systems as critical, non-critical or LEV in accordance with SHTM 03-01, Part B, Para 4.7. Retain the schedule in the Documents Register.	Lead AP	08-Jan-15
8	8	141208/18	Display safety signs at the entrance to all plant rooms.	Lead AP	08-Mar-15
9	8	141208/19	Display unique plant room identity signs at the entrance to all plant rooms.	Lead AP	08-Mar-15
10	16	141208/23	Implement a planned maintenance regime for emergency lights fitted in plant rooms. Where DALI systems are installed a formal check of the automatic test results should be carried out.	Lead AP	08-Jan-15

SHTM 03-01 SPECIALISED VENTILATION FOR HEALTHCARE PREMISES

Page 132

11	20	141208/37	Carry out annual inspections on the retained estate non-critical ventilation systems in accordance with SHTM 03-01, Part B, Appendix 1.	Lead AP	08-Mar-15
12	25	141208/40	Test fire dampers in accordance with SHTM 03-01, Part B, Para 4.13.	Designated Person	08-Mar-15
13	8	141208/42	Oversee the 14 monthly examinations of LEVs to ensure all the LEVs listed in the schedule of ventilation systems are examined.	Lead AP	08-Mar-15
14	20	151209/7	Use permits to work when taking critical systems out of service and when carrying out intrusive maintenance on hazardous LEVs.	D Bratney and P Allan	12-Jan-16
15	12	151209/9	Only issue permits to work to appointed NHS CPs or contractor CPs listed in the CP Register.	All APs	12-Jan-16
16	20	151209/11	Populate the CAFM system (FM First) with planned maintenance tasks for all ventilation systems and retain records of all planned maintenance tasks carried out.	DP	12-Jun-16
17	20	151209/14	Rectify the unserviceable lighting on the Old Maternity 4th floor plant room and install emergency lighting.	Lead AP	12-Mar-16
18	12	151209/15	Fit identify signs or labels to the HEPA filter enclosures in the Adult and Children's Plant room 21.	Lead AP	12-Mar-16
19	8	151209/17	Fit access hatches to all AHU intake ductwork sections to allow inspections.	Lead AP	12-Dec-16
20	4	151209/18	Fit drainage pipework to the glass drain traps on the retained estate Neurosurgery AHUs.	Lead AP	12-Mar-16
21	4	151209/21	Consider fitting inspection windows and internal lighting on all Lab Block AHU's.	Lead AP	12-Jun-16
22	12	151209/24	Rectify the collapsing pre-filters on the Old Maternity level 4 plant room intake plenum and fit a pressure differential gauge/manometer.	Lead AP	12-Jun-16
23	8	151209/25	Fit direction of flow labels to the isolation room extract ductwork in the Adult & Children's Plant room 21.	Lead AP	12-Mar-16
24	20	151209/26	Carry out annual verifications on the Adult & Children's isolation rooms, critical care and MRI ventilation systems. Carry out annual verifications on the retained estate Neonatal and MRI/CT ventilation systems.	Lead AP	12-Mar-16
25	12	151209/27	Record annual the annual cleaning of AHUs in the Lab Block. Carry out and record the annual cleaning of all AHUs in the retained estate.	Lead AP	12-Dec-16

26	20	151209/29	Ensure that LEV examinations and tests are carried out on the Mortuary dissection tables every 14 months in accordance with the COSHH Regulations.	Lead AP	12-Jan-16
27	5	151209/31	Survey the Clinical Research department to identify any LEVs. Subject all identified LEVs to examinations and tests every 14 months in accordance with the COSHH Regulations.	Lead AP	12-Mar-16
28	12	151209/32	Critical ventilation systems that do not meet the performance criteria specified in SHTM 03-01 should be taken out of service. If the clinical requirement prevents this the User and infection control should be notified in writing by the AP.	Lead AP	13-Mar-16
29	8	161114/1	Produce a local action plan to address the actions raised in this report.	Lead AP	14-Dec-16
30	12	161114/2	Review the time available for APs to carry out AP (V) duties taking into consideration other disciplines they are responsible for.	DP	14-Feb-17
31	12	161114/6	Populate the existing Document Register with information relating to the retained estate and Adult & Children's, or setup and populate individual document registers.	All APs	14-Feb-17
32	16	161114/7	Carry out planned maintenance on the retained estate AHUs. Carry out quarterly hygiene checks on split air conditioning units. Carry out 6 monthly chilled beam cleaning.	Lead AP	14-May-17
33	12	161114/8	Inspect the half masks issued to the CPs annually and retain a record of the inspections.	Lead AP	14-May-17

Action points from this audit

34	25	20171113/01	An open bottle of lubricating oil and drip tray was observed on the top of Theatre No 2 AHU in the Neonatal plant room. Various wood and materials were leaning against the AHU. These must be removed.	Lead AP	ASAP
35	25	20171113/02	Fire dampers were not subject to annual testing. This should be actioned at a strategic level.	DP	ASAP
36	8	20171113/03	Paul Allan should attend a AP (V) refresher course.	Lead AP	31-Mar-18
37	20	20171113/04	The number of AP (V) should be assessed against other workloads. A further 2 APs are recommended.	DP	31-Mar-18

38	20	20171113/05	The use of authority for disconnection (permit to work) should be reintroduced to prevent unintentional loss of supplies to the theatres and critical equipment.	Lead AP	ASAP

Date(s) of Audit 11-12 Dec 18

Date(s) of Previous Audit 07 & 10 Nov 17

Site Address

1345 Govan Road,
Glasgow
G51 4TF

Reference 20181212-250-QEUH-V-JM-002

1. Terms of Reference

1.1 This audit was conducted in accordance with the following current reference documents:

- a. Scottish Health Technical Memorandum 00: Policies and principles of healthcare engineering.
- b. Scottish Health Technical Memorandum 03-01: Specialised ventilation for healthcare premises.

2. Executive Summary

2.1 Introduction. The purpose of this audit was to assess the compliance, operation and maintenance of the Safe System of Work at the Hospital(s) in accordance with the discipline specific Health Technical Memoranda, Acts, Regulations and HSE Guidance documents. The resulting Action Plan will be reviewed periodically. The appointments of the discipline specific Authorised Persons were also assessed during the audit.

2.2 Report Summary

Steady good progress has been made at QEUH under the direction of the compliance manager and interim site manager (operational estates). Some issues remain unresolved and are placing the board at risk:

1. Fire dampers were not subject to annual testing.
2. Maintenance of ventilation systems is not planned and appears to be done on a reactive basis following planned inspections when faults are identified. The planned maintenance issued to NHS competent persons should be reviewed.
3. The schedule of ventilation assets should be extended to include LEV's, Split AC's, Cassette Units, FCU's, and ACB's.
4. The criticality of all ventilation systems should be reviewed with user groups to positively identify all systems that should be deemed critical. This should be recorded in the ventilation assets schedule.
5. Once identified, all critical systems should be subjected to performance verification at least annually and inspected every 3 months using the 40 point check or appropriate inspection template.
6. Split AC's, Cassette Units and FCU's should be subjected to 3m inspections and cleaning.
7. All Active Chilled Beams (ACB's) should be inspected on a 6m basis and cleaned as required.

3. Conclusion

ASSESSMENT OF SAFE SYSTEM OF WORK	CONCLUSION
1. Assessment of the Management Policy.	4
2. Assessment of the Authorised Persons.	8
3. Assessment of the Competent Persons.	9
4. Assessment of Incidents, Accidents and Dangerous Occurrences.	1
5. Assessment of the Safety Documentation.	20
6. Assessment of the Operating Records.	16
7. Assessment of the Safety equipment & Access Control.	8
8. Assessment of the Engineering Systems.	8
9. Assessment of the Engineering Work Spaces.	8

Is the system safe to continue?	Yes, under the supervision of the AE
---------------------------------	--------------------------------------

4. Next Audit Date

The next audit visit is planned to take place in

November 2019

PREVIOUS ACTION PLAN

Serial	Rating	Reference	Action Required	Remarks
1	6	141208/4	CPs should be occasionally monitored when carrying out works and a record of monitoring activities retained in the Documents Register.	No progress to date. Review at next audit.
2	20	141208/6	In-house CPs should be trained, assessed and appointed. Certificates of appointment and evidence of training should be retained in the Documents Register.	CP's have now been trained but are yet to be formally appointed. Reduced risk rating applied, review at next audit.
3	20	141208/7	Letters of competency should be obtained from the employers of contractor CPs and retained in the Documents Register.	No progress to date. Reduced risk rating applied. Review at next audit.
4	12	141208/8	A CP Register should be produced listing the contractor CPs and should be retained in the Documents Register.	Now on SMART sheet. Closed.
5	20	141208/9	Plant shutdown/make-safe risk assessments should be produced to identify the hazards associated with taking critical ventilation systems out of use and for work on LEVs that present a hazard to the maintainer. The risk assessments should be retained in the Documents Register.	No progress to date. Reduced risk rating applied. Review at next audit.
6	20	141208/10	Ensure task risk assessments are held for all works on ventilation systems. This documentation should be retained or referenced in the Documents Register.	No progress to date. Review at next audit.
7	20	141208/12	Produce a schedule of ventilation systems to identify all systems as critical, non-critical or LEV in accordance with SHTM 03-01, Part B, Para 4.7. Retain the schedule in the Documents Register.	Schedule is now compiled, it should include columns for "area served" and "Critical or Non-Critical". Reduced risk rating, review at next audit.
8	8	141208/18	Display safety signs at the entrance to all plant rooms.	Works in progress, review at next audit.
9	8	141208/19	Display unique plant room identity signs at the entrance to all plant rooms.	Works in progress, review at next audit.
10	16	141208/23	Implement a planned maintenance regime for emergency lights fitted in all plant rooms. Where DALI systems are installed a formal check of the automatic test results should be carried out.	On-going, review at next audit.

SHTM 03-01 SPECIALISED VENTILATION FOR HEALTHCARE PREMISES

Page 140

11	20	141208/37	Carry out annual inspections on all non-critical ventilation systems in accordance with SHTM 03-01, Part B, Appendix 1.	As of Nov 18 all AHU's are inspected. Reduced risk rating applied. The requirements of SHTM03/01 Pt B Appendix 1 and 2 is being developed. Review at next audit.
12	25	141208/40	Test fire dampers in accordance with SHTM 03-01, Part B, Para 4.13.	Discussed with the DP, No progress to date, review at next audit.
13	8	141208/42	Oversee the 14 monthly examinations of LEVs to ensure all the LEVs listed in the schedule of ventilation systems are examined.	On-going, review at next audit.
14	20	151209/7	Use permits to work when taking critical systems out of service and when carrying out intrusive maintenance on hazardous LEVs.	Permits have been produced and will be put into use ASAP.
15	12	151209/9	Only issue permits to work to appointed NHS CPs or contractor CPs listed in the CP Register.	Not yet in use, overtaken by events, closed.
16	20	151209/11	Populate the CAFM system (FM First) with planned maintenance tasks for all ventilation systems and retain records of all planned maintenance tasks carried out.	The FM First system is not yet in use however a spreadsheet is in use to plan maintenance and inspections at QEUH. New action raised, closed.
17	20	151209/14	Rectify the unserviceable lighting on the Old Maternity 4th floor plant room and install emergency lighting.	Lighting repaired. Closed.
18	12	151209/15	Fit identify signs or labels to the HEPA filter enclosures in the Adult and Children's Plant room 21.	Bio Hazard signs fitted. Closed.
19	8	151209/17	Fit access hatches to all AHU intake ductwork sections to allow inspections.	On-going, review at next audit.
20	4	151209/18	Fit drainage pipework to the glass drain traps on the retained estate Neurosurgery AHUs.	Unit planned for replacement. Review at next audit.
21	4	151209/21	Consider fitting inspection windows and internal lighting on all Lab Block AHU's.	Not SMART, closed.
22	12	151209/24	Rectify the collapsing pre-filters on the Old Maternity level 4 plant room intake plenum and fit a pressure differential gauge/manometer.	Completed, closed.
23	8	151209/25	Fit direction of flow labels to the isolation room extract ductwork in the Adult & Children's Plant room 21.	No progress to date, review at next audit.
24	20	151209/26	Carry out annual verifications on the Adult & Children's isolation rooms, critical care and MRI ventilation systems. Carry out annual verifications on the retained estate Neonatal and MRI/CT ventilation systems.	Works have started with isolation rooms. Discussion to be held at TUM regarding definition of critical systems for MRI/CT. New action raised. Closed.

SHTM 03-01 SPECIALISED VENTILATION FOR HEALTHCARE PREMISES

Page 141

25	12	151209/27	Record annual the annual cleaning of AHUs in the Lab Block. Carry out and record the annual cleaning of all AHUs in the retained estate.	No records for any cleaning of AHUs was witnessed. Discussed with lead AP. New action raised, closed.
26	20	151209/29	Ensure that LEV examinations and tests are carried out on the Mortuary dissection tables every 14 months in accordance with the COSHH Regulations.	Works in the planning to incorporate with the Joiners LEV. Review at next audit.
27	5	151209/31	Survey the Clinical Research department to identify any LEVs. Subject all identified LEVs to examinations and tests every 14 months in accordance with the COSHH Regulations.	No progress to date, new action raised, closed.
28	12	151209/32	Critical ventilation systems that do not meet the performance criteria specified in SHTM 03-01 should be taken out of service. If the clinical requirement prevents this the User and infection control should be notified in writing by the AP.	This is now directed in the ventilation SOP. Closed.
29	8	161114/1	Produce a local action plan to address the actions raised in this report.	Now on SMART sheet. Closed.
30	12	161114/2	Review the time available for APs to carry out AP (V) duties taking into consideration other disciplines they are responsible for.	Completed. 4 APs to be trained and appointed.
31	12	161114/6	Populate the existing Document Register with information relating to the retained estate and Adult & Children's, or setup and populate individual document registers.	No progress to date, new action raised, closed.
32	16	161114/7	Carry out planned maintenance on the retained estate AHUs. Carry out quarterly hygiene checks on split air conditioning units. Carry out 6 monthly chilled beam cleaning.	No progress to date. New action raised, closed.
33	12	161114/8	Inspect the half masks issued to the CPs annually and retain a record of the inspections.	No progress to date.
34	25	20171113/01	An open bottle of lubricating oil and drip tray was observed on the top of Theatre No 2 AHU in the Neonatal plant room. Various wood and materials were leaning against the AHU. These must be removed.	Completed. Closed.
35	25	20171113/02	Fire dampers were not subject to annual testing. This should be actioned at a strategic level.	Overtaken by events. Closed.
36	8	20171113/03	Paul Allan should attend a AP (V) refresher course.	Overtaken by events. Closed.

37	20	20171113/ 04	The number of AP (V) should be assessed against other workloads. A further 2 APs are recommended.	Overtaken by events. Closed.
38	20	20171113/ 05	The use of authority for disconnection (permit to work) should be reintroduced to prevent unintentional loss of supplies to the theatres and critical equipment.	Overtaken by events. Closed.

Comments

Darryl Conner, Melville MacMillan and Mark McKaig should be assessed and appointed for AP Ventilation duties.

REPORT			
Personnel			
Duty Holder	Mary-Anne Kane		1
Designated Person	Alan Gallacher		5
Authorising Engineer	Jamie Minhinnick		1
Authorised Persons	Darryl Conner		5
	Paul Allan		1
	Cyril Dowson		1
1. Management Policy			
	Y/N	Comments	
Is there a Board Ventilation Safety Policy In place?	Y	NHS GG&C Ventilation Safety Policy.	1
Is the Ventilation Safety Policy approved at Board level?	Y	The policy was approved.	1
Is the Board Ventilation Safety Policy reviewed periodically?	Y	The policy was reviewed in Nov 17 and will be reviewed bi-annually.	1
Is the Board Ventilation Safety Policy a controlled Document?	Y	The policy is a controlled document. A copy was held on SMART sheet.	1
Are the Duty Holder (V) responsibilities clearly defined in the Policy?	Y	The policy states that the Duty Holder is responsible for ensuring the ventilation systems are operated, maintained and repaired in accordance with SHTM 03-01.	1
Is the Designated Person appointed in writing?	N	No appointment made or held on SMART sheet.	5
Does the Board Ventilation Safety Policy include emergency procedures?	N	Emergency procedures were not yet included in the policy but are in development with the compliance manager.	5
Have the emergency procedures been validated or tested during the current audit period?	N/A	Not applicable.	
Has the Authorising Engineer (AE) (V) appointment been correctly made and is it in date?	Y	No issues found.	1
2. Authorised Persons (V)			
	Y/N	Comments	
Are all APs (V) currently certified?	N	Only 2 of the 5 AP's are formally appointed.	8
Are the APs (V) due for refresher training in SHTM 03-01?	N	No issues found.	1
Are the APs (V) due for training in emergency first-aid?	Y	No issues found.	1

Are the APs (V) carrying out AP (V) duties on a regular basis?	N	The APs are not using permits to control maintenance activities.	8
Are the APs (V) formally monitoring the work-in-progress and are they recording their observations?	N	CP Monitoring had not been carried out. Identified in previous audit.	12
Is the provision of APs (V) adequate?	N	5 AP's have been identified and trained but only 3 are appointed. See training summary.	16

3. Competent Persons (V)			
	Y/N	Comments	
Have the NHS CPs (V) been formally assessed and appointed by an AP (V)?	N	In house CPs have been trained but are yet to be formally appointed.	8
Is evidence of the competency of Contractor CPs (V) held in the Document Register?	Y	Evidence is held on Smart Sheet for H&V and Howarths. MAT and other ventilation contractors should be added.	8
Are the roles and responsibilities of Contractor CPs (V) defined in writing?	N/A	Not checked.	
Are records held in the Document Register of the site induction for the Contractor CPs (V)?	Y	The GG&C Contractor Control & Permit Register includes the issue of an identity card that listed the fundamental site rules and procedures.	1
Is there an up to date Register of CPs (V) appointed for the Trust included in the Document Register?	N	A register is held on SMART sheet.	1
Are the NHS CPs (V) carrying out their duties on a regular basis?	Y	In-house CPs and contractor CPs had been carrying out duties on a regular basis.	1

4. Incidents, Accidents and Dangerous Occurrences			
	Y/N	Comments	
Sine the last audit has the site been free from any accidents, incidents, dangerous occurrences or "near misses" in connection with the ventilation systems?	Y	None reported.	1
Have the details of incidents, accidents or dangerous occurrences been properly recorded and reported?	N/A	Not applicable.	

5. Safety Documentation

Job Number:

Originating AP (V):

Y/N

Comments

Was there a suitable & sufficient Risk Assessment to cover the work undertaken?	n/a	No permits issued since last audit.	
Was the permit-to-work completed by the AP (V) specifying the work to be carried out?	n/a	No permits issued since last audit.	
Was the permit-to-work signed by the User (V) to allow the work to proceed?	n/a	No permits issued since last audit.	
Was the permit-to-work issued to a CP (V)?	n/a	No permits issued since last audit.	
Was the permit-to-work cleared by a CP (V) and did they state that system was fit or unfit for use?	n/a	No permits issued since last audit.	
Was the permit-to-work cancelled by an AP (V) and did they acknowledge that the system was fit or unfit for use?	n/a	No permits issued since last audit.	
Did the User (V) acknowledge that the system should or should not be brought back into use?	n/a	No permits issued since last audit.	
Were the site records up-dated on completion of the work?	n/a	No permits issued since last audit.	

6. Operating Records

General

Y/N

Comments

Are the ventilation operating record documents kept in a secure location?	Y	The ventilation documents register is held electronically on SMART sheet.	1
Do the APs (V) have access to copies of relevant SHTMs and other reference documents?	Y	An electronic copy was held.	1
Does the Document Register index include all of the subjects required by SHTM 03-01?	Y	Held on SMART sheet.	1
Is the working Ventilation Document Register periodically reviewed and out-of-date information transferred to the archive Ventilation Document Register?	N/A	The Document Register was in the process of being populated. Not assessed.	
Is there a schedule of ventilations systems detailing which are critical, non-critical or LEVs?	Y	Modify the existing ventilation schedule to include LEV's, ACB's, Split AC's, Cassettes, FCU's etc and add columns for "area served" and "Critical or Non-Critical".	12
Are adequate technical drawings available to the APs?	Y	Technical drawings are held on Zutec. Can be difficult to navigate.	4

Are adequate O&M manuals available to the APs?	Y	O&M information was held electronically (Zutec) and on the shared drive for the Adult & Children's and the Lab Block. Original O&M information for the retained estate maternity theatres was reported to be held.	4
Are all of the ventilation systems included in the Trust's planned maintenance programme?	N	Maintenance of ventilation systems is not planned and appears to be done on a reactive basis following planned inspections when faults are identified. The planned maintenance issued to NHS competent persons should be reviewed and risk assessed. It is recommended that SFG 20 is used as a maintenance schedule for ventilation systems and implemented.	16
Are the planned maintenance records suitable, sufficient and accessible to the APs?	N	In-house maintenance was documented manually on check sheets. Service sheets were held for work carried out by contractor CPs. None of the maintenance was scheduled on FM First.	12
Are the results of the Trust's planned maintenance programme formally reviewed annually to establish trends and gaps? Are these reviews recorded?	N/A	Not checked.	

Inspection and Verification	Y/N	Comments	
Are critical ventilation systems being inspected quarterly?	Y	PPM files were held for all critical AHU. Monthly and quarterly checks were retained.	1
Are non-critical systems being inspected annually?	Y	PPM files were held for all non critical AHU. Monthly and quarterly checks were retained.	1
Are critical ventilation systems being verified annually?	Y	All theatres were subject to a rolling programme of annual verifications. Other critical systems in the Adult & Children's such as isolation wards are in the process of being verified with 50% complete. The retained estate ventilations systems for MRI/CT were not subject to annual verifications.	12

Are the inspections and verifications being recorded as per SHTM 03-01, Part B, Appendices 1 & 2 and the records retained in the Ventilation Documents Register?	Y	Verification reports produced by H&V Commissioning Services Ltd provided an executive summary, air change rates, pressure differentials and noise levels. The quarterly inspections carried out on the Adult & Children's isolation rooms, MRI/CT and critical care areas did not conform fully to Appendix 1.	8
Are the main components in AHUs serving critical and non-critical areas being cleaned annually?	Y	Annual cleaning of the AHUs is reportedly being carried out but was difficult to evidence with paperwork.	8
Are the fire dampers being tested annually?	N	Fire dampers were not subject to annual testing. A list of the fire dampers in the Lab Block had begun to be populated.	20
Are the LEV systems being examined and tested by a competent person at least every 14 months?	N	All Lab Block safety cabinets and fume cupboards have had COSHH LEV performance tests carried out in the past 14 months. Records were held by Estates. The Mortuary dissection table had not been subjected to a COSHH LEV test in the past 14 months.	8
Are critical systems that are unable to meet the required standards being taken out of service after receipt of condemnatory reports?	Y	All critical AHU's verified in the last 12 months are performing to the required standard. Immediate reports are given to estates before H&V leave site allowing problems to be rectified in the shut down period. A process is documented in an SOP held on SMART sheet.	1

7. Safety Equipment & Access Control		Y/N	Comments	
Do the APs (V) have sufficient isolation safety devices for the likely number of concurrent jobs?	Y	Adequate safety devices were held at the hospital.	1	
Do the APs (V) have sufficient safety signage for the likely number of concurrent jobs?	Y	Adequate safety signs were held at the hospital.	1	
Do the NHS CPs (V) have sufficient safety devices and signs for their routine work?	N/A	Not checked.		
Are records available of annual NHS safety and protective equipment inspections by an AP (V)?	N	The half masks issued to the CPs should be visually inspected annually by an AP and a record kept of the inspections.	8	
Do all NHS test instruments have in date calibration certificates?	N	Micro Manometer 4902159510 and Anememomter13450118 were calibrated on 24 Feb 16. Certificates could not be located during this audit.	5	
Have contractors provided in-date calibration certificates for all of their test instruments and safety equipment?	Y	Copies of calibration certificates were provided for the test instruments used by H&V Commissioning Services Ltd who carry out annual verifications.	1	
Is there an effective and auditable system for the control of plant room access in use?	Y	An access control procedure was held in the document register.	1	

8. Engineering Systems

Air Handling Units (AHUs)	Y/N	Comments	
Is each AHU clearly and uniquely labelled and does this label exactly correspond to the AHU Register?	Y	Those checked.	1
Is the general condition of each AHU satisfactory?	Y	Those checked.	1
Is the AHU constructed according to the principles in SHTM 03-01, Part A, Figure 1?	Y	Those checked.	1
Are the automatic controls fitted to critical systems capable of being overridden in the event of a software failure?	Y	Those checked.	1
Are fresh air intakes sited correctly, constructed correctly and are access hatches or hinged louvres installed?	N	AHUs in the Adult & Children's Plant rooms 21 & 22 and in the Lab Block Cat 2 and Cat 3 plant rooms did not have access hatches fitted to the intake ducts to allow for inspection.	8
Are drainage systems installed for wet components and are the drainage systems properly constructed?	N	Some of the traps fitted to the retained estate neurosurgery AHUs had no drainage pipework fitted. Some drain traps were visibly dirty. The drain traps on the Lab Block AHUs were connected directly to drain with no air gap.	8
Are belt driven fan drives situated outside of the air stream?	N	Some fan drives were internal to the AHUs. No action required.	4

Is there adequate access around the AHU and are access doors provided for all major components?	Y	The Lab Block Cat AHUs had no inspection windows fitted.	5
Are inspection windows and internal lights provided for cooling coils and filters?	Y	Those checked.	1
Are the filters the correct grade and correctly fitted to minimise bypass?	Y	No issues found.	1
Are the filters provided with a means of checking the differential pressure across them?	Y	There was no means of checking pressure differential on the pre filters fitted to the walk-in plenum in the retained estate Old Maternity Level 4 plant room.	8
Is the direction of air flow clearly marked on all main and branch ducts?	N	The extract ductwork serving the isolation rooms in Adult & Children's Plant room 21 did not have direction of flow labels fitted.	8
Are all air flow test-points properly located, clearly identified and is the size of the duct provided at each point?	Y	No issues found.	1

9. Engineering work spaces

Plant room externals	Y/N	Comments	
Is there a legible and secure safety sign displayed at the entrance to the plant room?	N	Adult & Children Plant rooms 21 & 22 and the Old Maternity 4th floor plant room did not have warning signs displayed at the entrance doors.	8
Is the name of the plant room exactly the same as the AHU Register?	N	Adult & Children Plant rooms 21 & 22 and the Old Maternity 4th floor plant room did not have unique name signs displayed at the entrance doors.	8
Is the correct contact telephone number shown?	N/A	Not applicable.	
Plant room security	Y/N	Comments	
Is the door soundly made and kept secure?	Y	No issues found.	1
Is there an emergency escape door and can it be opened from the inside?	N/A	Not checked.	
Is there a clear escape route outside the plant room?	Y	No issues found.	1
Are adequate emergency communications systems available?	Y	Staff entering plant rooms carry either a mobile telephone or PDA.	1
Is the plant room free from any unauthorised items stored within?	Y	No issues found.	1
If so, are the access arrangements to the plant room adequately controlled?	N/A	Not applicable.	

Plant room structure

Is the plant room structure and condition satisfactory?	Y	No issues found.	1
Are posters and drawings displayed as required?	N/A	Not checked.	

Fire Precautions

Y/N

Comments

Is the plant room free from combustion equipment?	Y	No issues found.	1
Is the plant room free from rubbish or fire hazardous materials stored inside or immediately outside the plant room?	Y	No issues found.	1
Is there at least one suitable fire extinguisher provided in the plant room and has it been inspected in the last 12 months?	Y	All fire extinguishers checked were serviced in April 2018.	1

I confirm that, where actions are required, a report has been submitted to the Designated Person

UPDATED ACTION PLAN

Serial	Rating	Reference	Action Required	Responsible Person	Date due
Action points carried forward from previous audit					
1	8	141208/4	CPs should be occasionally monitored when carrying out works and a record of monitoring activities retained in the Documents Register.	All APs	31-Mar-19
2	9	141208/6	In-house CPs should be trained, assessed and appointed. Certificates of appointment and evidence of training should be retained in the Documents Register.	Lead AP	31-Mar-19
3	6	141208/8	A CP Register should be produced listing the contractor CPs and should be retained in the Documents Register.	Lead AP	31-Mar-19
4	16	141208/9	Plant shutdown/make-safe risk assessments should be produced to identify the hazards associated with taking critical ventilation systems out of use and for work on LEVs that present a hazard to the maintainer. The risk assessments should be retained in the Documents Register.	Lead AP	30-Nov-19
5	16	141208/10	Ensure task risk assessments are held for all works on ventilation systems. This documentation should be retained or referenced in the Documents Register.	Lead AP	30-Nov-19
6	12	141208/12	Produce a schedule of ventilation systems to identify all systems as critical, non-critical or LEV in accordance with SHTM 03-01, Part B, Para 4.7. Retain the schedule in the Documents Register.	Lead AP	31-Mar-19
7	8	141208/18	Display safety signs at the entrance to all plant rooms.	Lead AP	31-May-19
8	8	141208/19	Display unique plant room identity signs at the entrance to all plant rooms.	Lead AP	31-May-19
9	16	141208/23	Implement a planned maintenance regime for emergency lights fitted in plant rooms. Where DALI systems are installed a formal check of the automatic test results should be carried out.	Lead AP	31-May-19

SHTM 03-01 SPECIALISED VENTILATION FOR HEALTHCARE PREMISES

Page 153

10	12	141208/37	Carry out annual inspections on the retained estate non-critical ventilation systems in accordance with SHTM 03-01, Part B, Appendix 1.	Lead AP	31-Mar-19
11	20	141208/40	Test fire dampers in accordance with SHTM 03-01, Part B, Para 4.13.	DP	TBC
12	8	141208/42	Oversee the 14 monthly examinations of LEVs to ensure all the LEVs listed in the schedule of ventilation systems are examined.	Lead AP	31-Mar-18
13	20	151209/7	Use permits to work when taking critical systems out of service and when carrying out intrusive maintenance on hazardous LEVs.	Lead AP	ASAP
14	8	151209/17	Fit access hatches to all AHU intake ductwork sections to allow inspections.	Lead AP	12-Dec-19
15	4	151209/18	Fit drainage pipework to the glass drain traps on the retained estate Neurosurgery AHUs.	Lead AP	12-Dec-19
16	8	151209/25	Fit direction of flow labels to the isolation room extract ductwork in the Adult & Children's Plant room 21.	Lead AP	31-Mar-19
17	16	151209/29	Ensure that LEV examinations and tests are carried out on the Mortuary dissection tables every 14 months in accordance with the COSHH Regulations.	Lead AP	31-Mar-19
18	12	161114/8	Inspect the half masks issued to the CPs annually and retain a record of the inspections.	Lead AP	31-Mar-19

Action points from this audit

19	16	20181212/01	Introduce a true planned maintenance regime for ventilation systems from an agreed maintenance schedule and add to all ventilation assets.	Lead AP	01-Jun-19
20	9	20181212/02	Modify the existing ventilation schedule to include LEV's, ACB's, Split AC's, Cassettes, FCU's etc and add columns for "area served" and "Critical or Non-Critical".	Lead AP	01-Jun-19
21	16	20181212/03	The criticality of all ventilation systems should be reviewed with user groups to positively identify all systems that should be deemed critical.	Lead AP/DP	01-Jun-19
22	9	20181212/04	Populate all relevant information into the documents register on SMART sheet.	Lead AP	01-Jun-19
23	16	20181212/05	Split AC's, Cassette Units and FCU's should be subjected to 3m inspections and cleaning.	Lead AP	01-Jun-19

SHTM 03-01 SPECIALISED VENTILATION FOR HEALTHCARE PREMISES

Page 154

24	16	20181212/ 06	All Active Chilled Beams (ACB's) should be inspected on a 6m basis and cleaned as required.	Lead AP	01-Jun-19
25	12	20181212/ 07	Darryl Conner, Melville MacMillan and Mark McKaig should be assessed and appointed for AP Ventilation duties.	Compliance Manager / AE	31-Mar-19

Date(s) of Audit 17-18 Dec 19

Date(s) of Previous Audit 11-12 Dec 18

Site Address

1345 Govan Road,
Glasgow
G51 4TF

Reference 20191218-250-QEUH-V-JM-003

1. Terms of Reference

1.1 This audit was conducted in accordance with the following current reference documents:

- a. Scottish Health Technical Memorandum 00: Policies and principles of healthcare engineering.
- b. Scottish Health Technical Memorandum 03-01: Specialised ventilation for healthcare premises.

2. Executive Summary

2.1 Introduction. The purpose of this audit was to assess the compliance, operation and maintenance of the Safe System of Work at the Hospital(s) in accordance with the discipline specific Health Technical Memoranda, Acts, Regulations and HSE Guidance documents. The resulting Action Plan will be reviewed periodically. The appointments of the discipline specific Authorised Persons were also assessed during the audit.

2.2 Report Summary

Another good year of progress was witnessed at QEUH Campus in terms of management of ventilation. Progress on the action plan was pleasing to see with 23/25 actions completed or in progress.

Some areas that still need to be addressed are as follows:

1. Fire damper testing has not been carried out in the adults and children's hospital. There has been good progress with a survey of the retained estates but the vast proportion are in the A&C.
2. The updated policy should be published and roles communicated accordingly following proposed structure changes. Once completed the AP's should be appointed formally.
3. Safety paperwork and 40 point checks are auditable and accountable documents. Care should be taken by both AP's and CP's to ensure they are filled out correctly and in line with guidance.
4. If the Neurology AHU's on level 2 are to be retained works should be carried out to prolong the life and improve the standards. It is the opinion of the AE that the units are capable of being refurbished in situ and have a number of years of life remaining if action is taken within the next 12m.
5. It is strongly recommended that an AP(V) is trained and appointed for each shift to assist in the delivery of the safe system of work.

Overall a good audit. Details of new actions are contained within this report.

3. Conclusion

ASSESSMENT OF SAFE SYSTEM OF WORK	CONCLUSION
1. Assessment of the Management Policy.	6
2. Assessment of the Authorised Persons.	10
3. Assessment of the Competent Persons.	6
4. Assessment of Incidents, Accidents and Dangerous Occurrences.	1
5. Assessment of the Safety Documentation.	12
6. Assessment of the Operating Records.	20
7. Assessment of the Safety equipment & Access Control.	1
8. Assessment of the Engineering Systems.	8
9. Assessment of the Engineering Work Spaces.	1

Is the system safe to continue?	Yes, under the supervision of the AE
---------------------------------	--------------------------------------

4. Next Audit Date

The next audit visit is planned to take place in

December 2020

REVIEW OF 2018 ACTION PLAN

Serial	Rating	Reference	Action Required	
1	8	141208/4	CPs should be occasionally monitored when carrying out works and a record of monitoring activities retained in the Documents Register.	All available CPs have been assessed by J Guthrie and works are monitored through the use of a PTW system. Well done closed.
2	9	141208/6	In-house CPs should be trained, assessed and appointed. Certificates of appointment and evidence of training should be retained in the Documents Register.	10 in house CPs are trained assessed and appointed at QEUH with 4 potential CPs to be appointed. Closed.
3	6	141208/8	A CP Register should be produced listing the contractor CPs and should be retained in the Documents Register.	Held in the VDR on SMARTSHEET. T Ramsay and G Bennett should be added to the CP register on SMARTSHEET. Closed.
4	16	141208/9	Plant shutdown/make-safe risk assessments should be produced to identify the hazards associated with taking critical ventilation systems out of use and for work on LEVs that present a hazard to the maintainer. The risk assessments should be retained in the Documents Register.	Risk assessment V/001 "Shutting Down of AHU for Planned Maintenance Tasks" was held dated 17/12/19. Hazardous LEV's are included in the PTW system. Closed.
5	16	141208/10	Ensure task risk assessments are held for all works on ventilation systems. This documentation should be retained or referenced in the Documents Register.	Task risk assessments for maintenance of ventilation AHU are now held for the main areas. This should be developed to include all assets and LEV's. Updated action, closed.
6	12	141208/12	Produce a schedule of ventilation systems to identify all systems as critical, non-critical or LEV in accordance with SHTM 03-01, Part B, Para 4.7. Retain the schedule in the Documents Register.	A comprehensive working schedule of ventilation systems is held and maintained on the shared drive VSDR. Closed.
7	8	141208/18	Display safety signs at the entrance to all plant rooms.	Completed, closed.
8	8	141208/19	Display unique plant room identity signs at the entrance to all plant rooms.	Completed, closed.
9	16	141208/23	Implement a planned maintenance regime for emergency lights fitted in plant rooms. Where DALI systems are installed a formal check of the automatic test results should be carried out.	Planned maintenance is now scheduled on FM First. Closed.

SHTM 03-01 SPECIALISED VENTILATION FOR HEALTHCARE PREMISES

Page 160

10	12	141208/37	Carry out annual inspections on the retained estate non-critical ventilation systems in accordance with SHTM 03-01, Part B, Appendix 1.	Completed, closed.
11	20	141208/40	Test fire dampers in accordance with SHTM 03-01, Part B, Para 4.13.	Retained estates have now been surveyed. No progress to date on A&C Hospitals.
12	8	141208/42	Oversee the 14 monthly examinations of LEVs to ensure all the LEVs listed in the schedule of ventilation systems are examined.	All captured LEVs are now listed and subjected to 14m examination and testing. Records are retained in the shared drive VSDR. Closed.
13	20	151209/7	Use permits to work when taking critical systems out of service and when carrying out intrusive maintenance on hazardous LEVs.	Now in place. New action raised. Closed.
14	8	151209/17	Fit access hatches to all AHU intake ductwork sections to allow inspections.	Works progressing as funds/time allows. Approx. 100 fitted in last 12m. Review at next audit.
15	4	151209/18	Fit drainage pipework to the glass drain traps on the retained estate Neurosurgery AHUs.	Completed, closed.
16	8	151209/25	Fit direction of flow labels to the isolation room extract ductwork in the Adult & Children's Plant room 21.	Completed, closed.
17	16	151209/29	Ensure that LEV examinations and tests are carried out on the Mortuary dissection tables every 14 months in accordance with the COSHH Regulations.	Completed, closed.
18	12	161114/8	Inspect the half masks issued to the CPs annually and retain a record of the inspections.	Disposable masks are routinely used and a PPE issued following a toolbox talk in Jan 18. Closed.
19	16	20181212/01	Introduce a true planned maintenance regime for ventilation systems from an agreed maintenance schedule and add to all ventilation assets.	Planned maintenance is now scheduled on FM First. Closed.
20	9	20181212/02	Modify the existing ventilation schedule to include LEV's, ACB's, Split AC's, Cassettes, FCU's etc and add columns for "area served" and "Critical or Non-Critical".	Completed, closed.
21	16	20181212/03	The criticality of all ventilation systems should be reviewed with user groups to positively identify all systems that should be deemed critical.	A ventilation safety group has been set up for QUEH and these topics are now being discussed. As decisions are made the schedule is updated to reflect the changes and maintenance regimes adjusted accordingly. Closed.

SHTM 03-01 SPECIALISED VENTILATION FOR HEALTHCARE PREMISES

Page 161

22	9	20181212/ 04	Populate all relevant information into the documents register on SMART sheet.	A comprehensive working documents register is held on the shared drive. A link should be added to SMARTSHEET. Closed.
23	16	20181212/ 05	Split AC's, Cassette Units and FCU's should be subjected to 3m inspections and cleaning.	All assets have been captured and have been cleaned within the last 3m. Contract let with Correct Air Solutions. Closed.
24	16	20181212/ 06	All Active Chilled Beams (ACB's) should be inspected on a 6m basis and cleaned as required.	Chilled beams are now cleaned and inspected every 6m or less depending on location and risk. Closed.
25	12	20181212/ 07	Darryl Conner, Melville MacMillan and Mark McKaig should be assessed and appointed for AP Ventilation duties.	Overtaken by events. New action raised. Closed.

Comments

D Conner, J Guthrie, M McKaig and P Allen should be formally appointed in writing as AP(V) by the designated person.

C Dowson should be re-assessed for continued competency as AP(V).

P Allen and C Dowson should provide evidence of first aid training.

Further work should be done to populate the competences of APs in the documents register on SMARTSHEET.

Due to the size and scale of the systems a QEUH Campus it is recommended that at least 1 AP(V) is trained and appointed on each shift to cover shift work.

REPORT			
Personnel			
Duty Holder	Jane Grant		1
Designated Person	Tom Steele/Alan Gallacher tbc		5
Authorising Engineer	Jamie Minhinnick		1
Authorised Persons	Darryl Conner		5
	Jim Guthrie		5
	Cyril Dowson		5
	Paul Allan		5
	Mark McKaig		5
1. Management Policy			
	Y/N	Comments	
Is there a Board Ventilation Safety Policy In place?	Y	A copy was held on SMARTSHEET. Overdue review as at 23/11/19.	6
Is the Ventilation Safety Policy approved at Board level?	Y	The policy has been reviewed and updated. Pre-approved by the SCART group and awaiting second review for the addition of asbestos guidance.	6
Is the Board Ventilation Safety Policy reviewed periodically?	Y	Overdue review in November 2019.	6
Is the Board Ventilation Safety Policy a controlled Document?	Y	Held securely on SMARTSHEET.	1
Are the Duty Holder (V) responsibilities clearly defined in the Policy?	Y	No significant issues identified.	1
Is the Designated Person appointed in writing?	N	The DP is identified as the Director of Estates and Facilities. No written appointment was available.	6
Does the Board Ventilation Safety Policy include emergency procedures?	N	Emergency procedures are not included. They are incorporated in the re-write.	6
Have the emergency procedures been validated or tested during the current audit period?	N/A	See above.	
Has the Authorising Engineer (AE) (V) appointment been correctly made and is it in date?	Y	No significant issues identified.	1
2. Authorised Persons (V)			
	Y/N	Comments	
Are all APs (V) currently certified?	N	None of the trained and assessed APs have been formally appointed.	10
Are the APs (V) due for refresher training in SHTM 03-01?	N	No issues found.	1
Are the APs (V) due for training in emergency first-aid?	Y	P Allen and C Dowson should provide evidence of first aid training in the VDR.	6
Are the APs (V) carrying out AP (V) duties on a regular basis?	Y	J Guthrie and D Conner are actively involved in writing permits. C Dowson and M McKaig are also involved in ventilation works.	1

Are the APs (V) formally monitoring the work-in-progress and are they recording their observations?	Y	CP work is monitored by APs using the permit to work system.	1
Is the provision of APs (V) adequate?	N	Due to the size and scale of the systems at QEUH Campus it is recommended that at least 1 AP(V) is trained and appointed on each shift to cover shift work.	12
3. Competent Persons (V)			
	Y/N	Comments	
Have the NHS CPs (V) been formally assessed and appointed by an AP (V)?	Y	10 in house CPs have been assessed and appointed in writing by J Guthrie. Records are held on SMARTSHEET.	1
Is evidence of the competency of Contractor CPs (V) held in the Document Register?	N	A boardwide ventilation contractor competence register is held on SMARTSHEET. More work should be done to enhance the information on SMARTSHEET.	6
Are the roles and responsibilities of Contractor CPs (V) defined in writing?	Y	Verification reports produced by H&V and Correct Air Solutions detail the scope of works.	1
Are records held in the Document Register of the site induction for the Contractor CPs (V)?	Y	The GG&C Contractor Control & Permit Register includes the issue of an identity card that listed the fundamental site rules and procedures.	1
Is there an up to date Register of CPs (V) appointed for the Trust included in the Document Register?	Y	A register is held on SMART sheet.	1
Are the NHS CPs (V) carrying out their duties on a regular basis?	Y	In-house CPs and contractor CPs had been carrying out duties on a regular basis.	1
4. Incidents, Accidents and Dangerous Occurrences			
	Y/N	Comments	
Sine the last audit has the site been free from any accidents, incidents, dangerous occurrences or "near misses" in connection with the ventilation systems?	Y	None reported.	1
Have the details of incidents, accidents or dangerous occurrences been properly recorded and reported?	N/A	Not applicable.	
5. Safety Documentation			
Job	2270	Originating AP (V):	J Guthrie
		Y/N	Comments
Was there a suitable & sufficient Risk Assessment to cover the work undertaken?	Y	Risk assessment for the maintenance of Air Handling Equipment in plantroom 21 was held and dated 04/01/19. SOP held for occupied critical area ppm procedure 17/7/19.	1
Was the permit-to-work completed by the AP (V) specifying the work to be carried out?	N	J Guthrie is not yet formally appointed. Isolation time was not agreed.	5
Was the permit-to-work signed by the User (V) to allow the work to proceed?	Y	Signed by A Moyes.	1

Was the permit-to-work issued to a CP (V)?	Y	Issued to T Ramsay who was not appointed at the time but has been since.	4
Was the permit-to-work cleared by a CP (V) and did they state that system was fit or unfit for use?	N	Strike through box not completed.	5
Was the permit-to-work cancelled by an AP (V) and did they acknowledge that the system was fit or unfit for use?	N	Signed but strike through box not completed.	12
Did the User (V) acknowledge that the system should or should not be brought back into use?	Y	Signed by A Moyes.	1
Were the site records up-dated on completion of the work?	Y	Verification documentations were provided within 24 hours.	1
5. Safety Documentation			
Job	2253	Originating AP (V): Y/N	D Connor Comments
Was there a suitable & sufficient Risk Assessment to cover the work undertaken?	Y	Risk assessment for the maintenance of Air Handling Equipment in plantroom 22 was held and dated 04/01/19.	1
Was the permit-to-work completed by the AP (V) specifying the work to be carried out?	N	D Connor is not yet formally appointed. Isolation time was not agreed.	5
Was the permit-to-work signed by the User (V) to allow the work to proceed?	Y	Signed by A Morrison.	1
Was the permit-to-work issued to a CP (V)?	Y	Issued to G Harvey who was not appointed at the time but has been since.	4
Was the permit-to-work cleared by a CP (V) and did they state that system was fit or unfit for use?	N	Strike through box not completed.	5
Was the permit-to-work cancelled by an AP (V) and did they acknowledge that the system was fit or unfit for use?	N	Signed but with errors above not rectified.	8
Did the User (V) acknowledge that the system should or should not be brought back into use?	Y	Signed by A Morrison.	1
Were the site records up-dated on completion of the work?	Y	Verification documentations were provided within 24 hours.	1
6. Operating Records			
General	Y/N	Comments	
Are the ventilation operating record documents kept in a secure location?	Y	There is an electronic VDR held on the SGH shared S drive. Access should be restricted to APs and the compliance team. Each critical system has a hard file log book held securely in the CAP office.	6
Do the APs (V) have access to copies of relevant SHTMs and other reference documents?	Y	An electronic copy was held.	1
Does the Document Register index include all of the subjects required by SHTM 03-01?	Y	A comprehensive file structure is held in the shared drive.	1

Is the working Ventilation Document Register periodically reviewed and out-of-date information transferred to the archive Ventilation Document Register?	Y	The VDR is well maintained by the CAP.	1
Is there a schedule of ventilations systems detailing which are critical, non-critical or LEVs?	Y	Good registers are maintained for critical and non-critical AHU. Information is held for LEVs, split AC's and FCU/chilled beams. These should be collated into a master schedule.	6
Are adequate technical drawings available to the APs?	Y	Technical drawings are held on Zutec. Can be difficult to navigate.	4
Are adequate O&M manuals available to the APs?	Y	O&M information was held electronically (Zutec) and on the shared drive for the Adult & Children's and the Lab Block. Original O&M information for the retained estate maternity theatres was reported to be held.	4
Are all of the ventilation systems included in the Trust's planned maintenance programme?	Y	FM first is now in place to schedule maintenance and hard check sheets are retained in the theatre files.	1
Are the planned maintenance records suitable, sufficient and accessible to the APs?	Y	Maintenance is recorded on FM first and 40 point checks are held in hard copy in each ventilation file.	1
Are the results of the Trust's planned maintenance programme formally reviewed annually to establish trends and gaps? Are these reviews recorded?	N/A	Not checked.	
Inspection and Verification			
	Y/N	Comments	
Are critical ventilation systems being inspected quarterly?	Y	PPM files were held for all critical AHU. Monthly and quarterly checks were retained. RHC Theatre 4 (22 AHU 17) was witnessed as in date.	1
Are non-critical systems being inspected annually?	Y	PPM files were held for all non critical AHU. Monthly and quarterly checks were retained.	1
Are critical ventilation systems being verified annually?	Y	All critical ventilation systems have been verified within the last 12m with the exception of the MRI which is planned for January.	1
Are the inspections and verifications being recorded as per SHTM 03-01, Part B, Appendices 1 & 2 and the records retained in the Ventilation Documents Register?	Y	Good records are now held in the log books in the CAPs office.	1

Are the main components in AHUs serving critical and non-critical areas being cleaned annually?	Y	Records retained with the annual inspections in the log books. 121 AHU 26 was witnessed as last cleaned on 22/11/19.	1
Are the fire dampers being tested annually?	N	Fire dampers were not subject to annual testing in the A&C hospital. All retained buildings have been surveyed and tested this year. Remedial works are now required to complete this area.	20
Are the LEV systems being examined and tested by a competent person at least every 14 months?	Y	All Lab Block safety cabinets and fume cupboards and the Mortuary dissection tables have had COSHH LEV performance tests carried out in the past 14 months. Records were held by Estates. A register of all LEVs should be populated and maintained by the CAP.	6
Are critical systems that are unable to meet the required standards being taken out of service after receipt of condemnatory reports?	Y	All critical AHU's verified in the last 12 months are performing to the required standard. Immediate reports are given to estates before Correct air Solutions leave site allowing problems to be rectified in the shut down period. A process is documented in an SOP.	1
7. Safety Equipment & Access Control			
	Y/N	Comments	
Do the APs (V) have sufficient isolation safety devices for the likely number of concurrent jobs?	Y	Adequate safety devices were held at the hospital.	1
Do the APs (V) have sufficient safety signage for the likely number of concurrent jobs?	Y	Adequate safety signs were held at the hospital.	1
Do the NHS CPs (V) have sufficient safety devices and signs for their routine work?	N/A	Not checked.	
Are records available of annual NHS safety and protective equipment inspections by an AP (V)?	Y	PPE toolbox talk records are held.	1
Do all NHS test instruments have in date calibration certificates?	N	None held	1
Have contractors provided in-date calibration certificates for all of their test instruments and safety equipment?	Y	Copies of calibration certificates were provided for the test instruments used by Correct Air Solutions who carry out annual verifications.	1
Is there an effective and auditable system for the control of plant room access in use?	Y	An access control procedure was held in the document register.	1

8. Engineering Systems			
		Visited Childrens Hospital Plantroom 41A	
Air Handling Units (AHUs)	Y/N	Comments	
Is each AHU clearly and uniquely labelled and does this label exactly correspond to the AHU Register?	Y	Those checked.	1
Is the general condition of each AHU satisfactory?	Y	Those checked.	1
Is the AHU constructed according to the principles in SHTM 03-01, Part A, Figure 1?	Y	Those checked.	1
Are the automatic controls fitted to critical systems capable of being overridden in the event of a software failure?	Y	Those checked.	1
Are fresh air intakes sited correctly, constructed correctly and are access hatches or hinged louvres installed?	N	All AHU in plantroom 41A should have access hatches cut into the intake plenums to facilitate cleaning and inspection.	8
Are drainage systems installed for wet components and are the drainage systems properly constructed?	N	Suitable air breaks should be installed on each drain as they currently terminate at the floor drain in plantroom 41A.	5
Are belt driven fan drives situated outside of the air stream?	N	No issues found.	1
Is there adequate access around the AHU and are access doors provided for all major components?	Y	No issues found.	1
Are inspection windows and internal lights provided for cooling coils and filters?	Y	Those checked.	1
Are the filters the correct grade and correctly fitted to minimise bypass?	Y	No issues found.	1
Are the filters provided with a means of checking the differential pressure across them?	Y	Magnehelic type gauges fitted. These should be fitted with clean/dirty indicators.	6
Is the direction of air flow clearly marked on all main and branch ducts?	Y	Printed identification labels were fitted.	1
Are all air flow test-points properly located, clearly identified and is the size of the duct provided at each point?	N	Not found. These should be located and labelled.	6
9. Engineering work spaces Visited Plant Room 21			
Plant room externals	Y/N	Comments	
Is there a legible and secure safety sign displayed at the entrance to the plant room?	Y	No issues found.	1
Is the name of the plant room exactly the same as the AHU Register?	Y	No issues found.	1
Is the correct contact telephone number shown?	N/A	Not applicable.	

Plant room security		Y/N	Comments	
Is the door soundly made and kept secure?	Y	No issues found.		1
Is there an emergency escape door and can it be opened from the inside?	Y	2 x escapes onto the roof space.		1
Is there a clear escape route outside the plant room?	Y	No issues found.		1
Are adequate emergency communications systems available?	Y	Staff entering plant rooms carry either a mobile telephone or PDA.		1
Is the plant room free from any unauthorised items stored within?	Y	No issues found.		1
If so, are the access arrangements to the plant room adequately controlled?	N/A	Not applicable.		
Plant room structure				
Is the plant room structure and condition satisfactory?	Y	No issues found.		1
Are posters and drawings displayed as required?	Y	No issues found.		1
Fire Precautions		Y/N	Comments	
Is the plant room free from combustion equipment?	Y	No issues found.		1
Is the plant room free from rubbish or fire hazardous materials stored inside or immediately outside the plant room?	Y	No issues found.		1
Is there at least one suitable fire extinguisher provided in the plant room and has it been inspected in the last 12 months?	Y	All fire extinguishers checked were serviced in April 2019. By contract arrangement with interserve.		1

I confirm that, where actions are required, a report has been submitted to the Designated Person

UPDATED ACTION PLAN

Serial	Rating	Reference	Action Required	Responsible Person	Date due
Action points carried forward from previous audit					
1	20	141208/40	Test fire dampers in accordance with SHTM 03-01, Part B, Para 4.13.	DP	TBC
2	8	151209/17	Fit access hatches to all AHU intake ductwork sections to allow inspections.	Lead AP	12-Dec-20
Action points from this audit					
3	5	20191218/02	T Ramsay and G Bennet should be added to the CP register on SMARTSHEET.	Compliance Manager	17-Mar-20
4	12	20191218/03	A PTW should be used when taking critical systems out of use at all times. The 29 permits issued since 21/01/19 is not representative of the work carried out.	AP's	NTQ
5	12	20191218/04	Due to the size and scale of the systems a QEUH Campus it is recommended that at least 1 AP(V) is trained and appointed on each shift to cover shift work.	DP	17-Dec-20
6	6	20191218/05	The information held in the shared drive documents register should be linked to SMARTSHEET if possible.	Compliance Manager	17-Mar-20
7	6	20191218/06	The designated person should be appointed in writing by the duty holder.	DP	17-Mar-20
8	6	20191218/07	D Conner, J Guthrie, M McKaig and P Allen should be formally appointed in writing as AP(V) by the designated person.	DP	17-Mar-20
9	6	20191218/08	C Dowson should be re-assessed for continued competency as AP(V).	AE	17-Mar-20
10	6	20191218/09	Further work should be done to populate the competences of APs in the documents register on SMARTSHEET.	Compliance Manager/CAP	17-Jan-20
11	6	20191218/10	P Allen and C Dowson should provide evidence of in date first aid training.	CAP	31-Jan-20
12	6	20191218/11	The updated ventilation systems policy should be ratified and published.	DP	ASAP

13	6	20191218/ 12	Further work should be done to populate the competences of contractors in the documents register on SMARTSHEET (Correct Air Solutions, ATLAS etc).	Compliance Manager/CAP	NTQ
14	12	20191218/ 13	Care should be taken to ensure that permits to work are correctly issued and cancelled. Strike through boxes and signatures were missing in multiple permits.	AP's	NTQ
15	12	20191218/ 14	Risk assessments for maintaining/working on LEV's that present a hazard to the maintainer should be produced.	AP's	17-Mar-20
16	6	20191218/ 15	Access to the electronic VDR should be restricted to APs and the compliance team.	CAP	TBC
17	6	20191218/ 16	A register of all LEV's, split AC's, ACBs and FCU's should be collated and maintained by the CAP.	CAP	17-Jan-20
18	6	20191218/ 17	The ventilation serving the MRI suites should be subjected to annual performance verification.	CAP	28-Feb-20
19	6	20191218/ 18	All magnehelic gauges and manometers should be fitted with clean/dirty filter indication labels.	AP's	17-Dec-20
20	6	20191218/ 19	Care should be taken by CP's when completing 40 point checks. The guidance provided in the CP course notes and SHTM03/01 Pt B should be followed.	CP's	NTQ
21	12	20191218/ 20	The quality of maintenance at the Neurology level 2 roof AHU plant space should be addressed. The following issues should be rectified: 1. The AHU externals should be cleaned, primed and painted to prolong the life and prevent ingress of contamination. 2. The duct flexible connections between AHU sections should be repaired. (This should be surveyed for asbestos). 3. The roof flooring should be cleaned of algae and vegetation below the AHU and around the intakes. 4. The intakes should be cleaned and repaired to remove corrosion. 5. Small areas of internal corrosion should be removed and treated.	AP's	17-Dec-20
22	12	20191218/ 21	Where steam humidification is fitted to AHUs but not used it should be physically disconnected at the AHU and ideally stripped back to the running main.	AP's	17-Jan-20

DP-Designated Person : AE- Authorising Engineer : AP- Authorised Person with Line Management Support

The **Designated Person** should sign this Action Plan to acknowledge the contents. The original copy should then be filed in the Document Register.

Date(s) of Audit 15-16 Dec 20

Date(s) of Previous Audit 17-18 Dec 19

Site Address

1345 Govan Road,
Glasgow
G51 4TF

Reference 20201216-250-QEUH-V-JM-004

1. Terms of Reference

1.1 This audit was conducted in accordance with the following current reference documents:

- a. Scottish Health Technical Memorandum 00: Policies and principles of healthcare engineering.
- b. Scottish Health Technical Memorandum 03-01: Specialised ventilation for healthcare premises.

2. Executive Summary

2.1 Introduction. The purpose of this audit was to assess the compliance, operation and maintenance of the Safe System of Work at the Hospital(s) in accordance with the discipline specific Health Technical Memoranda, Acts, Regulations and HSE Guidance documents. The resulting Action Plan will be reviewed periodically. The appointments of the discipline specific Authorised Persons were also assessed during the audit.

2.2 Report Summary

Another good year of progress was witnessed at QEUH Campus in terms of management of ventilation. Progress on the action plan was pleasing to see with 9/22 actions completed or in progress.

Some areas that still need to be addressed are as follows:

1. Fire damper testing has not been carried out in the adults and children's hospital. There has been good progress with a survey of the retained estates but the vast proportion are in the A&C.
2. Safety paperwork and 40 point checks are auditable and accountable documents. Care should be taken by both AP's and CP's to ensure they are filled out correctly and in line with guidance.
3. Efforts should continue to have AP(V)'s trained and appointed for each shift to assist in the delivery of the safe system of work.
4. AP's should interrogate 40 point checks for accuracy and ensure issues identified are rectified in a suitable timeframe.

Overall a good audit. Details of new actions are contained within this report.

3. Conclusion

ASSESSMENT OF SAFE SYSTEM OF WORK	CONCLUSION
1. Assessment of the Management Policy.	1
2. Assessment of the Authorised Persons.	1
3. Assessment of the Competent Persons.	1
4. Assessment of Incidents, Accidents and Dangerous Occurrences.	1
5. Assessment of the Safety Documentation.	12
6. Assessment of the Operating Records.	20
7. Assessment of the Safety equipment & Access Control.	1
8. Assessment of the Engineering Systems.	12
9. Assessment of the Engineering Work Spaces.	4

Is the system safe to continue?	Yes, under the guidance of this report.
---------------------------------	---

4. Next Audit Date

The next audit visit is planned to take place in

December 2021

REVIEW OF PREVIOUS ACTION PLAN

Serial	Rating	Reference	Action Required	Remarks
1	20	141208/40	Test fire dampers in accordance with SHTM 03-01, Part B, Para 4.13.	Works reportedly progressing but no evidence presented at audit. Review at next audit.
2	8	151209/17	Fit access hatches to all AHU intake ductwork sections to allow inspections.	Works progressing. Not all yet fitted. A plan should be put in place to identify areas still required and a time frame for completion. Review at next audit.
3	5	20191218/02	T Ramsay and G Bennet should be added to the CP register on SMARTSHEET.	Completed and held on the estates shared. Closed.
4	12	20191218/03	A PTW should be used when taking critical systems out of use at all times. The 29 permits issued since 21/01/19 is not representative of the work carried out.	Works progressing with 115 permits issued in the audit period. It is estimated for maintenance there should be circa 400 per annum. Review at next audit.
5	12	20191218/04	Due to the size and scale of the systems a QEUH Campus it is recommended that at least 1 AP(V) is trained and appointed on each shift to cover shift work.	Work in progress with David Smeaton and Grant Bennett going through the assessment process. Review at next audit.
6	6	20191218/05	The information held in the shared drive documents register should be linked to SMARTSHEET if possible.	Work in progress with Lead AP and Compliance Manager.
7	6	20191218/06	The designated person should be appointed in writing by the duty holder.	No progress to date. Review at next audit.
8	6	20191218/07	D Conner, J Guthrie, M McKaig and P Allen should be formally appointed in writing as AP(V) by the designated person.	Completed closed. 5 AP's are now appointed in writing with 1 due imminent appointment and 4 Designate AP's. Well done.
9	6	20191218/08	C Dowson should be re-assessed for continued competency as AP(V).	Overtaken by events. Closed.
10	6	20191218/09	Further work should be done to populate the competences of APs in the documents register on SMARTSHEET.	Works in progress. Review at next audit.
11	6	20191218/10	P Allen and C Dowson should provide evidence of in date first aid training.	Completed. Closed.

12	6	20191218/ 11	The updated ventilation systems policy should be ratified and published.	Completed in Feb 20. Closed.
13	6	20191218/ 12	Further work should be done to populate the competences of contractors in the documents register on SMARTSHEET (Correct Air Solutions, ATLAS etc).	Completed, Closed.
14	12	20191218/ 13	Care should be taken to ensure that permits to work are correctly issued and cancelled. Strike through boxes and signatures were missing in multiple permits.	The standards of permits has improved significantly with most AP's issuing these documents during the audit period. Closed.
15	12	20191218/ 14	Risk assessments for maintaining/working on LEV's that present a hazard to the maintainer should be produced.	A risk assessment is now held on the estates shared drive. Closed.
16	6	20191218/ 15	Access to the electronic VDR should be restricted to APs and the compliance team.	The documents register is the process of being transferred to SMARTSHEET. Review at next audit.
17	6	20191218/ 16	A register of all LEV's, split AC's, ACBs and FCU's should be collated and maintained by the CAP.	Schedules are now held on the shared drive. Closed.
18	6	20191218/ 17	The ventilation serving the MRI suites should be subjected to annual performance verification.	Completed in Jan 20. Closed.
19	6	20191218/ 18	All magnehelic gauges and manometers should be fitted with clean/dirty filter indication labels.	Works in progress. Review at next audit.
20	6	20191218/ 19	Care should be taken by CP's when completing 40 point checks. The guidance provided in the CP course notes and SHTM03/01 Pt B should be followed.	Works in progress. Review at next audit.
21	12	20191218/ 20	The quality of maintenance at the Neurology level 2 roof AHU plant space should be addressed. The following issues should be rectified: 1. The AHU externals should be cleaned, primed and painted to prolong the life and prevent ingress of contamination. 2. The duct flexible connections between AHU sections should be repaired. (This should be surveyed for asbestos). 3. The roof flooring should be cleaned of algae and vegetation below the AHU and around the intakes. 4. The intakes should be cleaned and repaired to remove corrosion. 5. Small areas of internal corrosion should be removed and treated.	The plant in this area has been subjected to upgrades in situ to rectify. Well done. Closed.

22	12	20191218/ 21	Where steam humidification is fitted to AHUs but not used it should be physically disconnected at the AHU and ideally stripped back to the running main.	A survey should be conducted to identify all areas requiring this action. Review at next audit.

1. Management Policy			
	Y/N	Comments	
Is there a Board Ventilation Safety Policy In place?	Y	NHS GG&C Ventilation Policy dated 21/02/20 was held on SMARTSHEET policies.	1
Is the Ventilation Safety Policy approved at Board level?	Y	Approved by the SCART group.	1
Is the Board Ventilation Safety Policy reviewed periodically?	Y	Last reviewed Feb 20.	1
Is the Board Ventilation Safety Policy a controlled Document?	Y	Held securely on SMARTSHEET.	1
Are the Duty Holder (V) responsibilities clearly defined in the Policy?	Y	No significant issues identified.	1
Is the Designated Person appointed in writing?	N	No written appointment was available.	5
Does the Board Ventilation Safety Policy include emergency procedures?	N	Emergency procedures are not included.	5
Have the emergency procedures been validated or tested during the current audit period?	N/A	See above.	
Has the Authorising Engineer (AE) (V) appointment been correctly made and is it in date?	Y	No significant issues identified.	1
2. Authorised Persons (V)			
	Y/N	Comments	
Are all APs (V) currently certified?	Y	5 APs are now appointed with 1 due appointment and 4 AP's designate in training/mentoring.	1
Are the APs (V) due for refresher training in SHTM 03-01?	N	No issues found.	1

Are the APs (V) due for training in emergency first-aid?	N	All appointed AP's were in date for first aid training.	1
Are the APs (V) carrying out AP (V) duties on a regular basis?	Y	Ap's are actively involved in the day to day operational management of ventilation systems at QEUH.	1
Are the APs (V) formally monitoring the work-in-progress and are they recording their observations?	Y	CP work is monitored by APs using the permit to work system.	1
Is the provision of APs (V) adequate?	Y	Once AP's are appointed to cover shift patterns the provision of staff will be adequate.	1
3. Competent Persons (V)			
	Y/N	Comments	
Have the NHS CPs (V) been formally assessed and appointed by an AP (V)?	Y	10 in house CPs have been assessed and appointed in writing by J Guthrie. Records are held on SMARTSHEET and in the shared drive.	1
Is evidence of the competency of Contractor CPs (V) held in the Document Register?	Y	Good evidence was held for Correct Air Solutions, FREWS, H&V and Livingston Mechanical in the estates shared drive.	1
Are the roles and responsibilities of Contractor CPs (V) defined in writing?	Y	Verification reports produced by H&V and Correct Air Solutions detail the scope of works.	1
Are records held in the Document Register of the site induction for the Contractor CPs (V)?	Y	The GG&C Contractor Control & Permit Register includes the issue of an identity card that listed the fundamental site rules and procedures.	1
Is there an up to date Register of CPs (V) appointed for the Trust included in the Document Register?	Y	A register is held on SMART sheet.	1
Are the NHS CPs (V) carrying out their duties on a regular basis?	Y	In-house CPs and contractor CPs had been carrying out duties on a regular basis.	1
4. Incidents, Accidents and Dangerous Occurrences			
	Y/N	Comments	
Sine the last audit has the site been free from any accidents, incidents, dangerous occurrences or "near misses" in connection with the ventilation systems?	Y	None reported.	1
Have the details of incidents, accidents or dangerous occurrences been properly recorded and reported?	N/A	Not applicable.	
5. Safety Documentation			
Job	2112	Originating AP (V):	J Guthrie
		Y/N	Comments
Was there a suitable & sufficient Risk Assessment to cover the work undertaken?	Y	Risk assessment for the maintenance of Air Handling Equipment in plantroom 41 was held and dated 17/12/19. SOP held for occupied cortical area ppm procedure 17/7/19.	1

Was the permit-to-work completed by the AP (V) specifying the work to be carried out?	Y	J Guthrie is formally appointed.	1
Was the permit-to-work signed by the User (V) to allow the work to proceed?	Y	Signed by L Bleasdale.	1
Was the permit-to-work issued to a CP (V)?	Y	Issued to S Gilmour (NHS CP) details are in the shared drive.	1
Was the permit-to-work cleared by a CP (V) and did they state that system was fit or unfit for use?	Y	No issues found.	1
Was the permit-to-work cancelled by an AP (V) and did they acknowledge that the system was fit or unfit for use?	Y	No issues found.	1
Did the User (V) acknowledge that the system should or should not be brought back into use?	Y	Signed by L Bleasdale.	1
Were the site records up-dated on completion of the work?	Y	No issues found.	1
5. Safety Documentation			
Job	2127	Originating AP (V): Y/N	M McKaig Comments
Was there a suitable & sufficient Risk Assessment to cover the work undertaken?	N	No risk assessment by Correct Air Solutions was witnessed.	12
Was the permit-to-work completed by the AP (V) specifying the work to be carried out?	N	Mark McKaig AP is appointed.	1
Was the permit-to-work signed by the User (V) to allow the work to proceed?	Y	Signed by Ian Thomson.	1
Was the permit-to-work issued to a CP (V)?	Y	Signed by Sharon McLaughlan. Correct air solutions. Evidence of competence held in shared drive.	1
Was the permit-to-work cleared by a CP (V) and did they state that system was fit or unfit for use?	Y	No issues found.	1
Was the permit-to-work cancelled by an AP (V) and did they acknowledge that the system was fit or unfit for use?	Y	No issues found.	1
Did the User (V) acknowledge that the system should or should not be brought back into use?	Y	Signed by Ian Thomson.	1
Were the site records up-dated on completion of the work?	Y	Verification documents were provided within 24 hours.	1
6. Operating Records			
General	Y/N	Comments	
Are the ventilation operating record documents kept in a secure location?	Y	There is an electronic VDR held on the shared S drive. Access should be restricted to APs and the compliance team. Each critical system has a hard file log book held securely in the supervisors office.	6

SHTM 03-01 SPECIALISED VENTILATION FOR HEALTHCARE PREMISES

Page 184

Do the APs (V) have access to copies of relevant SHTMs and other reference documents?	Y	An electronic copy was held.	1
Does the Document Register index include all of the subjects required by SHTM 03-01?	Y	A comprehensive file structure is held in the shared drive.	1
Is the working Ventilation Document Register periodically reviewed and out-of-date information transferred to the archive Ventilation Document Register?	Y	The VDR is well maintained by the CAP.	1
Is there a schedule of ventilations systems detailing which are critical, non-critical or LEVs?	Y	Good registers are maintained for critical and non-critical AHU. Information is held for LEVs, split AC's and FCU/chilled beams. These should be collated into a master schedule.	6
Are adequate technical drawings available to the APs?	Y	Technical drawings are held on Zutec. Can be difficult to navigate.	4
Are adequate O&M manuals available to the APs?	Y	O&M information was held electronically (Zutec) and on the shared drive for the Adult & Children's and the Lab Block. Original O&M information for the retained estate maternity theatres was reported to be held.	4
Are all of the ventilation systems included in the Trust's planned maintenance programme?	Y	FM first is now in place to schedule maintenance and hard check sheets are retained in the theatre files.	1
Are the planned maintenance records suitable, sufficient and accessible to the APs?	Y	Maintenance is recorded on FM first and 40 point checks are held in hard copy in each ventilation file.	1
Are the results of the Trust's planned maintenance programme formally reviewed annually to establish trends and gaps? Are these reviews recorded?	N/A	Not checked.	
Inspection and Verification			
	Y/N	Comments	
Are critical ventilation systems being inspected quarterly?	Y	PPM files were held for all critical AHU. Monthly and quarterly checks were retained. At the time of audit some filing needs to be completed but on the whole satisfactory.	1
Are non-critical systems being inspected annually?	Y	PPM files were held for all non critical AHU. Monthly and annual checks were retained.	1
Are critical ventilation systems being verified annually?	Y	All identified critical ventilation systems have been verified within the last 12m.	1

Are the inspections and verifications being recorded as per SHTM 03-01, Part B, Appendices 1 & 2 and the records retained in the Ventilation Documents Register?	Y	Good records are now held in the log books in the Supervisors office.	1
Are the main components in AHUs serving critical and non-critical areas being cleaned annually?	Y	Records retained with the annual inspections in the log books.	1
Are the fire dampers being tested annually?	N	Fire dampers were not subject to annual testing in the A&C hospital. All retained buildings have been surveyed and tested this year. Remedial works are now required to complete this area.	20
Are the LEV systems being examined and tested by a competent person at least every 14 months?	Y	All Lab Block safety cabinets and fume cupboards and the Mortuary dissection tables have had COSHH LEV performance tests carried out in the past 14 months. Records were held by Estates. A register of all LEVs was held on the shared drive.	1
Are critical systems that are unable to meet the required standards being taken out of service after receipt of condemnatory reports?	Y	All critical AHU's verified in the last 12 months are performing to the required standard. Immediate reports are given to estates before Correct air Solutions leave site allowing problems to be rectified in the shut down period. A process is documented in an SOP in the shared drive.	1
7. Safety Equipment & Access Control			
	Y/N	Comments	
Do the APs (V) have sufficient isolation safety devices for the likely number of concurrent jobs?	Y	Adequate safety devices were held at the hospital.	1
Do the APs (V) have sufficient safety signage for the likely number of concurrent jobs?	Y	Adequate safety signs were held at the hospital.	1
Do the NHS CPs (V) have sufficient safety devices and signs for their routine work?	N/A	Not checked.	
Are records available of annual NHS safety and protective equipment inspections by an AP (V)?	Y	PPE toolbox talk records are held.	1
Do all NHS test instruments have in date calibration certificates?	N	None held	1
Have contractors provided in-date calibration certificates for all of their test instruments and safety equipment?	Y	Copies of calibration certificates were provided for the test instruments used by Correct Air Solutions who carry out annual verifications.	1
Is there an effective and auditable system for the control of plant room access in use?	Y	An access control procedure was held in the document register.	1

8. Engineering Systems		Visited Maternity Hospital Level 3 Plant Room AHU 9 Serving Theatre 2	
Air Handling Units (AHUs)	Y/N	Comments	
Is each AHU clearly and uniquely labelled and does this label exactly correspond to the AHU Register?	Y	A clear label was affixed to the end of the AHU. Including area served.	1
Is the general condition of each AHU satisfactory?	Y	The general condition of the AHU is assessed as fair to poor.	1
Is the AHU constructed according to the principles in SHTM 03-01, Part A, Figure 1?	Y	The basic fundamentals have been followed.	1
Are the automatic controls fitted to critical systems capable of being overridden in the event of a software failure?	Y	Local control panel with ability to switch to hand. The panel light functions could not be checked.	1
Are fresh air intakes sited correctly, constructed correctly and are access hatches or hinged louvres installed?	N	A fine mesh vermin screen was fitted and completely clogged. Evidence of rain water ingress was witnessed corroding the exhaust ductwork and tracking into the AHU.	12
Are drainage systems installed for wet components and are the drainage systems properly constructed?	N	Insufficient air gaps and dirty traps were observed.	8
Are belt driven fan drives situated outside of the air stream?	N	No issues found.	1
Is there adequate access around the AHU and are access doors provided for all major components?	N	Items of waste material were stacked against the AHU obstructing access to the VSD's.	8
Are inspection windows and internal lights provided for cooling coils and filters?	Y	Those checked.	1
Are the filters the correct grade and correctly fitted to minimise bypass?	N	The pre-filters were showing evidence of failure in situ.	8
Are the filters provided with a means of checking the differential pressure across them?	N	No means provided for the pre-filter.	8
Is the direction of air flow clearly marked on all main and branch ducts?	Y	Printed identification labels were fitted.	1
Are all air flow test-points properly located, clearly identified and is the size of the duct provided at each point?	N	Not found. These should be located and labelled.	6
9. Engineering work spaces Maternity Hospital Level 3 Plant Room			
Plant room externals	Y/N	Comments	
Is there a legible and secure safety sign displayed at the entrance to the plant room?	Y	No issues found.	1

Is the name of the plant room exactly the same as the AHU Register?	Y	No issues found.	1
Is the correct contact telephone number shown?	N/A	Not applicable.	

Plant room security		Y/N	Comments	
Is the door soundly made and kept secure?	Y	No issues found.		1
Is there an emergency escape door and can it be opened from the inside?	Y	No issues found.		1
Is there a clear escape route outside the plant room?	Y	No issues found.		1
Are adequate emergency communications systems available?	Y	Staff entering plant rooms carry either a mobile telephone or PDA.		1
Is the plant room free from any unauthorised items stored within?	N	Waste materials stored within and workshop for Medical Gas repairs.		6
If so, are the access arrangements to the plant room adequately controlled?	N/A	Not applicable.		
Plant room structure				
Is the plant room structure and condition satisfactory?	N	Extract plenums were leaking rainwater.		12
Are posters and drawings displayed as required?	Y	No issues found.		1
Fire Precautions		Y/N	Comments	
Is the plant room free from combustion equipment?	Y	No issues found.		1
Is the plant room free from rubbish or fire hazardous materials stored inside or immediately outside the plant room?	N	Waste timber and scrap material though stored out of escape routes.		6
Is there at least one suitable fire extinguisher provided in the plant room and has it been inspected in the last 12 months?	Y	All fire extinguishers checked were serviced in April 2018.		8

I confirm that, where actions are required, a report has been submitted to the Designated Person

SCART Risk Grades	
	Very High
	High
	Medium
	Low

UPDATED ACTION PLAN

Serial	Rating	Reference	Action Required	Responsible Person	Date due
Action points carried forward from previous audit					
1	20	141208/40	Test fire dampers in accordance with SHTM 03-01, Part B, Para 4.13.	DP	TBC
2	8	151209/17	Fit access hatches to all AHU intake ductwork sections to allow inspections.	Lead AP	16-Dec-21
3	12	20191218/03	A PTW should be used when taking critical systems out of use at all times. The 110 permits issued since 18/12/19 is not representative of the work carried out.	AP's	NTQ
4	12	20191218/04	Due to the size and scale of the systems a QEUH Campus it is recommended that at least 1 AP(V) is trained and appointed on each shift to cover shift work.	DP	16-Dec-21
5	6	20191218/05	The information held in the shared drive documents register should be linked to SMARTSHEET if possible.	Compliance Manager	16-Mar-21
6	6	20191218/06	The designated person should be appointed in writing by the duty holder.	DP	16-Mar-21
7	6	20191218/09	Further work should be done to populate the competences of APs in the documents register on SMARTSHEET.	Compliance Manager/CAP	16-Mar-21
8	6	20191218/12	Further work should be done to populate the competences of contractors in the documents register on SMARTSHEET (Correct Air Solutions, ATLAS etc).	Compliance Manager/CAP	NTQ
9	12	20191218/13	Care should be taken to ensure that permits to work are correctly issued and cancelled. Strike through boxes and signatures were missing in multiple permits.	AP's	NTQ
10	6	20191218/15	Access to the electronic VDR should be restricted to APs and the compliance team.	AP	16-Mar-21
11	6	20191218/18	All magnehelic gauges and manometers should be fitted with clean/dirty filter indication labels.	AP's	16-Dec-21

12	6	20191218/ 19	Care should be taken by CP's when completing 40 point checks. The guidance provided in the CP course notes and SHTM03/01 Pt B should be followed.	CP's	NTQ
13	12	20191218/ 21	Where steam humidification is fitted to AHUs but not used it should be physically disconnected at the AHU and ideally stripped back to the running main.	AP's	16-Mar-21
Action points from this audit					
14	8	20201216/ 01	The risk assessments for working on ventilation systems should include Covid19 as a hazard and appropriate mitigation included.	AP's	ASAP
15	12	20201216/ 02	The fine mesh vermin screens in the Maternity Hospital Level 3 Plant room should be replaced with appropriate sized (6-12mm) mesh.	AP's	16-Mar-21
16	12	20201216/ 03	The rainwater leaking into AHU 9 exhaust at Maternity Hospital Level 3 Plant room should be investigate and rectified as necessary.	AP's	16-Mar-21
17	8	20201216/ 04	The AHU pre-filters in the Maternity Hospital Level 3 Plant room should be provided with a means to observe the differential pressures.	AP's	16-Jun-21
18	16	20201216/ 05	The services preventing the removal of AHU cooling coil drip trays in the Maternity Hospital Level 3 Plant room should be moved to allow inspection and cleaning of this critical area.	AP's	ASAP
19	8	20201216/ 06	Ap's should ensure contractors provide risk assessments for all works prior to issuing safety paperwork.	AP's	NTQ

SOP Objective

To ensure that patients are cared for in the appropriate area in order to minimise the risk of cross-infection, and to protect immune compromised patients from environmental infection.

This SOP applies to all staff employed by NHS Greater Glasgow & Clyde and locum staff on fixed term contracts and volunteer staff.

KEY CHANGES FROM THE PREVIOUS VERSION OF THIS GUIDANCE

- Addition 2A RHC and 4B QEUH.

1. Responsibilities

Health Care Workers (HCW) must:

- Follow this SOP.
- Follow the advice of the Infection Prevention Control Team (IPCT)
- Escalate to line manager if they are unable to follow this SOP.

Managers must:

- Support HCWs in following this SOP.
- Cascade new policies/SOPs to clinical staff.

Infection Prevention and Control Teams must:

- Keep this SOP up-to-date.
- Provide education opportunities on this SOP.

Facilities / Estates Teams must:

- Carry out verifications on all rooms annually or following any works carried out on the room.
- Keep up-to-date verification records.

2. General Information on Specialist Ventilation

Across NHS Greater Glasgow and Clyde there are a number of specially ventilated rooms designed to protect patients within the healthcare environment from potentially harmful pathogens. The tables below provide a list of wards and rooms on each of the main hospital sites, indicating the type of ventilation and filtration available in each. This will direct staff to the correct placement of patients who are suspected or confirmed to have an airborne or high consequence infectious disease, as well as airborne protective isolation for immune compromised patients. Below is a description of what each type of ventilation means, while Table 1 should be used to guide staff to the type of patient that can be safely cared for in each.

What is a Positive Pressure Ventilated Lobby (PPVL) Room? (HEPA filtered air)

A PPVL room has a flow of air from the lobby which moves into the main room. The contaminated air is extracted via a vent in the en suite toilet when one is available. In all instances in QEUG and RHC there is an additional extract in variable locations in the ceiling of the patient room. The lobby itself is positively pressurised to both the patient's room and the outer corridor providing a barrier between the patient within the room and the surrounding ward. This movement of air effectively prevents infection spreading between the room and the surrounding ward. Some PPVL rooms have an air supply to the lobby via a filter (HEPA filter) providing some further protection for patients who are immunosuppressed within the room. It is important to keep the door to the main room and to the lobby closed when not in use to ensure that this flow of air is maintained. The pressure on the gauge from corridor to lobby should read +8 to +12 PA.

What is a Negatively Pressured Room?

A negative pressure room has a flow of air which moves from the corridor into the room preventing the escape of room air to the surrounding ward. The ventilation within the room is such that it dilutes any airborne pathogens which are circulating. The room provides a negative air flow / 'cascade' from ward corridor to lobby, and lobby to isolation room, whilst allowing control of room temperature. The room is validated for 10 air changes per hour within an isolation room and a pressure differential of -8Pa to -10Pa in relation to the corridor. It is important to keep the door to the main room and the lobby closed when not in use to ensure that this flow of air is maintained.

What is a Bone Marrow Transplant (BMT) Room?

BMT rooms are reserved for use by those patients who are highly susceptible to infection, for example, those undergoing bone marrow transplant. The air supply to the room is via a filter (HEPA filter) to further provide protection to the vulnerable patient within the room from external airborne pathogens such as fungi. These rooms are currently only located within Ward 2A Children Hospital and also Ward 4B in the QEUG, and are reserved for use by BMT patients.

3. Room Types

Type of Room	Patient allocation / suitability
PPVL with Lobby HEPA	Immunosuppressed patients, i.e. Haem-onc patients, should be prioritised for these rooms
	Immunosuppressed with chickenpox / measles
	Patients with Atypical Mycobacteria
	Patients with infections (non-airborne route)
Negative pressure	Chickenpox, Measles, Pathogens of High Consequence
	Tuberculosis (incl MDRTB and XDRTB) Prioritise airborne infection
BMT Rooms	Bone Marrow Transplant patients These are located in specialist units: QEUH 4B RHC 2A

The most up-to-date version of this guidance can be viewed at the following web page:

The most up-to-date version of this guidance can be viewed at the following web page: www.nhsggc.scot/hospitals-services/services-a-to-z/infection-prevention-and-control			

4. Signage

Patient bedrooms with specialist ventilation will have a sign at the door indicating the specific ventilation afforded by that particular room. The signs will be one of the following (QEUH):

Negative Pressure Isolation Room

Pressure gauge should be between
-8Pa & -12Pa

If the positive side of the gauge is out of range please contact estates department
Help desk 5555

HEPA FILTERED PPVL Isolation Room

Pressure gauge should be between
+8Pa & +12Pa

If the positive side of the gauge is out of range please contact estates department
Help desk 5555

These templates only and should be modified for local use.

Guidance Objective

To ensure that patients suspected of or confirmed to have tuberculosis are diagnosed and treated promptly and their contacts followed-up to minimise the risk of cross-infection and identify further cases.

This guidance applies to all staff employed by NHS Greater Glasgow & Clyde and locum staff on fixed term contracts and volunteer staff.

KEY CHANGES FROM THE PREVIOUS VERSION OF THIS GUIDANCE

- Updated definition of XDR-TB
- Minor wording changes
- Updated references and links

1. Responsibilities

Healthcare Workers (HCWs) must:

- Follow this guidance.
- Wear Personal Protective Equipment (PPE) and respiratory protection if advised to do so.
- Inform a member of the Infection Prevention Control Team (IPCT) if this policy cannot be followed.

Managers must:

- Ensure HCWs have access to this guidance.
- Support HCWs and IPCTs in following this guidance.
- Ensure HCWs are aware how to use respiratory protection and have access to effective equipment and are fit tested.

Infection Prevention and Control Teams (IPCTs) must:

- Keep this guidance up-to-date.
- Provide education opportunities on this policy.
- Take the lead role in conjunction with the ward manager, consultant in charge and microbiologist to identify In-patients who have had sufficient exposure to the index case to merit screening.
- If HCW unable to follow this guidance, IPCT will support staff to carry out a risk assessment

Clinicians must:

- Notify Public Health of any newly diagnosed patient.
- Notify the TB Liaison Nurse of any newly diagnosed patients.
- Assess inpatient contacts of smear positive patients and liaise with GP and TB liaison

TB Liaison Nurse:

- Liaise with Clinicians, Infection Prevention and Control and CPHM.
- Identify community contacts promptly and arrange appropriate screening.
- Take a leading role in advising and informing the patient and the patient's contacts in the community for the duration of therapy.
- Liaise with Occupational Health regarding the provision of information and advice to staff exposed to a patient with smear/ sputum positive TB.

Occupational Health:

- Take the lead role in identifying, advising and informing staff exposed to a patient with smear positive pulmonary TB and arrange appropriate screening as required.

2. General Information on Tuberculosis

Communicable Disease/ Alert Organism	Tuberculosis is a disease caused by infection with the <i>Mycobacterium tuberculosis</i> complex of organisms (<i>M. tuberculosis</i> , <i>M. Bovis</i> , <i>M. Africanum</i> and <i>M. Micoti</i>) which may cause pulmonary and/ or non- pulmonary tuberculosis.
Clinical Condition(s)	Pulmonary and laryngeal TB both require the respiratory precautions set out in this guidance. From this point both these forms of TB will be referred to as pulmonary TB For respiratory granuloma without cavity standard infection control precautions are recommended.
Definitions	<u>TB Infection</u> : defined as the bacteria having caused an immune reaction with no evidence of disease. <u>TB Disease</u> : the patient has symptoms or clinical evidence of disease. Sputum smear positive = infectious Sputum smear negative = low infectivity risk
Mode of Spread	Airborne: The infectious particles are very small droplets (1-5µ) containing tubercle bacilli expelled during talking, singing but especially coughing, and inhaled by susceptible individuals.
Incubation period	2-8 weeks to cause an immune reaction. May be many years before disease develops.
Notifiable disease	Yes. It is the clinician's responsibility to notify the Public Health Protection Unit (PHPU), Gartnavel Royal Hospital (West House, 1055 Great Western Road, Glasgow G12 0XH. Notification may also be by the Pathologist. NB notification (not confirmed) is on suspicion – usually considered to be equivalent to initiation of therapy. Telephone PHPU - 0141 201 4917 (64917)
Persons most at Risk	- Individuals whose cumulative exposure time is more than 8 hours to a sputum smear positive patient. - Those who have immunodeficiency for any reason.

	NHS GREATER GLASGOW & CLYDE CONTROL OF INFECTION COMMITTEE	Page	Page 209
		Effective From	June 2021

3. Transmission Based Precautions

Accommodation	• Suspected TB: single-room is required for all patients thought to have pulmonary tuberculosis until the patient has 3 smear negative sputum/bronchial alveolar lavage specimens or in the case of a child, negative gastric washings. • Sputum smear positive TB: if possible, place patient in a negative pressure single room (where available) until 14 days of appropriate tolerated drug treatment and there is definite clinical improvement on treatment; for example, absence of cough, remaining afebrile for a week The patient may be discharged before the 14 days. • Confirmed Multi-Drug Resistant TB: negative pressure in a single room with an en suite is mandatory for those patients with, or suspected of having pulmonary multi-drug resistant (MDR-TB, XDR-TB) until discharge from hospital. Patients who have had sputum smear positive TB and have had 14 days adequate therapy and are improved must not on release from isolation be placed next to HIV positive or other immunocompromised patients, if remaining in hospital. Where possible they should be on a separate ward from such patients. If the patient is clinically unsuitable to be placed in a single room or door cannot remain closed, a risk assessment must be undertaken by the clinical team. The risk assessment should be documented and reviewed daily. • If XDR TB/MDR TB, isolations should continue until discharge.
Care Checklist available	Yes.
Clinical / Healthcare Waste	Waste should be designated as clinical/ healthcare waste and placed In an orange bag. Please refer to the NHSGCC Waste Management Policy .

	NHS GREATER GLASGOW & CLYDE CONTROL OF INFECTION COMMITTEE	Page	Page 210
		Effective From	June 2021
	TUBERCULOSIS Guidance (INCLUDING MULTI-DRUG RESISTANT TB)	Review date	June 2023
		Version	9
The most up-to-date version of this guidance can be viewed at the following web page: www.nhsggc.scot/hospitals-services/services-a-to-z/infection-prevention-and-control			

Contact tracing	The TB Liaison Nurse will assess all community contacts of the patient. Working with the TB Liaison Nurse, the IPCT, microbiologist and senior ward staff will assess if any other patients have had sufficient exposure during the patient stay (>8hours close contact with a sputum smear positive patient). In paediatrics resident parents/guardians must be assessed. For hospital patient contacts, the clinician in charge of the patient must ensure follow up with the patients either via their GP or with the assistance of the HPN/TB liaison. Any hospital patient contacts will also be informed of any relevant subsequent action. The Immediate Discharge Letter must be completed at the time of discharge and include details of planned screening and follow up after discussion with the TB liaison nurse.(8 weeks after exposure)
Discharge Planning	A treatment plan and follow up must be arranged prior to discharge and discussed with TB liaison and any relevant carers. Arrangements must be in place for accommodation, necessary support, and supervision of therapy. It is important to communicate the infectious status of the patient to clinical teams and precautions required when arranging follow up clinic or community visits. If the patient self-discharges or absconds from the ward and is still considered to be an infection risk contact the CPHM via 0141 201 4917 (64917). The TB Liaison nurse should also be informed
Drug Resistance	All patients with, or suspected of having TB must be assessed for risk of drug resistance by a respiratory /ID consultant. This is done by identifying on admission if the patient has had: • previous treatment for tuberculosis, • previous history of poor compliance with TB treatment • contact with a person with known drug resistant disease • History of travel to a country with high risk of MDR TB http://www.who.int/tb/publications/global_report/en/ Discuss with microbiology about rapid molecular testing and fast track of samples to the TB reference lab and during therapy monitoring for: • Failure of clinical response, e.g. temperature remains elevated after 4 months. If the patient is suspected of having MDRTB then until confirmed otherwise the procedures for multi-drug resistance will be followed.

	NHS GREATER GLASGOW & CLYDE CONTROL OF INFECTION COMMITTEE	Page	Page 211
		Effective From	June 2021
	TUBERCULOSIS Guidance (INCLUDING MULTI-DRUG RESISTANT TB)	Review date	June 2023
		Version	9
The most up-to-date version of this guidance can be viewed at the following web page: www.nhsggc.scot/hospitals-services/services-a-to-z/infection-prevention-and-control			

	MDR TB - TB that is resistant to at least isoniazid and rifampicin XDR TB - TB caused by M. tuberculosis strains that fulfil the definition of MDR/Rifampicin Resistant-TB and which are also resistant to any fluoroquinolone and at least one additional group A drug. Group A drugs are the most potent group of drugs in the ranking of second-line medicines for the treatment of drug-resistant forms of TB, using longer treatment regimens and comprise levofloxacin, moxifloxacin, bedaquiline and linezolid.
Equipment	No special requirements provided equipment is decontaminated as per NHSGGC Decontamination Guidance .
Exposures	The primary measure to reduce exposure in healthcare settings are; early diagnosis, early isolation, appropriate application of TBPs and early commencement of appropriate therapy. All HCWs who have been involved in the care of a sputum smear positive patient with pulmonary Tuberculosis prior to infection control precautions being instigated who have had 8 or more hours close contact with the index case, or who are immunocompromised will be referred to the Occupational Health Service (OHS).
Hand Hygiene	See NHSGGC Hand Hygiene Guidance
Last Offices	Special precautions are required for Last Offices. See National Guidance for Last Offices .
Moving between wards, hospitals and departments (including theatres)	If possible avoid unnecessary movement of patient until therapy has been established. If movement is necessary, for smear positive adult patients within the first 14 days of therapy, ask the patient to wear a fluid repellent surgical mask. Notify the receiving department.
Notice for Door	Yes, if patient is isolated a yellow IPC sign should be placed on door. NB Keep door closed until restrictions are lifted.
Outbreak	Unlikely in hospital settings provided infection control precautions are followed.
Patient Clothing	No special requirements. Advise relatives that there is no risk from washing the patient's clothes at home. See NHSGGC Washing Clothes at Home Leaflet

	NHS GREATER GLASGOW & CLYDE CONTROL OF INFECTION COMMITTEE	Page	Page 212

		Version	9
The most up-to-date version of this guidance can be viewed at the following web page: www.nhsggc.scot/hospitals-services/services-a-to-z/infection-prevention-and-control			

Personal Protective Equipment (PPE)	HCWs caring for patients with suspected of or confirmed (sputum smear positive) tuberculosis, a yellow disposable apron, disposable gloves and a face fit tested FFP3 mask must be worn for both routine care and when undertaking aerosol generating procedures (AGP's) Where there is an identified risk of splashing of blood and or body fluids into the mucous membranes of the eyes, suitable eye protection must also be worn. All PPE should be kept on for up to 2 hours after an AGP if remaining in the patient's room, and the FFP3 mask should be removed outside the room. Once the patient has had 14 days of treatment and shown signs of clinical improvement following review by medical staff and a risk assessment carried out, PPE can be discontinued. For full list of AGPs see Appendix 11 NIPCM Footnote 3 https://hpspubsrepo.blob.core.windows.net/hps-website/nss/3032/documents/1_nipcm-appendix-11.pdf For PPE information: https://hpspubsrepo.blob.core.windows.net/hps-website/nss/3037/documents/1_nipcm-appendix-16.pdf For suspected and confirmed MDR TB/ XDRTB: PPE should be worn as above. https://www.nhsggc.org.uk/working-with-us/hr-connect/health-safety/policies-guidance-documents-forms/personal-protective-equipment/respiratory-protection-equipment-ffp3-masks/

Precautions Required Until	Sputum Smear positive not MDR TB / XDR TB: • had a minimum of 14 days appropriate therapy, which has been tolerated e.g. no diarrhoea or vomiting and patient has been fully compliant • Definite clinical improvement as a response to therapy, e.g. cessation of cough Seek the advice of a member of the IPCT before removing a patient from isolation. Once removed from isolation keep the patient under review. Return to isolation if they deteriorate clinically. Pulmonary MDR TB: For duration of stay Pulmonary XDR TB: For duration of stay Discuss all cases of MDR or XDR TB with infection specialist / ICD. Smear negative / Suspected TB: Three separately taken microscopy sputum smears /gastric washings. (ideally early morning and taken on consecutive days). Samples should be sent for both <u>smear</u> and <u>culture</u> Extra-pulmonary TB: Pulmonary disease must be excluded before transmission based precautions are stopped. Unless TB lesions draining, in which case SICPs should be followed.
---------------------------------------	---

	NHS GREATER GLASGOW & CLYDE CONTROL OF INFECTION COMMITTEE	Page	Page 214
		Effective From	June 2021
	TUBERCULOSIS Guidance (INCLUDING MULTI-DRUG RESISTANT TB)	Review date	June 2023
		Version	9
The most up-to-date version of this guidance can be viewed at the following web page: www.nhsggc.scot/hospitals-services/services-a-to-z/infection-prevention-and-control			

Procedure Restrictions	- Sputum and cough inducing procedures should be undertaken by HCWs wearing full PPE as above in a single / negatively-pressurised room with the door closed. HCW should continue to wear their PPE for up to 2 hours following an AGP. Each area will differ depending on air exchanges. Discuss with ICD if not known. - Patient procedures to reduce aerosolisation of droplet nuclei: patients should be taught to cover both the nose and mouth with a tissue whenever they cough or sneeze; - In-patients should be asked to wear fluid repellent surgical masks if they are required to leave their room, until they have had 14 days of appropriate tolerated drug treatment and shown clinical improvement. - Bronchoscopy's in those suspected of Pulmonary TB should be done last with adequate ventilation as above. Bronchoscopy suites managers should be aware of the number of air exchanges and the duration of time required before staff and other patients can re-enter the area.
Referral	All patients suspected of having TB should be referred to a Respiratory Physician or Infectious Diseases Physician before commencing TB treatment. Microbiologist to inform the clinician by telephone of positive smear results.
Risk assessment	- For patients with extra-pulmonary disease the transmission based precautions in this guidance must be followed until pulmonary involvement can be ruled out. - Young children are broadly considered to be paucibacillary and unlikely to be of high infectivity risk. TBP in paediatric inpatients will require a case by case risk assessment.
Screening on Admission	Pulmonary tuberculosis should be considered in any patient with an unexplained cough lasting more than three weeks, with or without weight loss, anorexia, fever, night sweats or haemoptysis. They should usually have three separate sputum samples sent to the laboratory and a chest X-Ray. These specimens should be marked 'URGENT' and AAFB requested in addition to culture. Patients whose history is indicative of pulmonary tuberculosis on admission should be isolated as stated in the <i>Accommodation</i> section.
Terminal Cleaning of Room	Follow NHSGGC SOP Terminal Clean of Ward/Isolation Room

Visitors	Restrict visitors to contacts who have visited the patient prior to hospitalisation until 14 days after therapy has commenced and tolerated. Children should not be allowed to visit unless exceptional circumstances. Visitors who do not fit the criteria of household contacts should not visit unless under exceptional circumstances when consideration of fit testing should be undertaken. Paediatric patients: It is important to make sure that parents/carers are not themselves infectious with Tb before allowing them to visit/stay in hospital with the child. In the case of suspected or proven pulmonary MDR or XDR TB a plan for visiting should be discussed with the local IPCT in the first instance. If visitors are unwell or have symptoms of TB, they should not visit until assessed by the TB liaison nurse. Those who are immunocompromised should not visit. Visitors should only visit the patient with TB and not other patients.

5. List of AGPs

Aerosol Generating Procedures	During certain healthcare procedures, small particle aerosols may be generated which could increase the risks to HCWs in the immediate vicinity. These aerosol generating procedures include: • Intubation, extubation and related procedures, e.g. manual ventilation and open suctioning. • Cardiopulmonary resuscitation. • Induction of sputum • Bronchoscopy. • Positive pressure ventilation via face mask, e.g. BiPAP, CPAP • High frequency oscillating ventilation • Some Dental procedures (e.g. drilling) • Surgery and post mortem procedures in which high speed devices are used • High flow nasal oxygen

SOP Objective

To provide Healthcare Workers (HCW) with details of the care required to prevent cross-infection in adult patients with known/suspected *Clostridioides difficile* Infection (CDI).

This SOP applies to all staff employed by NHS Greater Glasgow & Clyde and locum staff on fixed term contracts and volunteer staff.

KEY CHANGES FROM THE PREVIOUS VERSION OF THIS SOP

- Updates to wording Section 3. Daily assessment of Severity by Clinical Team

1. Responsibilities

Healthcare Workers (HCWs) must:

- Follow this SOP.
Commence a CDI Care Checklist while patient is symptomatic, update daily and complete the risk assessment for any aspect of transmission based precautions (TBP) for CDI that cannot be implemented

[Clostridioides Difficile – IPC Care checklist](#)

- Inform their line manager and a member of the Infection Prevention and Control Team if this SOP cannot be followed.
- Provide written and verbal information on CDI for patients and their relatives as appropriate

[Clostridioides Difficile Fact Sheet](#)

Senior Charge Nurse (SCN) must:

- Ensure that the IPC Care checklist is in place while patient is deemed infectious.
- Ensure that written information is provided / available for patients and relatives.
- Ensure a failure to isolate risk assessment is in place if any aspect of TBPs for CDI cannot be implemented

Managers must:

- Support HCWs and IPCTs in following this SOP.
- Cascade new SOPs to clinical staff after approval by the Board Infection Control Committee (BICC).

Infection Prevention and Control Teams (IPCTs) must:

- Keep this SOP up-to-date.
- Provide education opportunities on this SOP.

The most up-to-date version of this SOP can be viewed at the following web page:
www.nhsggc.scot/hospitals-services/services-a-to-z/infection-prevention-and-control

- Monitor epidemiology of *Clostridioides difficile* Infection (CDI) within healthcare facility(ies) and advise on infection prevention and control precautions as necessary.
- Advise and support HCWs to undertake a Risk Assessment if unable to follow this SOP.

Occupational Health Service (OHS) must:

- Advise HCW regarding possible infection exposure and return to work issues as necessary

2. General Information on *Clostridioides difficile* Infection (CDI)

Communicable Disease/ Alert Organism	<i>C. difficile</i> is a Gram positive, anaerobic, spore-forming organism implicated in CDI and pseudomembranous colitis (PMC). The overgrowth of the organism within the large intestine and toxin production causes cellular damage and increased fluid accumulation in the gut. <i>C. difficile</i> is part of the normal flora of up to 3% of the adult population and up to 90% of children less than 2 years. Asymptomatic carriage in healthcare patients is relatively common.
Case definition	<i>Clostridioides difficile</i> Infection (CDI) is defined as any patient in whose stool <i>C. difficile</i> toxin has been identified at the same time they have experienced diarrhoea not attributable to any other cause; or from patients whose stool <i>C. difficile</i> has been cultured at the same time as they have been diagnosed with pseudomembranous colitis (PMC). Health Protection Scotland (2017). Mild CDI: associated with mild diarrhoea (3 liquid/loose stools or more frequently than normal) Moderate CDI: associated with a raised WBC count above normal but $<15 \times 10^9$ /L cells , (typically 3 or more loose/liquid stools per day) Severe CDI: when a patient has at least one severity marker including temperature $>38.5^\circ\text{C}$, WBC 15×10^9/L cells, or acute rising serum creatinine ($>1.5 \times$ baseline), or evidence of severe colitis in CT scan/ abdominal X-ray examination, suspicion of PMC, toxic megacolon or ileus.

		Effective From	Jan 2022
	<i>Clostridioides difficile</i> Infection (CDI) Adults	Review Date	Jan 2024
		Version	8
The most up-to-date version of this SOP can be viewed at the following web page: www.nhsggc.scot/hospitals-services/services-a-to-z/infection-prevention-and-control			

	Life-threatening CDI is when a patient has any of the following attributable to CDI: admission to ICU, hypotension with or without need for vasopressors, ileus or significant abdominal distension, mental status changes, WBC $\geq 35 \times 10^9$/L cells or $< 2 \times 10^9$/L cells, serum lactate > 2.2 mmol/l, end organ failure (mechanical ventilation, renal failure). <u>Recurrence</u> is defined as CDI which re-occurs within 2-8 weeks of previous episode, provided symptoms from previous episode resolved after completion of initial treatment.
Clinical Condition	Clinical onset of CDI often occurs when patients are on antibiotics, or within 4 weeks and up to 12 weeks of finishing a course of antibiotics. Patients may be colonised with <i>C. difficile</i> without symptoms. <u>CDI</u> may present with malaise, abdominal pain, nausea, anorexia, watery diarrhoea, low-grade fever, and a peripheral leukocytosis. Colonoscopy reveals a non-specific diffuse or patchy erythematous colitis without pseudomembranes. <u>Pseudomembranous colitis (PMC)</u> Sigmoidoscopy reveals raised yellow/ orange plaques from 2-10mm in size scattered over the colorectal mucosa. Patients with PMC have a more serious illness than CDI. Diarrhoea may also contain blood and mucous. NB: Life-threatening symptoms develop in 1.2-3.2% of patients with CDI. This disease is a very important co-morbidity in frail, elderly patients and can have high in-patient mortality.
Mode of Spread	There is evidence of both direct and indirect spread through the hands of HCWs and patients; and environmental contamination via equipment and instruments, e.g. commodes, bedpans and washbowls. <i>C. difficile</i> produces

	spores which can survive for long periods in the environment. Environmental cleaning is paramount.
<i>Incubation period</i>	Up to 12 weeks.
<i>Notifiable disease</i>	Notifiable under Public Health (Scotland) Act 2008 : Yes
<i>Persons most at risk</i>	Certain persons are at increased risk of acquiring CDI. CDI should be considered in persons with diarrhoea who also have : • Current or recent (within last 3 months) use of antimicrobial agents, in particular cephalosporins, broad-spectrum penicillins, fluoroquinolones and clindamycin • Increased age (over 65 years). • Prolonged stay in healthcare settings. • Serious underlying disease • Surgical procedures (in particular bowel procedures). • Immunosuppression (incl. HIV and transplant) • Use of proton pump inhibitors or H2 antagonists, e.g. omeprazole, lansoprazole, which reduce production of stomach acid.

3. Transmission Based Precautions for CDI

Accommodation (patient placement)	The patient should be placed in a single room, with ensuite or own commode. The door to the room must be closed and a yellow IPCT sign placed on the door. If a single room is unavailable the IPCT will help the clinical team to undertake a risk assessment and advise where to nurse the patient. This must be documented on the CDI Care Checklist. Precautions should continue until the patient has been asymptomatic for 48 hours and bowel movements have returned to normal or, on the advice of a member of the IPCT. Transmission based precautions are not recommended for asymptomatic carriers.
Antibiotics	Antibiotic prescribing should be in accordance with the NHSGGC Infection Management Guidelines. Prescribing should be regularly monitored and feedback should be returned to prescribers as appropriate. • NHSGGC Antimicrobial Prescribing Policies • The Management of Suspected <i>Clostridioides difficile</i> Infection (CDI) in Adults
IPC Care Checklist available	Yes. Clostridioides difficile IPC Care Checklist
Healthcare/Clinical Waste	All non-sharps waste should be designated as Healthcare/Clinical Waste (HCW) and placed in an orange clinical waste bag within the room. Please refer to the NHSGCC Waste Management Policy.
Contacts	Specimens should not be sent from patients deemed to be contacts unless they develop loose stools, where there is no other cause for this.
Domestic Services/Facilities	Domestic staff must follow the NHSGGC Twice Daily Clean of Isolation Rooms SOP. Cleans should be undertaken at least four hours apart
Equipment	

The most up-to-date version of this SOP can be viewed at the following web page:
www.nhsggc.scot/hospitals-services/services-a-to-z/infection-prevention-and-control

	NHS GREATER GLASGOW & CLYDE CONTROL OF INFECTION COMMITTEE STANDARD OPERATING PROCEDURE (SOP)	Page	9 of 18
		Effective From	Jan 2022
	<i>Clostridioides difficile</i> Infection (CDI) Adults	Review Date	Jan 2024
		Version	8
The most up-to-date version of this SOP can be viewed at the following web page: www.nhsggc.scot/hospitals-services/services-a-to-z/infection-prevention-and-control			

	Patient equipment, e.g. commode, BP cuff, washbowl should be allocated to the patient until no longer considered infectious. Consider single-use or single patient use equipment. Commodes should be decontaminated after each use with chlorine based detergent.
Hand Hygiene	Alcohol based hand rub is <u>not</u> effective against CDI: Soap and water must be used for all patients with loose stools. Hand hygiene is the single most important measure to prevent cross infection with CDI. Hands must be decontaminated before and after each direct patient contact, after contact with the environment, after exposure to body fluids and before any aseptic tasks. Patients should be encouraged to carry out thorough hand hygiene.
Health Protection Scotland (HPS) Trigger Tool	The Health Protection Scotland (HPS) Trigger Tool must be completed by the IPCT and Clinical Staff if there are two HAI CDI cases in the same ward in a two week period. IPCNs and ward staff will complete the tool daily until there is no longer a trigger i.e. one or both patients are no longer symptomatic or have been discharged. The following actions will be taken by the IPCT when a trigger is met: - request a terminal clean of the ward at the start of the trigger - advise on enhanced IPC precautions to be in place. - undertake SICPs audit with SCN - hand hygiene audit - ask the antimicrobial pharmacist to review prescribing Findings will be reported to the SCN and ward staff who will liaise with IPC and pharmacy colleagues on any actions required as a result. Following this, should another case of HAI CDI emerge, the IPCT will complete a PAG to determine the requirement for an IMT and ward closure.
Linen	Treat used linen as soiled/infected, i.e. place in a water soluble bag then a clear bag, tied and then into a laundry

The most up-to-date version of this SOP can be viewed at the following web page:
www.nhsggc.scot/hospitals-services/services-a-to-z/infection-prevention-and-control

	NHS GREATER GLASGOW & CLYDE CONTROL OF INFECTION COMMITTEE STANDARD OPERATING PROCEDURE (SOP)	Page	10 of 18

	bag. (Brown bag used in Mental Health areas) Please refer to National Guidance on the safe management of linen.
<i>Moving between wards, hospitals and departments (including theatres)</i>	Except in clinical emergencies, transfer of patients who remain in isolation is not advisable. However, acute receiving units have a high patient turnover and transfer of patients is necessary for effective patient flow and to ensure that patients receive the appropriate care within their specialty. Therefore, receiving areas MUST be informed of the patient's condition and requirement for a single room BEFORE the patient is transferred. Please follow NHSGGC Terminal Clean of Ward/Isolation Rooms SOP
<i>Notice for Door</i>	The yellow IPC isolation sign must be placed on the door to the patient's room. In Mental Health Services (MHS), on advice of IPCT.
<i>Patient Clothing</i>	Whilst patients are symptomatic they should be advised to wear hospital gowns if suitable. If relatives or carers take personal clothing home, staff must place clothing into a domestic water soluble bag then into a patient clothing bag and staff must ensure that a Washing Clothes at Home Leaflet is issued. NB: It should be recorded in the nursing notes that both the advice and information leaflet have been issued.
<i>Patient Information</i>	Inform the patient and / or if relevant, the patient's relative/ carer of their condition and the necessary precautions if required. Answer any questions and concerns they may have. A CDI Fact sheet for patients and their relatives is available to download from the IPCT web page. NB: Record in the IPC Care checklist / clinical notes that the fact sheet has been issued. IPCTs are available to speak to patients and / or relatives / carers if required.
<i>Personal Protective Equipment (PPE)</i>	To prevent spread through direct contact PPE (disposable gloves and yellow apron) must be worn for all direct contact

	with the patient or the patient's environment/equipment. If there is a risk of splashing of blood/body fluids, then facial protection i.e. mask/visor should also be considered. Hand hygiene must be performed using liquid soap and water before donning and after doffing PPE. Alcohol based hand rub is not effective against CDI.
<i>Precautions required until</i>	Precautions should continue until the patient has been asymptomatic for 48 hours and bowel movements have returned to normal or, on advice of a member of the IPCT. If symptoms recur, reinstate precautions immediately, send further specimens and inform a member of the IPCT.
<i>Daily and weekly check by IPCT</i>	IPCNs will check daily (Monday -Friday) on the condition of patients with CDI until TBPs are no longer required and thereafter weekly for 4 weeks.

The most up-to-date version of this SOP can be viewed at the following web page:
www.nhsggc.scot/hospitals-services/services-a-to-z/infection-prevention-and-control

<i>Daily assessment of severity by clinical team</i>	A patient diagnosed with CDI must be reviewed daily by the medical staff regarding fluid balance, electrolyte replacement, nutrition review, and monitoring for signs of increasing severity. Severity assessment (See below) must be scored and documented in the patient notes. Patients must have severity assessment carried out daily by medical staff until patient is asymptomatic for 48 hours and bowel movements have returned to normal. Severity markers include: • Temperature of >38.5°C • Suspicion of PMC, toxic megacolon, ileus • Colonic dilatation in CT scan/ abdominal x-ray >6cm • WBC > 15 x 10⁹ /L cells • Creatinine > 1.5 x baseline National guidance on CDI provides a list of severity markers for severe disease based on consensus and therefore is not exhaustive. A template for severity assessment is available from the IPCT. Please see The Management of Suspected <i>Clostridioides difficile</i> Infection (CDI) in Adults to determine antimicrobial therapy. Clinical cases of CDI In some circumstances the clinical team will treat a patient for CDI because either they have an equivocal result (GDH positive, toxin negative, the patient has <i>C. difficile</i> in their bowel that has the potential to produce <i>C. difficile</i> toxin, however the toxin has not been detected at this time but may cause disease) or without any positive microbiology following assessment of their presentation and symptoms. In these cases severity scores still need to be completed. Referral of severe cases onto Datix is the principle responsibility of IPCTs however if a clinician suspects a severe case of CDI they can also log this onto Datix for review.

<i>Clinical review assessment (CRA) and Reporting of Severe Cases of CDI</i>	A Clinical Review is required if the patient: • has severe or life threatening CDI • was admitted to ITU for treatment of CDI or its complications • had endoscopic diagnosis of pseudomembranous colitis with or without toxin confirmation • had surgery for the complications of CDI (toxic megacolon, perforation or refractory colitis) • died within 30 days following a diagnosis of CDI where it is recorded as either the primary or a major contributory factor on the death certificate • had persisting CDI where the patient has remained symptomatic and toxin positive despite two courses of appropriate therapy
<i>Deaths due to CDI (Underlying or Contributing)</i>	Patients who have died will have their cause of death reviewed as soon as possible via the ward death certificate records. If death certificate records are not available, the lead IPCN will contact the General Manager (GM) for the service, and advise them that the records are not available. The Lead Infection Prevention and Control Doctor (LIPCD), Infection Prevention and Control Manager (IPCM), Associate Nurse Director, Infection Prevention and Control (ANDIPC), Clinical Services Manager (CSM) and Lead Nurse for the area must be informed of all patients who died in hospital who are or who have been positive for CDI during their current admission, and the cause of death if available. Medical staff completing a death certificate in which CDI is noted (part 1 or 2) should discuss this with the consultant in charge of the patient's clinical care and refer case to the Procurator Fiscals Office. If CDI is placed on part 1, medical staff should inform the CSM and GM for the area. Medical staff should familiarise themselves with NHSGGC Guidance on the Completion of Medical Certificates of Cause of Death.
<i>Specimens required</i>	Faecal specimens from any patient who has loose stools must

The most up-to-date version of this SOP can be viewed at the following web page:

	be sent if no other cause of diarrhoea is known (Norovirus is not a reason to exclude CDI as a diagnosis as co-infection is possible). If negative and loose stools persist, another two samples should be sent at 24-hour intervals. Relevant clinical information must be supplied with the specimen. Stool specimens should be obtained as soon as possible after onset of diarrhoea. Toxin testing should only be requested on stool specimens that conform to the shape of the container. See Appendix 1. • Send faecal specimens from patients who develop loose stools for culture and sensitivity– mark the form for <i>C. diff</i> toxin testing if CDI is suspected. • There is no requirement to send clearance specimens from patients who become asymptomatic. • Only when a relapse of CDI is suspected should you repeat the toxin testing and exclude other potential causes of diarrhoea, and 48 hours after completion of treatment. • Specimens should not be sent whilst patient is on treatment.
Stool Charts	It is the responsibility of staff looking after the patient within the area to record signs and symptoms of infection as appropriate, e.g. Bowel Movement Record, Appendix 1. The date, time, size and nature of the stool should be recorded while symptomatic and continued until discharge in order to reduce the risk of cross infection.
Surveillance	Surveillance of CDI is mandatory in Scotland and is reported to HPS by the Diagnostic Laboratory. Local surveillance in NHSGGC is returned to wards with a prevalence of CDI monthly using Statistical Process Control Charts (SPCs). The trigger for action is when the numbers in a ward reach the upper control limit in the SPC. SPCs are not a substitute for local referral by clinical staff and IPCTs but should be used to monitor trends and promote quality improvement.

<i>Terminal Cleaning of Room</i>	Follow NHSGGC Terminal Clean of Ward/Isolation Rooms SOP If isolation is discontinued and the patient remains in hospital, undertake a terminal clean of the patient's room, including bed, bed locker, chair and table. Consider moving the patient to a new bed-space for ease of access. NB: relapse and re-infection from the environment can be as high as 20% in patients with CDI.
<i>Visitors</i>	Visitors are not required to wear aprons and gloves unless performing personal care. Visitors should be advised to decontaminate their hands with liquid soap and water on leaving the room/ patient. Visitors should be advised not to sit on the patient's bed at any time during visiting.

Guidance Objective

To ensure all relevant clinical staff are aware of the risks associated with
Respiratory Tract Infections

This guidance applies to all staff employed by NHS Greater Glasgow & Clyde and locum staff on fixed term contracts.

KEY CHANGES FROM THE PREVIOUS VERSION OF THIS GUIDANCE

1. Responsibilities

Healthcare Workers (HCWs) must:

- Follow this guidance.
- Inform a member of the Infection Prevention and Control Team (IPCT) if this guidance cannot be followed.
- Must ensure care checklists are implemented and up to date.

Senior Charge Nurses (SCNs) / Managers must:

- Support HCWs in following this guidance.
- Cascade new policies/SOPs/guidance to clinical staff after approval by the Board Infection Control Committee (BICC).
- Ensure HCW are aware how to use respiratory protection and have access to appropriate PPE including fit testing for FFP3 masks.
- Provide staff the opportunity to receive the staff flu vaccination each year

Infection Prevention and Control Teams (IPCTs) must:

- Keep this guidance up-to-date.
- Support the clinical team to undertake a risk assessment where this guidance cannot be followed.
- Provide education opportunities on this guidance.

Occupational Health Service (OHS) must:

- Public Health and OHS will plan and promote the uptake of staff seasonal flu vaccination
- OHS will provide opportunity for staff to receive their flu vaccination during working hours

	NHS GREATER GLASGOW & CLYDE CONTROL OF INFECTION COMMITTEE POLICY	Page	5 of 16

		Version	7
The most up-to-date version of this guidance can be viewed at the following web page: www.nhsggc.scot/hospitals-services/services-a-to-z/infection-prevention-and-control			

Influenza

Infections with a particular strain of influenza (type A or B) occur every year and are referred to as seasonal influenza. Pandemic influenza occurs when a new influenza sub-type appears that is different to previous sub-types and can:

- infect humans
- spread effectively from human to human
- causes significant clinical illness in a high proportion of those who acquire the virus

Primary strategies for preventing influenza are:

- **VACCINATION - the most effective way of preventing the spread of influenza**
- early detection and treatment
- standard infection control precautions and transmission based precautions must be followed, to prevent transmission during patient care

2. Symptoms of Influenza

Influenza is a respiratory illness characterised by coryzal symptoms including fever, cough, headache, sore throat and aching muscles and joints. There is a wide spectrum of illness ranging from minor symptoms through to pneumonia and death. The most common complications of influenza are bronchitis and secondary bacterial pneumonia.

The typical incubation period for non-pandemic influenza is one to four days, with an average of two to three days. Adults can be infectious from the day before symptoms begin to approximately five days after illness onset. Children can be infectious for seven or more days, and young children can shed virus for several days before their illness onset. Severely immunocompromised persons can shed virus for weeks or months.

Routes of Transmission

There are three main routes of transmissions:

i. Droplet Transmission

Large droplets (greater than 5 microns in size) may be generated from a person with clinical disease during coughing or sneezing and may land directly on the conjunctiva, or mucous membranes of the nose and mouth of a susceptible person. Large droplets are heavy and do not remain suspended in the air for long periods of time and only travel for up to 1 metre, so close contact is required for transmission.

	NHS GREATER GLASGOW & CLYDE CONTROL OF INFECTION COMMITTEE POLICY	Page	6 of 16
		Effective From	May 2022
	SEASONAL INFLUENZA GUIDANCE	Review Date	May 2024
		Version	7
The most up-to-date version of this guidance can be viewed at the following web page: www.nhsggc.scot/hospitals-services/services-a-to-z/infection-prevention-and-control			

ii. Direct / Indirect Contact Transmission

Direct contact transmission is when the virus is spread person to person either by contact with the infectious person skin or droplet transmission, e.g. symptomatic patient to a HCW, from a sneeze or cough directly onto the nose or mouth.

Indirect contact transmission is the transfer of an infectious agent through a contaminated intermediate object or person, e.g. from a contaminated surface, bed table, to the hands of another person who then transfers the virus to their nose, mouth or eyes. Influenza virus is known to survive well in the environment; up to 24 hours.

iii. By the Airborne Route during and after Aerosol Generating Procedures (AGPs)

Transmission may occur at short distances through inhalation of small particle aerosols which are produced during Aerosol Generating Procedures (AGPs).
(See section 5 below)

Smaller droplets or aerosol produced during these types of procedures can be inhaled and cause infection. They may also remain in the air for a prolonged period and travel over distances.

3. Aerosol Generating Procedures (AGPs)

Healthcare staff that perform AGPs on patients with confirmed or suspected influenza should don additional protective clothing (see **Section 5E** Personal Protective Equipment).

Where possible, AGPs should be avoided or alternative methods considered. Only essential staff should be present.

Aerosol Generating Procedures (AGPs) are defined as:

Tracheal intubation and extubation

- Manual ventilation
- Tracheotomy or tracheostomy procedures (insertion or removal)
- Bronchoscopy
- Dental procedures (using high-speed devices, for example, ultrasonic scalers/high-speed drills)

	NHS GREATER GLASGOW & CLYDE CONTROL OF INFECTION COMMITTEE POLICY	Page	7 of 16
		Effective From	May 2022
	SEASONAL INFLUENZA GUIDANCE	Review Date	May 2024
		Version	7
The most up-to-date version of this guidance can be viewed at the following web page: www.nhsggc.scot/hospitals-services/services-a-to-z/infection-prevention-and-control			

- Non-invasive ventilation (NIV): Bi-level Positive Airway Pressure Ventilation (BiPAP) and Continuous Positive Airway Pressure Ventilation (CPAP)
- High flow nasal oxygen (HFNO)
- High frequency oscillatory ventilation (HFOV)
- Induction of sputum using nebulised saline
- Respiratory tract suctioning
- Upper ENT airway procedures that involve respiratory suctioning
- Upper gastrointestinal endoscopy where open suction beyond the oro-pharynx occurs
- High speed cutting in surgery/post-mortem procedures

4. Testing for Influenza

- Patients who present to hospital with flu-like illness should be tested **if** clinically relevant.
- Repeat testing to confirm clearance of influenza is **not** required.

Anti-viral Prescribing for patients with flu-like illness

Treatment and prophylaxis

Please contact infectious disease consultant or virologist to obtain advice regarding treatment of suspected or known cases of influenza and / or prophylaxis of specific vulnerable groups. The most up-to-date information on treatment issued by the Scottish Government Health Directorates (SGHD) can be viewed at <https://www.hps.scot.nhs.uk/a-to-z-of-topics/influenza/>

5. Limiting the Spread of Influenza

A. Patient Placement

- All patients with confirmed or suspected influenza should be nursed in a single room with en suite facilities. If a single room is not available staff must contact a member of the local IPCT for further advice.
- A yellow IPC isolation sign should be clearly visible on the door.
- Patients should be considered infectious until patient is asymptomatic / back to their normal respiratory function for at least 24 hours OR patient has completed a course of antiviral treatment.
- Patients who are diagnosed as having influenza but are asymptomatic are unlikely to spread the virus and can be regarded as non-infectious.
- Patients who are immunocompromised or with prolonged illness or complications should be assessed by clinical staff and the IPCT, and isolation

	NHS GREATER GLASGOW & CLYDE CONTROL OF INFECTION COMMITTEE POLICY	Page	8 of 16
		Effective From	May 2022
	SEASONAL INFLUENZA GUIDANCE	Review Date	May 2024
		Version	7
The most up-to-date version of this guidance can be viewed at the following web page: www.nhsggc.scot/hospitals-services/services-a-to-z/infection-prevention-and-control			

precautions discontinued if deemed appropriate. Patients who fall into this category must be assessed individually.

- PCR tests can remain positive for considerable periods and should not be used to determine infectivity.
- Patients with underlying medical conditions or patients who have gone on to develop a secondary complication as a result of infection should be considered infectious until they return to their previous health state.
- If patient is in ICU please discuss with IPCT.
- Patients who are immunocompromised or with prolonged illness or complications should be assessed by clinical staff and the IPCT, and isolation precautions discontinued if deemed appropriate. Patients who fall into this category must be assessed individually.
- In the event of increase in the number of patients with influenza requiring admittance to hospital, in conjunction with the IPCT, an influenza cohort bay or ward can be considered. Please see [Appendix 2](#) for IPC guidance.

B. Patient Movement / Inter-Hospital Transfers

Influenza patients who are still infectious must not leave the area unless there is an urgent clinical need. If patient has to leave the single room while symptomatic, they should wear a fluid-resistant surgical mask (FRSM) if possible to minimise the dispersal of respiratory secretions and prevent environmental contamination. The FRSM should be worn until the patient is returned to the single room / cohort area. On removal of the FRSM, the patient should be offered the opportunity to undertake hand hygiene.

If a patient requires transfer to another department the following procedures must be followed:

- The department must be informed in advance.
- HCWs transporting the patient **do not need** to wear PPE if the patient is wearing an FRSM but must undertake hand hygiene.
- If the patient cannot wear/tolerate a FRSM then any HCW transporting the patient must wear a FRSM
- The patient must be taken straight to and returned from the department and must not wait in a communal area.
- If possible patients should be placed at the end of a list, to allow appropriate decontamination after any procedure.
- If the patient requires oxygen via a mask, then the patient need not wear the FRSM however, if nasal prongs are used to deliver oxygen then the patient should also wear an FRSM over the prongs.

Page 2 of 16

	NHS GREATER GLASGOW & CLYDE CONTROL OF INFECTION COMMITTEE POLICY	Page	9 of 16
		Effective From	May 2022
	SEASONAL INFLUENZA GUIDANCE	Review Date	May 2024
		Version	7

The most up-to-date version of this guidance can be viewed at the following web page:
www.nhsggc.scot/hospitals-services/services-a-to-z/infection-prevention-and-control

Hospital Transfers and Discharges

Patients must not be transferred from one hospital to another for routine care however some patients may require specialist care, e.g. renal dialysis. If a patient has to be transferred this **MUST** be discussed with the local IPCT who will alert the IPCT at the receiving hospital. It will be the responsibility of the clinical area that the patient is being discharged from to alert the Scottish Ambulance Service.

Discharge to residential care:

If a patient remains symptomatic or has not completed 5 days of appropriate antiviral treatment, this must be communicated to those receiving the patient, and appropriate IPC measures put in place prior to the transfer of the patient.

C. Visitor Restrictions

- Visiting in hospital should be restricted to 1-2 visitors only in order to reduce the risk of influenza transmission to visitors.
- All visitors must be free of flu-like symptoms, however in exceptional circumstances, e.g. when a patient is critically ill, then advice should be sought from the IPCT and a risk assessment will be undertaken.
- Visitors must speak to a member of staff and be instructed on hand hygiene practice and the wearing of protective clothing as appropriate prior to visiting the patient, such as a surgical mask, apron and gloves.
- Visitors to patients ventilated with NIV or HFOV may be exposed to potentially infectious aerosols. The number of such visitors should be limited to two unless there are exceptional circumstances. Visitors should be made aware of the risks and be offered PPE as recommended for staff.
- There may be further visiting restrictions if a ward is closed due to influenza.

D. Hand Hygiene

Hand hygiene remains the single most important measure to take against the spread of influenza. Effective hand hygiene with plain liquid soap and running water or alcohol based hand rub on visibly clean hands is effective, for a minimum of 20 seconds.

E. Personal Protective Equipment (PPE)

PPE is worn to protect staff from body fluids to reduce the risk of transmission of influenza between patients and staff and from one patient to another. The level of PPE used will vary based on the procedures being carried out and not all items of PPE

	NHS GREATER GLASGOW & CLYDE CONTROL OF INFECTION COMMITTEE POLICY	Page	10 of 16
		Effective From	May 2022
	SEASONAL INFLUENZA GUIDANCE	Review Date	May 2024
		Version	7
The most up-to-date version of this guidance can be viewed at the following web page: www.nhsggc.scot/hospitals-services/services-a-to-z/infection-prevention-and-control			

will always be required. Appropriate PPE for care of patients who are suspected or confirmed to have influenza is summarised **below**.

PPE to be worn when providing direct care for service users on the respiratory pathway. [National Infection Prevention and Control Manual: Winter \(21/22\), Respiratory Infections in Health and Care Settings Infection Prevention and Control \(IPC\) Addendum \(scot.nhs.uk\)](#)

Fluid resistant surgical mask (FRSM)

Fluid resistant surgical masks (FRSM) should be worn by HCWs for contact with patients suspected or known to have influenza. The mask provides a physical barrier which becomes ineffective once wet. As masks themselves may become a reservoir for the virus great care should be taken during their removal and disposal.

When to remove the FRSM

When visiting a number of patients within an influenza cohort or A&E department, it is acceptable to wear the same mask and change it at the end of the session and if it gets wet. Great care must be taken not to contaminate the hands during this time by touching the mask. HCW/ Visitors must removal all PPE before leaving a patient care area (single room/ cohort area), FRSM or FFP3 respirators should be removed last.

Hand hygiene must be performed after removal of all PPE.

When to wear an FFP3 respirator

FFP3 respirators should be worn only by those staff carrying out AGPs. To be effective, individual users must be trained to fit the respirator properly to their face.

When to remove the FFP3

The FFP3 mask must be worn for up to 2 hours following an AGP, until fallow times have been completed during which time the aerosols will have either been removed through the ventilation system or allowed to settle. If staff wish to leave the patient room within the fallow time, gloves and aprons should be removed in the room and hand hygiene performed. The FFP3 mask should be removed on leaving the room, placed in the nearest clinical waste receptacle and hand hygiene performed.

[National Infection Prevention and Control Manual: Appendix 17 - Aerosol Generating Procedures \(AGPs\) and post AGP Fallow time \(PAGPFT\) \(scot.nhs.uk\)](#)

Domestic staff where possible should wait for the fallow time to be over before entering the room.

F. Decontamination of Patient Equipment

	NHS GREATER GLASGOW & CLYDE CONTROL OF INFECTION COMMITTEE POLICY	Page	11 of 16
		Effective From	May 2022
	SEASONAL INFLUENZA GUIDANCE	Review Date	May 2024
		Version	7
The most up-to-date version of this guidance can be viewed at the following web page: www.nhsggc.scot/hospitals-services/services-a-to-z/infection-prevention-and-control			

Where practicable, the patient should be designated their own equipment.

See NHSGGC [Cleaning of Near Patient Equipment SOP](#)

G. Decontamination of the Environment

Domestic staff must follow the SOP for Twice Daily Clean of Isolation Rooms. Cleans should be undertaken at least four hours apart.

See NHSGGC [Twice Daily Clean of Isolation Rooms SOP](#)

All frequently touched surfaces should be decontaminated after any AGP using chlorine based detergent. Limit the amount of equipment in the room as far as possible.

H. Clinical/ Healthcare Waste

Waste should be designated as clinical / healthcare waste and placed in an orange bag.

Please refer to the NHSGGC [Waste Management Policy](#)

I. Laundry

Discard linen as soiled/ infected, i.e. in a water soluble bag then a clear plastic bag, tied and then placed into a laundry bag.

Please refer to [National guidance of the safe management of linen](#)

Sending Laundry Home

If relatives or carers wish to take personal clothing home, staff must place clothing into a domestic water soluble bag then into a patient clothing bag and ensure that a

[Washing Clothes at Home Information Leaflet](#) is issued.

NB Nursing staff in the ward should record in the nursing notes that both the advice and information leaflet has been issued.

J. Respiratory Hygiene / Cough Etiquette (Catch it, Bin it, Kill it)

Patients, staff and visitors should be encouraged to minimise potential influenza transmission by:

- Covering the nose and mouth with disposable single-use tissues when sneezing, coughing, wiping and blowing noses.
- Disposing of used tissues in nearest clinical/ healthcare waste bin, washing hands after coughing, and sneezing using tissues.
- Avoid touching eyes, mouth and nose.

	NHS GREATER GLASGOW & CLYDE CONTROL OF INFECTION COMMITTEE POLICY	Page	12 of 16
		Effective From	May 2022

		Version	7
The most up-to-date version of this guidance can be viewed at the following web page: www.nhsggc.scot/hospitals-services/services-a-to-z/infection-prevention-and-control			

Some patients may need assistance with containment of respiratory secretions, e.g. older people and children. Those who are immobile may need a personal waste bag readily at hand for immediate disposal of tissues. They should also have a supply of hand wipes and tissues.

Appendix 1: Influenza Cohort Nursing Aide Memoire

Planning and communications	On each hospital site, wards and wards with suitable bed bays will be identified and a respiratory pathway agreed from ED to discharge. This will be communicated to the appropriate staff at huddles/briefs to support patient/bed management. Daily updates on bed spaces on cohort wards/bays should be available to support patient transfers from ED and acute receiving. Wards with cohort bays will not be closed to other admissions.
Definition of a cohort ward or bay	A cohort area is a bay/ward in which a group of patients (cohort) with the same infection are placed together. Patient cohorting may be appropriate when single rooms are not available and there is more than one patient with the same confirmed infection.
Decision to create a Flu cohort	If a ward has bed bays and a number of confirmed FLU patients, those patients should be nursed in a single bay as a cohort. If there are empty beds in that cohort, they can be used for FLU patients from other areas. The decision to set up a cohort should be discussed with local IPCT/on call Microbiologist prior to being implemented.
Setting up the cohort	The cohort bay should have dedicated equipment as far as possible such as blood pressure, oxygen saturation and temperature recording devices within the cohort bay.
Staffing (cohort nursing)	Cohort nursing (dedicated teams) should be implemented to minimise the risk of contamination between groups of symptomatic and non-symptomatic patients <u>if</u> staff resource allows. If not, contact the local IPCT who will help to undertake a risk assessment
Bed spacing	Patients should be separated by at least 2.7 metres from each other in a cohort area, and bed curtains can be drawn as an additional physical barrier if required.
Cohort patients	Patients who have <u>confirmed Influenza</u> can be nursed in an influenza cohort until they have been asymptomatic / returned to normal respiratory function for at least 24 hours OR received 5 days of antiviral therapy. However, It should be noted that patients being nursed together in a cohort should all have the same type of FLU. e.g. Influenza A. Patients who remain symptomatic but are well enough to be discharged can be sent home. Patients who have FLU and another infection e.g. diarrhoea or MRSA, should be nursed in a single room.
Testing for influenza	Either laboratory or POCT testing is sufficient to identify patients with influenza. It is not necessary to test prior to discharge. Patients who are asymptomatic should not be tested.
PPE	For entering the cohort ward / bay, it is not necessary to wear PPE unless about to undertake patient care. For all direct care or contact with the patients environment staff should don a disposable plastic yellow apron, disposable gloves, a fluid resistant face mask and eye protection. For AGP, an FFP3 mask should be worn. If patients require routine AGPs, consider placing this patient in a single room.
Equipment	As far as possible, dedicated equipment should remain in the cohort bay for use on cohort patients only. For equipment that cannot be dedicated, items should be cleaned with a chlorine based solution containing 1,000 ppm active chlorine.
Ward rounds	Ward rounds within a cohort will consist of 1 member of medical team entering the cohort in appropriate PPE to examine the patient only. Once exam completed, removal of PPE and hand hygiene should be performed. Any equipment used will either stay in the cohort or be decontaminated before removal
Linen	Bed linen should be managed as infected linen
Waste	Waste should be managed as healthcare waste

Cleaning of Environment	Domestic services should clean the cohort bed bay/ ward a minimum of daily with a solution containing 1,000 ppm active chlorine. (Consideration should be given to a dedicated cleaning team on each site). If an AGP has been carried out the domestic staff should wait until the fallow time is complete before entering the room to clean.
Visitors	Visitors are allowed but no more than two per bed space. It may be necessary to stop visiting temporarily if the situation warrants this.

Abstract

Aerosol-generating procedures in the office represent a major concern for health care–associated infection of patients and health care providers by SARS-CoV-2, the causative agent for coronavirus disease 2019 (COVID-19). Although the Centers for Disease Control and Prevention has not yet provided any recommendations for the use of portable air purifiers, air purifiers with high-efficiency particulate air (HEPA) filters have been discussed as an adjunctive means for decontamination of SARS-CoV-2 aerosols in health care settings. This commentary discusses HEPA filter mechanisms of action, decontamination time based on efficiency and flow rate, theoretical application to SARS-CoV-2, and limitations. HEPA filter functionality and prior guidance from the Centers for Disease Control and Prevention for SARS-CoV-1 suggest theoretical efficacy for HEPA filters to decontaminate airborne SARS-CoV-2, although direct studies for SARS-CoV-2 have not been performed. Any portable HEPA purifier utilization for SARS-CoV-2 should be considered an adjunctive infection control measure and undertaken with knowledge of HEPA filter functionality and limitations in mind.

Keywords

high-efficiency particulate air filter, HEPA, air purifier, coronavirus, COVID-19, SARS-CoV-2

Received May 25, 2020; accepted May 29, 2020.

Airborne transmission of the severe acute respiratory syndrome coronavirus 2 (SARS-CoV-2), the causative agent of the coronavirus disease 2019 (COVID-19), occurs through respiratory droplets (generally $>5\ \mu\text{m}$) and aerosol droplets (generally $<5\ \mu\text{m}$) that are expectorated from the respiratory tracts of infected individuals.¹ Aerosol-generating procedures (AGPs) represent a major concern for health care–associated infection of patients and health care providers. As compared with large droplets, which are rapidly pulled downward by gravity, aerosols may remain suspended in the air for an hour or more.² Otolaryngology is one medical specialty at particularly high risk of health care–associated infection with SARS-CoV-2 due to

commonplace performance of AGPs in the office. Current guidance by the Centers for Disease Control and Prevention (CDC) is that AGPs be performed in airborne infection isolation rooms (ie, negative-pressure rooms) when possible; otherwise, procedure rooms should remain unoccupied until SARS-CoV-2-laden aerosols may be cleared through other means, such as room air exchanges from indwelling ventilation.³ The CDC has not provided any recommendations for the use of portable air purifiers. Nevertheless, air purifiers with high-efficiency particulate air (HEPA) filters have been discussed as an adjunctive means for decontamination of SARS-CoV-2 aerosols in health care settings. Consideration of portable air purifiers with HEPA filters (HEPA purifiers) during the SARS-CoV-2 pandemic should be with extensive knowledge about the functionality, efficacy, and limitations of HEPA purifiers.

Discussion

Mechanisms of Action

HEPA filters are usually manufactured by pleating microfiber glass or other fibrous media made with multiple layers of randomly arranged fibers, with diameters ranging from 2 to 500 nm.⁴ As air flows through the filter and in between the fibers, airborne particles—such as respiratory and aerosol droplets—will be trapped by 1 of 3 mechanisms: impaction, interception, and diffusion (**Figure 1**).⁵ Adhesion to filter fibers may occur through Van der Waals forces, electrostatic attraction, and capillary action. For particle sizes $>1\ \mu\text{m}$, impaction and interception are the most significant

Figure 1. Schematic of filtration mechanisms of impaction, interception, and diffusion. © R. Vijayakumar, reproduced with permission.

mechanisms of filtration, whereas diffusion is the dominant mechanism for trapping particles $<0.1 \mu\text{m}$.⁴ Particles between 0.1 and $1 \mu\text{m}$ are influenced by all 3 methods of capture to a lesser degree than those larger or smaller, which leads to a lower efficiency of filtration.⁴

Efficacy

To qualify as HEPA grade, filters must remove at least 99.97% of all particles that are 0.15 to $0.2 \mu\text{m}$, for which HEPA filters are least effective. Thus, HEPA filters have at least 99.97% efficiency for removing all particles, with even higher efficiencies for particles both larger and smaller than $0.15 \mu\text{m}$ (**Figure 2**). The interesting U-shaped efficiency curve of all HEPA filters, which has a minimum at $0.15 \mu\text{m}$, is due to the relative effectiveness of the 3 mechanisms of particle capture at various sizes. Filters with efficiencies $>99.99\%$ are also termed ultralow penetration air filters.

Clean Air Delivery Rate

HEPA purifiers of various sizes and power will remove particles at different rates. The clean air delivery rate (CADR) is an important performance parameter created by the Association of Home Appliance Manufacturers to quantify the cubic feet per minute of air completely filtered of a particle by the air purifier. The CADR is calculated as flow of air through the filtration system multiplied by the efficiency of filtration of the particular particle. CADR score is specific to particle sizes and typically reported for 3 categories of particle sizes: pollen (2.5 – $80 \mu\text{m}$), dust (1 – $30 \mu\text{m}$), and tobacco

Figure 2. High-efficiency particulate air filter efficiency as a function of particle size and filtration mechanism. MPPS, most penetrating particle size. © R. Vijayakumar, reproduced with permission.

smoke (0.1 – $1 \mu\text{m}$).⁶ The CADR for dust and tobacco smoke may be most useful for determining filtration rate of aerosols and viruses, respectively, which are generally in the corresponding size range.

A previously reported study by the Environmental Protection Agency illustrates practical considerations for airborne particle decontamination by HEPA purifiers.² Based on the assumption of complete mixing of the air during filtration, which was found to be a realistic approximation, the amount of time needed to filter a certain fraction of particles out of a volume of air was derived using the CADR:

$$C(t) = C_0 e^{-\left(\frac{\text{CADR}}{V}\right)t},$$

where $C(t)$ is the concentration of the particle as a function of time, C_0 is the initial particle concentration, V is the volume of the air being filtered, and t is time.² Therefore, a HEPA purifier that has a CADR score of 300 for tobacco smoke—indicating that the device removes all tobacco smoke particles from 300 cubic feet of air every minute—would be expected to clear 99% of all tobacco smoke particles in a 1000 cubic-foot room (eg, $10 \times 10 \times 10$ ft) in 15 minutes. Location of HEPA purifier placement within the room and presence of basic furniture, such as a desk and chair, did not substantially affect efficacy, although pointing the purifier's air intake toward the particle source improved decontamination.²

HEPA Filters Applied to SARS-CoV-2

The majority of aerosols that may be produced by human cough are $<1 \mu\text{m}$,⁷ and the SARS-CoV-2 virion is reported to be 60 to 140 nm (0.06 – $0.14 \mu\text{m}$).¹ Although the CDC has recommended the use of HEPA filters in powered air-purifying respirators for effective filtration of SARS-CoV-

2,⁸ at present the CDC has not provided any recommendations for the use of portable HEPA purifiers for decontamination of SARS-CoV-2 in clinical areas or procedure rooms. The US Food and Drug Administration recommends that manufacturers of air purifiers intended for use related to SARS-CoV-2 evaluate effectiveness against a representative virus.⁹ Coincidentally, the CDC previously suggested the use of portable HEPA purifiers as an adjunctive infection control strategy for SARS-CoV-1, the causative agent of the 2003 SARS outbreak.¹⁰

Considerations for Commercial Acquisition of HEPA Purifiers

Consumers are cautioned that commercially available air purifiers make claims with labels such as true HEPA, HEPA like, and HEPA type. However, to be labeled HEPA, a filter is required to be tested and individually certified according to standards by the US Institute of Environmental Sciences and Technology (IEST-RP-CC001.6) or the International Organization for Standardization (ISO 29463). Very few air purifiers meet this requirement. By comparison, CADR rating is a more reliable performance parameter. Medical HEPA air purifiers may additionally claim to have an ultraviolet light or other decontaminating agent to kill microbes that deposit on the filter itself. In most cases, their microbicidal effectiveness has not been independently verified. Manufacturer guidelines should be followed for when to change filters, as saturation of filters affects efficiency. Finally, proper personal protective equipment should be worn to exchange air purifier filters, as these filters may contain trapped SARS-CoV-2. Proper disposal procedures should be followed to avoid contamination.

Conclusion

At present, there are no formal recommendations by the CDC for use of portable HEPA purifiers for decontamination of airborne SARS-CoV-2. Knowledge of HEPA filter functionality and prior CDC guidance for SARS-CoV-1 suggests theoretical efficacy for HEPA filters to remove airborne SARS-CoV-2, although it is important to emphasize that direct studies for SARS-CoV-2 have not been performed. Any utilization of portable HEPA purifiers for SARS-CoV-2 should be considered an adjunctive infection control measure and be undertaken with knowledge of HEPA filter functionality and limitations in mind.

SUMMARY

High-efficiency particulate air supplied to a positive-pressure ventilation lobby (PPVL) in isolation rooms offers the dual advantage of protective and source isolation. This study demonstrates the in-use validity of PPVL rooms for protective isolation of patients. Of the 48 PPVL air samples investigated, *Aspergillus fumigatus* was detected from only one (2%) sample. Local and remote monitoring of the PPVL rooms is essential for the safety of patients and healthcare workers. Remote and point-of-use engineering controls are essential for ongoing ventilation monitoring, but this should be complemented by visual inspection of the isolation suite. Periodic microbiological monitoring should also be considered with other control measures.

Introduction

Positive-pressure ventilation lobby (PPVL) rooms were introduced with the arrival of UK Health Building Notes (HBN) 04–01, Supplement 1 (2005), and were hypothesized to provide a protective environment for patients. The PPVL room was

shown *in vitro* to be effective in providing the desired protection, but the literature supporting its clinical validity is sparse [1]. The HBN 04-01 Supplement 1 (2013) recommends a neutral-pressure ventilation (NPV) room with a PPVL for the prevention of transmission of infection by airborne pathogens [2]. Many newer healthcare facilities have provided PPVL-NPV rooms, and some are fitted with high-efficiency particulate air (HEPA) filters, but there are few data on their in-use effectiveness.

The at-risk patient groups for invasive aspergillosis (IA) have recently been expanded to include chronic lung disease,

patients in critical care, and liver cirrhosis. [3] Additionally, emerging multi-triazole resistance in *Aspergillus fumigatus* limits therapeutic and prophylactic options [3]. The Irish National Guidelines recommend the use of HEPA-filtered positive-pressure facilities for patients' at increased risk of IA [4].

The aim of the study was to evaluate the in-use efficacy of the HEPA-supplied PPVL-NPV rooms for protection of patients at risk of IA, using three parameters, i.e. visualizing the direction of air flow, pressure differentials, and the microbiological monitoring for the presence of moulds, including *Aspergillus* spp.

Methods

Setting

Beaumont Hospital is an 800-bed tertiary acute adult national referral healthcare facility in Dublin, Ireland, incorporating national services in neurosurgery and kidney transplantation with a substantial cohort of haematology, oncology, and cystic fibrosis patients. The hospital has several PPVL-NPV rooms fitted with HEPA supply (hereafter referred to as 'NPV rooms') for protective isolation of immunocompromised patients to prevent IA. For bed access to any room, an appropriately sized door is required. Our NPV rooms are fitted with double-leaf sealed doors, from the corridor to the room, for bed access only and are access-controlled. Subsequent to their installation and commissioning, no demolition, construction, or renovation works have been performed to 'the envelope' in these purpose-built PPVL-NPV rooms, other than routine preventive maintenance [2].

Positive-pressure ventilation lobby room

The physical layout and airflow direction of a PPVL room is shown in Figure 1. The ante-room is supplied with HEPA-filtered air with ≥ 12 air changes per hour (ACH). The patient room and en-suite facility should have ≥ 10 ACH. While in operation, the en-suite facility should be at negative pressure with respect to

the patient room. The airflow direction should be from the ante-room to the patient room to the en-suite facility. The doors leading into and out of the ante-room and patient room must be closed to facilitate the correct airflow. Engineering controls include a pressure differential display (magnahelic pressure gauge) and alarm lights. Air pressure displays of ≥ 10 Pa in a PPVL are a measure of adequate air supply. Visual display alarms are used for local monitoring and the safe functioning of these rooms. Pressure differential data are continuously recorded by estates and facilities.

Air flow test

The air flow was assessed by visualizing the direction of smoke into and out of the PPV lobby, patient room, and en-suite facility by using a smoke test (Smoke pen, Björnax, Nora, Sweden), on three non-consecutive time-points. The expected direction of the airflow is from the PPVL to the patient room through the pressure stabilizer, and through the diffuser grill to the extract in the en-suite facility. The smoke pen was directed to the door seals as well as to the door–floor–wall fittings, to observe any smoke penetration/leakage.

Pressure differential test

The doors leading into the ante-room from the corridor were held open for 30 s; the pressure reading should fall to '0' Pa. Thereafter, the door leading to the ante-room was closed; a reading of ≥ 10 Pa was deemed adequate. These tests were repeated weekly for eight weeks.

Microbiological monitoring

Environmental air sampling was done by active air sampling, ~ 1 m above the floor, where 1 m^3 of air per sample was collected to determine the fungal spore burden, most specifically *A. fumigatus* [4]. Air samples were collected from the NPV rooms at three locations: the ante-room (lobby), patient room,

and the en-suite facility. Two air samples were collected from atmospheric air outside the built-in areas which served as the environmental control.

Sabouraud Dextrose Agar (SDA) plates (Fannin Ltd, Dublin, Ireland) were used for air sampling using a Surface Air Sampler (SAS) PBI, Milan Italy, one day per week for eight consecutive weeks. Plates were incubated at 37°C for 48 h and suspect colonies for aspergillus were identified as described [5]. Ten air samples were collected each week for eight consecutive weeks; three each from two NPV rooms, two from the positive-pressure HEPA-ventilated 24-bed ward while occupied by patients, and two external atmospheric air samples).

Results

Air flow

In the lobby, smoke flow was observed diffusing into the patient room through the pressure stabilizers. From the patient room, the flow of smoke moved into the en-suite facility through the integrated grills while the door was closed. In the en-suite facility, smoke flow was towards the ceiling-mounted extractor. No smoke penetration was observed through the bed-access-only door seals or via the flush door–floor–wall fixtures.

Pressure differential

The pressure gauge differential reading was ≥ 10 Pa in both positive-pressure lobby rooms when the doors were closed, and fell to '0' Pa upon opening the lobby door, but returned to ≥ 10 Pa when the doors were closed. The observed pressure differential readings during the eight weeks in both PPVL rooms were consistently ≥ 10 Pa.

Microbiological monitoring

Eighty air samples were collected over eight weeks. No moulds, including *A. fumigatus*, were isolated in the PPV lobby

or in the patient rooms. Three colony-forming units (cfu) of *A. fumigatus* were isolated on one occasion from the en-suite facility of one of the NPV rooms. From the two open ward locations, mould was isolated on two separate sampling points, 1 cfu each, and identified as *A. fumigatus*. Of the eight sampling points, *A. fumigatus* was isolated on five occasions from atmospheric air, i.e. the environmental control. The air-sampling results are summarized in Table 1.

Discussion

Controlled ventilation is used in healthcare facilities for the protection of patients, healthcare workers and other users. It often does not deliver the recommended ventilation, it may fail to maintain negative pressure, and it may even be under positive pressure [5]. Other problems with mechanical ventilation include the loss of negative-pressure differentials in airborne isolation rooms due to the opening of the doors and clogged filters. The undesirable airflow in and out of the negative-pressure isolation room, i.e. permeability, shows how leaky it is, as any leak presents a route of airborne transmission. In the absence of works carried out in the isolation facility that affect the envelope of the isolation suite, or any physical defects in a PPVL-NPV room, an air leak may occur from broken door seals or faulty doors [2].

Historically, isolation rooms that are switchable from positive to negative air pressure were used, but investigators found that these units were not delivering air according to the set parameters. An evaluation of 115 negative-pressure ventilation isolation rooms in the USA found that 52 (40%) of these rooms had positive airflow to the corridor with the doors closed [5]. In the absence of well-sustained negative pressure, contamination of adjacent rooms is likely, therefore posing a significant clinical risk to patients and to others such as staff [6].

Investigators in Hong Kong assessed rooms used for severe acute respiratory syndrome isolation rooms for negative pressure, airflow path, air-change rate, and local ventilation effectiveness. They found that, of the 38 rooms tested, 97% met the recommended negative-pressure difference of 2.5 Pa between the corridor and the ante-room, and 89% met the same requirement between the ante-room and the patient room. Although no leakage to the corridor was found, 60% of the en-suite facilities were operating under positive pressure. More than 90% of the corridor–ante-room or ante-room–patient room doors had a bi-directional flow when the door was open [7]. This casts doubt on the efficacy of negative-pressure ventilated rooms for source isolation.

The latest UK guidelines no longer recommend isolation rooms that are switchable from positive to negative air pressure, because of the risk of an incorrect setting [2]. The HEPA-fitted PPVL rooms therefore offer the dual advantage of 'protective' clean air supply to prevent IA, and airborne isolation with negative-pressure ventilation. The design of the PPVL room stipulates unidirectional airflow from the lobby to the patient room and this air is extracted in the en-suite facility. The design of the NPV suite limits the risk of inadvertent exposure to airborne pathogens, in the event of a failure in the air supply or extractor, which are inter-locked. However, this is dependent on robust engineering and regular safety checks.

Air permeability tests should be done as part of commissioning, at regular intervals, following physical alterations to

the room structure or if breaches to the supply and air-handling units occur, as specified in HBN (2013), Appendix 2. The UK Building Services Research and Information Association (BSRIA) standards on air permeability testing (BTS 3/2018) recommend testing at intervals not exceeding 14-month intervals. If further work is carried out in the isolation facility that affects the envelope of the isolation suite, the test must be repeated [8]. In the absence of alterations in the regular air flow, smoke tests to observe the direction of air flow could be employed as these provide reassurance of a functioning ventilation system when the intentional air flow direction is observed. Local monitoring of the pressure differential readings should be incorporated into daily visual checks to confirm the adequate functioning of the ventilation system.

We recorded pressure differential readings of the PPV lobby with the doors (B, C) closed and opened which provided visible evidence on the functioning of the HEPA-ventilated lobby. Automated remote continuous-pressure differential monitoring should be incorporated into healthcare building management systems for safety and governance. However, the poor reliability of continuous monitoring devices has been reported elsewhere, emphasizing the benefits of frequent visible smoke tests [9]. We observed the appropriate direction of smoke flow from the PPV lobby to the patient room to the en-suite facility extract, while all the doors were closed. No leakage of smoke was observed through the door-lips or seals.

The effective functioning of a PPV lobby room is dependent on the doors leading into and out of the rooms (A–D), being closed at all times. This requires a coordinated effort from clinical, engineering, hygiene services staff, patients, and visiting public. Staff must be educated on the correct functioning of these rooms in addition to noting and acting on warning alarm lights. Local monitoring and troubleshooting must be part of staff training. Patients in such rooms and their visitors must be provided with appropriate information, including the necessity of keeping the doors closed. In our experience, where patients were not given appropriate information the lobby/ante-room doors were sometimes sealed with tape, pressure dampers were blocked, doors were wedged open, and window seals broken. Sealed bed-access-only doors must be access controlled to prevent accidental and inadvertent use of these doors and thus prevent the ingress of contaminated air.

Irish guidelines recommend environmental air sampling before construction and at intervals [4]. As clean-air-supplied PPVL rooms are also intended for protective isolation, microbiological monitoring of HEPA-ventilated rooms by air sampling is prudent [3,4]. Determining baseline fungal spore burden before building works will facilitate future comparison. In the HEPA-supplied PPVL rooms, the recovery of *A. fumigatus* is unexpected, and, if present, it must be investigated. A two-year study to assess whether the PPVL room provides a similar environment to positive-pressure rooms found that mould concentrations were similar in the positive- and neutral-pressure room [1].

In our study, *A. fumigatus* was cultured once from the NPV en-suite facility. The NPV room was occupied by a patient during sampling. No environmental deficits could be detected other than dust on the extract fan grills. A comparable study has reported similar contamination from en-suite facilities in controlled ventilation rooms [10]. In the absence of a numeric

threshold for *Aspergillus* counts to indicate when action needs to be taken, a threshold of <1 cfu/m³ HEPA-filtered rooms with $>99.95\%$ efficiency is suggested [3]. The absence of fungal growth from PPVLs and NPV patient room air samples confirms the capacity for protective isolation.

Following the isolation of aspergillus in environmental air samples in another HEPA ventilation room (not the two NPV rooms studied), we noted dampness on the ceiling and walls arising from water leaks as the most likely cause. Therefore, regular environmental checks of ceilings and walls for dampness and water leaks are essential. Our findings contribute to growing evidence on the efficacy of PPVL-NPV isolation rooms for protecting at-risk patients from airborne pathogens as well as source isolation of patients with airborne-transmissible infections.

Limitations to our study include assessing only two HEPA-supplied PPVL-NPV isolation rooms and only over a period of eight weeks, in one centre yielding a small sample size. Larger studies involving multiple NPV rooms for longer duration should be performed to validate clinically the safety and efficacy of these expensive specialized rooms.

Two metres or one: what is the evidence for physical distancing in covid-19?

Rigid safe distancing rules are an oversimplification based on outdated science and experiences of past viruses, argue **Nicholas R Jones and colleagues**

Nicholas R Jones, Zeshan U Qureshi, ² Robert J Temple, ³ Jessica P J Larwood, ⁴ Trisha Greenhalgh, ¹ Lydia Bourouiba⁵

Physical distancing is an important part of measures to control covid-19, but exactly how far away and for how long contact is safe in different contexts is unclear. Rules that stipulate a single specific physical distance (1 or 2 metres) between individuals to reduce transmission of SARS-CoV-2, the virus causing covid-19, are based on an outdated, dichotomous notion of respiratory droplet size. This overlooks the physics of respiratory emissions, where droplets of all sizes are trapped and moved by the exhaled moist and hot turbulent gas cloud that keeps them concentrated as it carries them over metres in a few seconds.^{1,2} After the cloud slows sufficiently, ventilation, specific patterns of airflow, and type of activity become important. Viral load of the emitter, duration of exposure, and susceptibility of an individual to infection are also important.

Instead of single, fixed physical distance rules, we propose graded recommendations that better reflect the multiple factors that combine to determine risk. This would provide greater protection in the highest risk settings but also greater freedom in lower risk settings, potentially enabling a return towards

normality in some aspects of social and economic life.

Origins of 2 metre rule

The study of how droplets are emitted during speech or more forcefully when coughing or sneezing began in the 19th century, with scientists typically collecting samples on glass or agar plates.³ In 1897, for example, Flugge proposed a 1-2 m safe distance based on the distance over which sampled visible droplets contained pathogens.⁴ In the 1940s, visual documentation of these emissions became possible with close-up still imaging of sneezing, coughing, or talking (fig 1).⁵ A study in 1948 of haemolytic streptococci spread found 65% of the 48 participants produced large droplets only, fewer than 10% of which travelled as far as 5½ feet (1.7 m).⁶ However, in 10% of participants, haemolytic streptococci were collected 9½ feet (2.9 m) away. Despite limitations in the accuracy of these early study designs, especially for longer ranges, the observation of large droplets falling close to a host reinforced and further entrenched the assumed scientific basis of the 1-2 m distancing rule.²

Fig 1 | Short range still imaging of stages of sneezing, revealing the liquid droplets from the 1942 Jennison experiment.⁵ Reproduced with permission

Yet eight of the 10 studies in a recent systematic review showed horizontal projection of respiratory droplets beyond 2 m for particles up to 60 μm .⁷ In one study, droplet spread was detected over 6-8 m (fig 2).²⁸ These results suggest that SARS-CoV-2 could spread beyond

1-2 m in a concentrated packet through coughs or sneezes.² In recent related viral outbreaks, such as SARS-CoV-1, MERS-CoV, and Avian flu, multiple studies reported suspected spread beyond 2 m.^{9 10}

Fig 2 | Long range video imaging over 8 m of the multiphase turbulent cloud (gas cloud containing liquid droplets of all sizes) from natural human violent emission such as a sneeze, revealing a range of the cloud, and its droplet concentrated payload, of up to 7-8 m. Reproduced with permission from Bourouiba²

Droplet size, droplet spread

The 1-2 m rule is based on a longstanding framework which dichotomises respiratory droplets into two sizes, large and small. The size of a droplet is thought to determine how far it will travel from the infected person. According to studies by Wells, emitted large droplets fall through the air more quickly than they evaporate and land within a 1-2 metre range.¹¹ Small droplets (later called aerosols or airborne droplets), typically invisible to the naked eye, evaporate more quickly than they fall. Without airflow, they cannot move far, remaining in the exhaler's vicinity. With airflow they can spread along greater distances.

While conceptually useful up to a point, this dichotomy framework overlooks contemporary science about respiratory exhalations.¹² Droplets exist across a continuum of sizes. Contextual factors such as exhaled air and ambient airflow are extremely important in determining how far droplets of all sizes travel. Without exhaled airflow, the largest droplets would travel furthest (1-2 m), while the small ones would encounter high resistance (drag) and stay close to the source. When accounting for the exhaled airflow, clouds of small droplets can travel beyond 2 m in the air, and even large droplets have enhanced range.^{1,2}

Airborne particle spread of SARS-CoV-2

Diseases that can be transmitted by airborne particles, such as measles and varicella, can travel much further, and in concentrated clouds, than those transmitted by large droplets, which drop from clouds more quickly. They can therefore expose others rapidly and at greater distance^{2,13} and may need different public health measures, including extended physical distancing. Laboratory studies also suggest SARS-CoV-1, SARS-CoV-2, and MERS-CoV viral particles are stable in airborne samples, with SARS-CoV-2 persistent for longest (up to 16 hours).^{14,15}

In a literature search for studies using air sampling techniques to detect viral particles surrounding covid-19 patients, we found nine studies in hospital and two in community settings. Seven of the hospital studies reported at least one airborne sample tested positive for SARS-CoV-2, though the proportion of positive samples across studies ranged between 2% and 64%.¹⁶⁻²² Only two reported positive results in relation to distance from an infected patient (one at 2 m¹⁸ and another at ≥ 4 m in the corridor¹⁷). Of the two hospital studies that did not find SARS-CoV-2 particles in air samples,^{23,24} one collected positive swab samples from ventilation units in the patient's room, which is consistent with airborne droplet spread.²³

Neither community study reported positive air samples, although one collected specimens up to 17 days after covid-19 carriers had left the room²⁵ and the other did not report time of sampling since

ANALYSIS

cleaning or sampling distance from the infected person.²⁶ These negative studies thus fall substantially short of proving that airborne spread does not occur.

Only two of the airborne sampling studies directly measured whether SARS-CoV-2 in the samples remained infectious, rather than just analysing for the presence of viral RNA.^{18,21} No viable virus was found in either, though one found signs of viral ability to replicate.¹⁸ Of note, no study found viable virus on surface swabs.

These studies were small, observational, and heterogeneous in terms of setting, participants, sample collection, and handling methods. They were prone to recall bias (few people can accurately recall how close they came to others when asked to remember some time later). Overall, these studies seem to support the possibility of airborne spread of SARS-CoV-2, but they do not confirm that there is a risk of disease transmission.

Force of emission, ventilation, exposure time

Breathing out, singing, coughing, and sneezing generate warm, moist, high momentum gas clouds of exhaled air containing respiratory droplets. This moves the droplets faster than typical background air ventilation flows, keeps them concentrated, and can extend their range up to 7–8 m within a few seconds.^{1,2,8}

These findings from fluid dynamic studies help explain why at one choir practice in the US, a symptomatic person infected at least 32 other singers, with 20 further probable cases, despite physical distancing.²⁷ Other indoor case clusters have been reported within fitness gyms, boxing matches, call centres, and churches, where people might sing, pant, or talk loudly.^{28–30} Interestingly, there have been few reports of outbreaks on aeroplanes,³¹ which may reflect current low volume of passengers, lack of contact tracing, or relatively low risk because speaking is limited. Although publication bias is likely (events linked to outbreaks are more likely to be reported than events where no outbreak occurred), well documented stories of outbreaks demand a scientific explanation.

The heavy panting from jogging and other sports produces violent exhalations with higher momentum than tidal breathing, closer to coughs in some instances. This increases the distance reached by the droplets trapped within the exhaled cloud and supports additional distancing during vigorous exercise.² However, respiratory droplets tend to be more quickly diluted in well aerated outdoor settings, reducing transmission risk (a preprint from Japan reports an 18.7-fold higher risk of transmission in indoor environments than outdoors).²⁸

Specific airflow patterns, and not just average ventilation and air changes, within buildings are also important in determining risk of exposure and transmission. A case report from an outbreak at a restaurant in China described 10 people within three families infected over one hour, at distances of up to 4.6 m and without direct physical contact. The pattern of transmission was consistent with the transient indoor localised ventilation airflow pattern.³²

Few studies have examined how airflow patterns influence viral transmission; most studies report (if anything) only average indoor ventilation rates. Neglecting variation in localised air flow within a space oversimplifies and underestimates risk modelling. In homogeneous flow, patterns are known to emerge in occupied indoor spaces that depend on air conditioning, ventilation system or location, occupancy of the space, air recirculation, and filtration.

Though it is widely assumed that duration of exposure to a person with covid-19 influences transmission risk (studies of contact tracing, for example, consider thresholds of 5–15 minutes beyond which risk increases^{33,34}), we are not aware of studies that quantified this variable.

Distance and transmission risk

The UK's Scientific Advisory Group for Emergencies (SAGE) estimates that the risk of SARS-CoV-2 transmission at 1 m could be 2–10 times higher than at 2 m.³⁵ A systematic review commissioned by the World Health Organization attempted to analyse physical distancing measures in relation to coronavirus transmission.³⁶ Physical distancing of <1 m was reported to result in a transmission risk of 12.8%, compared with 2.6% at distances ≥1 m, supporting physical distancing rules of 1 m or more. The review's limitations should be noted. Not all distances were explicit in the original studies; some were estimated by the review authors. Different distances were used to categorise social contact in different studies (1.8 m was considered close in one study but distant in another, for example), yet these were pooled within the same analysis. The summary relied heavily on data from the SARS-CoV-1 and MERS outbreaks and only partially accounted for environmental confounders.

More nuanced model

Environmental influences are complex and are likely to be mutually reinforcing. This is shown, for example, in meat packing plants, where outbreaks have been attributed to the combination of high levels of worker contagion, poor ventilation, cramped working conditions, background noise (which leads to shouting), and low compliance with mask wearing.³⁷ Similar compound risk situations might occur in other crowded, noisy, indoor environments, such as pubs or live music venues.

Physical distancing rules would be most effective if they reflected graded levels of risk. Figure 3 presents a guide to how transmission risk may vary with setting, occupancy level, contact time, and whether face coverings are worn. These estimates apply when everyone is asymptomatic. In the highest risk situations (indoor environments with poor ventilation, high levels of occupancy, prolonged contact time, and no face coverings, such as a crowded bar or night club) physical distancing beyond 2 m and minimising occupancy time should be considered. Less stringent distancing is likely to be adequate in low risk scenarios. People with symptoms (who should in any case be self-isolating) tend to have high viral load and more frequent violent respiratory exhalations.

Type and level of group activity	Low occupancy			High occupancy		
	Outdoors and well ventilated	Indoors and well ventilated	Poorly ventilated	Outdoors and well ventilated	Indoors and well ventilated	Poorly ventilated
Wearing face coverings, contact for short time						
Silent	Low	Low	Low	Low	Low	Medium
Speaking	Low	Low	Low	Low	Low	Medium
Shouting, singing	Low	Low	Medium	Medium	Medium	High
Wearing face coverings, contact for prolonged time						
Silent	Low	Low	Medium	Low	Medium	High
Speaking	Low	* Low	Medium	* Medium	Medium	High
Shouting, singing	Low	Medium	High	Medium	High	High
No face coverings, contact for short time						
Silent	Low	Low	Medium	Medium	Medium	High
Speaking	Low	Medium	Medium	Medium	High	High
Shouting, singing	Medium	Medium	High	High	High	High
No face coverings, contact for prolonged time						
Silent	Low	Medium	High	Medium	High	High
Speaking	Medium	Medium	High	High	High	High
Shouting, singing	Medium	High	High	High	High	High

Risk of transmission
 Low ■ Medium ■ High ■

* Borderline case that is highly dependent on quantitative definitions of distancing, number of individuals, and time of exposure

Fig 3 | Risk of SARS-CoV-2 transmission from asymptomatic people in different settings and for different occupation times, venting, and crowding levels (ignoring variation in susceptibility and viral shedding rates). Face covering refers to those for the general population and not high grade respirators. The grades are indicative of qualitative relative risk and do not represent a quantitative measure. Other factors not presented in these tables may also need to be taken into account when considering transmission risk, including viral load of an infected person and people's susceptibility to infection. Coughing or sneezing, even if these are due to irritation or allergies while asymptomatic, would exacerbate risk of exposure across an indoor space, regardless of ventilation

The levels of risk in [fig 3](#) are relative not absolute, especially in relation to thresholds of time and occupancy, and they do not include additional factors such as individuals' susceptibility to infection, shedding level from an infected person, indoor airflow patterns, and where someone is placed in relation to the infected person. Humidity may also be important, but this is yet to be rigorously established.

Further work is needed to extend our guide to develop specific solutions to classes of indoor environments occupied at various usage levels. Urgent research is needed to examine three areas of uncertainty: the cut-off duration of exposures in relation to the indoor condition, occupancy, and level of viral shedding (5-15 minute current ad-hoc rules), which does not seem to be supported by evidence; the detailed study of airflow patterns with respect to the infected source and its competition with average venting; and the patterns and properties of respiratory emissions and droplet infectivity within them during various physical activities.

Physical distancing should be seen as only one part of a wider public health approach to containing the covid-19 pandemic. It needs to be implemented alongside combined strategies of people-air-surface-space management, including hand hygiene, cleaning, occupancy and indoor space and air managements, and appropriate protective equipment, such as masks, for the setting.

Key messages

- Current rules on safe physical distancing are based on outdated science
- Distribution of viral particles is affected by numerous factors, including air flow
- Evidence suggests SARS-CoV-2 may travel more than 2 m through activities such as coughing and shouting
- Rules on distancing should reflect the multiple factors that affect risk, including ventilation, occupancy, and exposure time

Contributors and sources: This article was adapted from a rapid review undertaken as part of the Oxford COVID-19 Evidence Service (<https://www.cebm.net/covid-19/what-is-the-evidence-to-support-the-2-metre-social-distancing-rule-to-reduce-covid-19-transmission/>); all authors contributed to its development and approved the final manuscript.

ANALYSIS

Patient and public involvement: Three members of the public provided feedback on the article. They strongly supported the need for an in-depth analysis of physical distancing and thought our summary figure was helpful in presenting factors that influence categories of risk. Specific feedback led to additional discussion points addressing transmission risk in complex settings such as the meat packing industry and with exercise.

Competing interests: We have read and understood BMJ policy on declaration of interests and have no relevant interests to declare.

Provenance and peer review: Not commissioned; externally peer reviewed.

Abstract

OBJECTIVES

To evaluate the potential for long distance airborne transmission of SARS-CoV-2 in indoor community settings and to investigate factors that might influence transmission.

DESIGN

Rapid systematic review and narrative synthesis.

DATA SOURCES

Medline, Embase, medRxiv, Arxiv, and WHO COVID-19 Research Database for studies published from 27 July 2020 to 19 January 2022; existing relevant rapid systematic review for studies published from 1 January 2020 to 27 July 2020; and citation analysis in Web of Science and Cocites.

ELIGIBILITY CRITERIA FOR STUDY SELECTION

Observational studies reporting on transmission events in indoor community (non-healthcare) settings in which long distance airborne transmission of SARS-CoV-2 was the most likely route. Studies such as those of household transmission where the main transmission route was likely to be close contact or fomite transmission were excluded.

DATA EXTRACTION AND SYNTHESIS

Data extraction was done by one reviewer and independently checked by a second reviewer. Primary outcomes were SARS-CoV-2 infections through long distance airborne transmission (>2 m) and any modifying factors. Methodological quality of included

studies was rated using the quality criteria checklist, and certainty of primary outcomes was determined using the Grading of Recommendations, Assessment, Development, and Evaluation (GRADE) framework. Narrative synthesis was themed by setting.

RESULTS

22 reports relating to 18 studies were identified (methodological quality was high in three, medium in five, and low in 10); all the studies were outbreak investigations. Long distance airborne transmission was likely to have occurred for some or all transmission events in 16 studies and was unclear in two studies (GRADE: very low certainty). In the 16 studies, one or more factors plausibly increased the likelihood of long distance airborne transmission, particularly insufficient air replacement (very low certainty), directional air flow (very low certainty), and activities associated with increased emission of aerosols, such as singing or speaking loudly (very low certainty). In 13 studies, the primary cases were reported as being asymptomatic, presymptomatic, or around symptom onset at the time of transmission. Although some of the included studies were well conducted outbreak investigations, they remain at risk of bias owing to study design and do not always provide the level of detail needed to fully assess transmission routes.

CONCLUSION

This rapid systematic review found evidence suggesting that long distance airborne transmission of SARS-CoV-2 might occur in indoor settings such as restaurants, workplaces, and venues for choirs, and identified factors such as insufficient air replacement that probably contributed to transmission. These results strengthen the need for mitigation measures in indoor settings, particularly the use of adequate ventilation.

SYSTEMATIC REVIEW REGISTRATION

PROSPERO CRD42021236762.

Introduction

Since the early stages of the covid-19 pandemic and the first reports of superspreader events,^{1 2} the body of evidence suggesting airborne transmission of SARS-CoV-2 in the absence of aerosol generating procedures has grown. However, despite the publication of numerous opinion pieces and narrative reviews in support of airborne transmission of SARS-CoV-2,³⁻⁹ scientific consensus on the relative importance of this route of transmission is lacking. Part of the controversy arises from differences in terminology, definitions, and size thresholds for respiratory particles.¹⁰

Traditionally, close contact transmission was assumed to occur through droplets with ballistic trajectory that directly deposit on mucous membranes,

WHAT IS ALREADY KNOWN ON THIS TOPIC

The risk of SARS-CoV-2 transmission is likely to be greatest when in close proximity (<2 m) to someone who is infected

The potential for long distance airborne transmission (>2 m) is unclear, although widespread reporting of superspreader events suggests it may occur

Emission rates of respiratory particles released vary considerably between individuals but are generally higher for singing and speaking compared with breathing and tend to increase with loudness of vocalisation

WHAT THIS STUDY ADDS

The findings from this rapid systematic review suggest that long distance airborne transmission of SARS-CoV-2 might happen in indoor settings such as restaurants, public transport, workplaces, or choir venues

These results show that factors such as insufficient air replacement, directional air flow, and activities associated with increased emissions of respiratory particles (eg, singing or speaking loudly) might contribute to long distance airborne transmission

Well conducted epidemiological investigations can provide critical insight into transmission routes, especially when other types of studies are not feasible; the question of what level of public health evidence is sufficient to support decision making for a novel infection warrants further consideration

whereas airborne transmission was assumed to occur over longer distances via smaller particles (aerosols) that remained suspended in the air and were subsequently inhaled.^{10 11} Limitations of this dichotomy are well illustrated by the challenge in defining a size range to characterise particles that are droplets or aerosols.^{6 7 10 12} For example, the World Health Organization threshold is set at 5-10 microns¹³ whereas in the UK the threshold is based on the work by Milton¹⁴ and set to 100 microns.¹⁵ This is also complicated by the role of evaporation, as a particle will get smaller as it moves from human sources.

Regardless of terminology and definitions, it is now understood that short range transmission can occur through both droplets and aerosols and that the concentration of respiratory particles is higher at short range than over longer distances.^{7 11 16 17} Consensus is, however, still lacking on the risk for long distance airborne transmission in indoor settings in the community such as hospitality venues, leisure facilities, workplaces, or apartment blocks. This lack of consensus also reflects the challenging nature of the evidence base, and high quality review level evidence is still needed; some systematic reviews have relied on environmental sampling studies, which only provide indirect evidence of the potential risk of airborne transmission,¹⁸⁻²⁰ whereas systematic reviews that have included a wider range of study designs (epidemiological, environmental, and modelling) and settings (healthcare and community) remain inconclusive.²¹⁻²⁴

This gap needs to be addressed from a public health perspective, focusing on long distance transmission (>2 m) in indoor community settings. As evidence on the biological plausibility of long distance airborne transmission is available from environmental and experimental studies,^{18 21 22} we focused on epidemiological observational studies to assess where and when human-to-human transmission are likely to occur. In this rapid review we systematically identified and examined such studies to evaluate the potential for long distance airborne transmission of SARS-CoV-2 in indoor community settings and to assess the impact of potential modifying factors.

Methods

We used a rapid systematic review approach, following streamlined systematic methodologies to accelerate the review process,²⁵ and reported according to the Preferred Reporting Items for Systematic Reviews and Meta-Analyses (PRISMA) 2020 guidelines.²⁶ The protocol for this review was registered on PROSPERO before screening took place.²⁷

Data sources and searches

We identified primary studies through two sources. Firstly, we screened studies included in the rapid systematic review by Comber et al for those published from 1 January 2020 to 27 July 2020.²¹ This systematic review, assessed to be of moderate quality using the AMSTAR 2 (A MeaSurement Tool to Assess systematic

Reviews, revised) critical appraisal tool,²⁸ contains a comprehensive search strategy and wider inclusion criteria than the current rapid review (studies related to all airborne transmission of SARS-CoV-2) and was the only relevant review available at the time we wrote our protocol.

Secondly, we conducted electronic searches in Ovid Medline, Ovid Embase, medRxiv, Arxiv, and WHO COVID-19 Research Database for studies published from 27 July 2020 to 19 January 2022. The initial search was conducted on 8 February 2021 and last updated on 19 January 2022. The search strategy was drafted by an information scientist and peer reviewed by a second information scientist. Supplementary material 1 (section 1) shows the full search strategy.

Using the studies that met our inclusion criteria, we performed a citation analysis on 1 February 2022 on Web of Science and Cocites (co-citation analysis, forward and backwards snowballing). Although this was not part of the search strategy outlined in the protocol, it was agreed a posteriori by the review team to increase the chance of additional relevant studies being retrieved.

Eligibility criteria for study selection

Our eligibility criteria for study selection were published articles, accepted manuscripts, and preprints reporting on the potential for airborne transmission of SARS-CoV-2 in indoor community (non-healthcare) settings at a distance >2 m (the 2 m threshold is based on UK regulations; we also considered for inclusion non-UK studies that used thresholds based on their respective national recommendations, such as 1.5 m or 6 feet/1.8 m). The aim was to include all observational studies (outbreak investigations and epidemiological case series, cohort, case-control, and cross sectional studies) of any human population in non-healthcare settings. We excluded systematic or narrative reviews, guidelines, opinion pieces, intervention studies, modelling studies, environmental sampling studies without epidemiological investigation, laboratory or virology studies, and animal studies. We also excluded observational studies in which close contact or fomite were the most likely transmission routes (eg, studies reporting on transmission in households).

Screening was performed using Rayyan Systems, a freely available online screening tool.²⁹ Two reviewers independently screened the first 10% of records retrieved from the initial search on title and abstract, with substantial agreement (97.7%; Cohen's $\kappa=0.61$). A single reviewer screened the remainder, and two reviewers independently screened a further 10% (of the total number of records), with almost perfect agreement (99.6%; Cohen's $\kappa=0.92$). All records selected were screened at full text by one reviewer and checked by a second reviewer, with any discrepancies resolved by discussion with a third reviewer.

Outcomes

The primary outcomes were SARS-CoV-2 infections through long distance airborne transmission (at

a distance >2 m), and any factors that might have modified the risk of transmission under these conditions. Included measures for SARS-CoV-2 infections were number of covid-19 cases; secondary attack rates; risk, rate, or odds of transmission over the stipulated distances; or any other reported measure related to transmission rate. For the modifying factors, we considered narrative on the type of effect and any potentially relevant information to be acceptable.

Additional outcomes extracted, when available, were time spent in the setting and distance over which airborne transmission was thought to have occurred.

Data extraction and synthesis

We developed a data extraction table to gather information on methods, participants, settings, outcomes, key findings, and any additional relevant information (eg, whether participants wore face coverings). Data extraction was completed for each included study by one reviewer and independently checked by a second reviewer, with discrepancies resolved by discussion. Only evidence directly relevant to the review question was extracted. For example, if studies reported on different outbreaks or on onward transmission that might have happened in different settings, we only extracted the results of outbreaks or settings when distance and transmission routes could be assessed.

A narrative summary of results according to indoor setting was produced.

Quality assessment and certainty of evidence

We used a quality criteria checklist for primary research to assess the methodological quality of each included study.³⁰ This checklist tool is composed of 10 questions, four of which are considered critical (questions on selection bias, group comparability, description of exposure/assessment of transmission routes, and validity of outcome measurements). Strict criteria were used to assess the two critical questions related to exposure and outcome assessment. In particular, a cluster of covid-19 cases in the setting of interest had to be confirmed with viral genomic sequencing to be considered as low risk of bias for validity of outcome measurements. Supplementary material 1 (section 2) lists the 10 questions of the quality criteria checklist.

A study was rated as high methodological quality if the answers were yes to the four critical questions plus at least one of the remaining questions. A study was rated as low methodological quality if answers were no to ≥50% of the critical questions. Otherwise, the study was rated as medium methodological quality. Each study was assessed independently in duplicate, with disagreements resolved by consensus.

Certainty of the evidence was assessed using a variation of the Grading of Recommendations, Assessment, Development, and Evaluation (GRADE) framework for systematic reviews without meta-analysis.³¹ We assessed each of the five GRADE domains (methodological limitations of the studies,

indirectness, imprecision, inconsistency, and likelihood of publication bias) and classified them as no limitation or not serious (not important enough to warrant downgrading), serious (downgrading the certainty rating by one level), or very serious (downgrading the certainty rating by two levels). We then classified the body of evidence for a specific outcome as high certainty, moderate certainty, low certainty, or very low certainty.

Patient and public involvement

Patients and members of the public were not involved in this rapid systematic review mainly because of time restrictions. The review question was, however, developed with the input of several public health experts and stakeholders.

Results

Study selection

After removal of duplicates, 7439 records were screened for relevance on title and abstract, with 90 reports assessed for eligibility (fig 1). Fifty six additional reports identified from the Comber et al rapid review²¹ and by citation analysis were also assessed. From these 146 reports, 124 were excluded (see supplementary material 1 (section 3) for list of reasons for exclusion), and 22 reports^{1 32-52} relating to 18 studies were included. When two or more reports related to the same study, we considered the most comprehensive report as the main publication.

All the studies investigated outbreaks of clusters of SARS-CoV-2 infections, and one study had an analytical component.³⁶ Eight studies were conducted in Asia,^{34-40 45} five in Europe,^{41 43 44 47 48} three in Oceania,^{32 33 46} and two in the United States.^{1 42} Three studies reported on transmission between flats in apartment blocks,³⁸⁻⁴⁰ two in quarantine hotels,^{32 33} two in restaurants,^{34 35} two in buses,^{36 37} one in a food processing factory,⁴¹ one in a courtroom,⁴³ one in an office,⁴⁴ one in a fitness facility,⁴² one in a department store,⁴⁵ and four during singing events.^{1 46-48} All the outbreaks occurred in 2020, except for one in January 2021 in South Korea⁴⁰ (before vaccine rollout started in this country) and one in July 2021 in a quarantine hotel in New Zealand.³³

Table 1 and table 2 summarise the studies by setting. Supplementary material 2 provides detailed information on each study.

Quality assessment

Figure 2 provides details of the methodological quality ratings: three studies were rated as high quality,^{33 35 46} five as medium quality,^{32 34 36 41 47} and 10 as low quality.^{1 37-40 42-45 48} These ratings represent the methodological quality of descriptive studies.

Transmission settings

Quarantine hotels

Two outbreaks of covid-19 in quarantine hotels were identified, both in New Zealand and involving cases part of the same genomic cluster who had quarantined

RESEARCH

Fig 1 | Flow of articles through the review

in separate rooms. The first outbreak, reported by Eichler et al³² (rated as medium methodological quality) occurred in September 2020, and although primary and secondary cases had travelled on the same flight, transmission is believed to have happened in the hotel on day 12 of quarantine, after the primary case had developed symptoms on day 10. No information was provided on the measures in place at this quarantine hotel (eg, use of face coverings). The second outbreak, reported by Fox-Lewis et al³³ (rated as high methodological quality) occurred in July 2021. The primary case (asymptomatic) and secondary cases had travelled on different flights and arrived at the hotel on different days. Staff members, all vaccinated, wore full personal protective equipment and were regularly tested. Participants were asked to wear surgical masks when opening doors, but this could not be validated in the investigation. None of the cases (primary or secondary) were vaccinated; the only person who was vaccinated tested negative despite being part of the same travel group as the secondary cases.

Close contact and fomite transmission were ruled out by video analysis in both studies, although in the outbreak reported by Eichler et al³² fomite transmission through a communal bin—although unlikely, cannot be ruled out. Video analysis showed that in both outbreaks the doors of the rooms had

been opened simultaneously for a short period during which infected respiratory particles could have moved between rooms. Both investigations included a review of the ventilation systems and found that pressure differences between rooms and corridors could support this hypothesis. Long distance airborne transmission between a primary case and at least one secondary case was therefore considered to be the most likely route in both outbreaks.

Restaurants

Two separate outbreaks of covid-19 in restaurants were identified. The first outbreak, in China in January 2020, was mainly reported by Li et al³⁴ (rated as medium methodological quality), with additional evidence provided in two other reports.^{49 50} This outbreak involved a primary case (with symptom onset later that day) and at least two secondary cases who were seated on tables between 1.4 and 4.6 m away from the primary case. The second outbreak, reported by Kwon et al³⁵ (rated as high methodological quality), occurred in June 2020 in South Korea and involved three people with confirmed covid-19 who belonged to the same genomic cluster. The primary case, which was presymptomatic at the time, sat 6.5 m from one secondary case for five minutes, and 4.8 m from the other secondary cases for 21 minutes, all at different tables.

Table 1 | Summary of included studies, in chronological order by setting: quarantine hotels, restaurants, buses, and apartment blocks

Reference (quality rating)	Transmission event, setting, date	No of cases	Outcome and exposure assessment	Potential for other transmission routes	Potential for airborne transmission >2 m*	Modifying factors
Li et al, ³⁴ Lu et al, ⁴⁹ Zhang et al ⁵⁰ (medium)	Restaurant, China, January 2020	Ten confirmed cases from three tables	No genomic sequencing. Epidemiological data, video recording, on-site visit, design of air conditioning and ventilation system, experiments to assess airflow and ventilation rates	Close contact or fomite transmission unlikely (except for cases in same household). Transmission from outside event possible for some cases	Possible airborne transmission between primary case and at least two secondary cases; up to 1.4 m (53 min) and 4.6 m (75 min) from primary case	Insufficient air replacement. Directional air flow through air circulation units
Shen et al ³⁶ (medium)	Buses, China, January 2020	Twenty four confirmed cases	No genomic sequencing. Questionnaires and interviews, contact tracing data, bus design, and ventilation system	Close contact, fomite transmission, or transmission from outside event possible for some cases	Possible airborne transmission >2 m from primary case (50 min)	Insufficient air replacement. Directional air flow from central heating system
Luo et al, ³⁷ Ou et al ⁵¹ (low)	Buses, China, January 2020	Nine confirmed cases	No genomic sequencing. Epidemiological data, information on loading and unloading stops of all passengers, and seating positions, ventilation systems, tracer gas experiments	Close contact unlikely. Fomite transmission or transmission from outside event possible for some cases	Possible airborne transmission >2 m for some cases (1 hour to 2.5 hours)	Insufficient air replacement. Directional air flow due to exhaust system
Lin et al ³⁸ (low)	Apartment block, China, January 2020	Nine confirmed cases from three households	No whole genome sequencing (partial S gene only). Interviews with cases, CCTV of lift, tracer gas and wind speed experiments	Close contact or fomite transmission unlikely (except for cases in same household); transmission from outside event possible for some cases	Possible airborne transmission between cases in one flat to two different flats (up to 10 floors from flat of primary case)	Insufficient air replacement. Directional air flow through drainage and exhaust system
Kwon et al ³⁵ (high)	Restaurant, South Korea, June 2020	Three confirmed cases	Genomic sequencing. Contact tracing, interviews, credit card records, video recording, mobile phone location data, on-site visits, air flow measurement, environmental sampling	Close contact, fomite transmission, or transmission from outside event unlikely	Possible airborne transmission between cases seated 4.8 m (21 min) and 6.5 m (5 min) from the primary case	Insufficient air replacement. Directional air flow through air circulation units
Hwang et al ³⁹ (low)	Apartment block, South Korea, August 2020	Ten confirmed cases from seven households	No genomic sequencing. Epidemiological data, surface sampling, building assessment	Close contact or fomite transmission unlikely (except for cases in same household). Transmission from outside event possible	Possible airborne transmission through ventilation ducts across floors for some secondary cases	Directional air flow through vertical air duct or floor drain. Insufficient air replacement (unclear)
Eichler et al ³² (medium)	Quarantine hotel, New Zealand, August-September 2020	Nine confirmed cases, with one secondary case considered for long distance transmission	Genomic sequencing. Epidemiological data, surveillance video, review of ventilation system in hotel	Close contact or fomite transmission unclear. Transmission from outside event unlikely	Possible airborne transmission from hotel room of the primary case to doorway or corridor for one secondary case	Insufficient air replacement. Directional air flow
Han et al ⁴⁰ (low)	Apartment block, South Korea, January 2021	Five secondary cases (three households) considered for long distance transmission	Genomic sequencing. Epidemiological data, interviews, mobile phone location tracking, surface sampling	Close contact or fomite transmission unlikely (except for cases in same household). Transmission from outside event unlikely	Possible airborne transmission through floor drains across three floors for two secondary cases	Insufficient air replacement. Directional air flow through vertical floor drain
Fox-Lewis et al ³³ (high)	Quarantine hotel, New Zealand, July 2021	Five confirmed cases in two rooms	Genomic sequencing. Epidemiological data, surveillance video, review of ventilation system in hotel	Close contact, fomite transmission, or transmission from outside of event unlikely	Possible airborne transmission from hotel room of primary case to hotel room for at least one secondary case (2.1 m)	Insufficient air replacement. Directional air flow

This review's assessment of likelihood of airborne transmission of SARS-CoV-2 over distances >2 m is based on likelihood of it occurring in some, but not necessarily all, transmission events.

*Exposure distance and time are stated when known; if not stated they are categorised as not clear or not specified.

After extensive epidemiological and environmental investigations, both studies suggested that the most plausible route was long distance airborne transmission, which could have been facilitated by air circulation units generating a directional air flow from the primary to secondary cases combined with lack of air replacement. In both outbreaks close contact and fomite transmission were ruled out based on video surveillance analysis.

Buses and coaches

Two separate outbreaks of covid-19 on buses in China in January 2020 were identified, one on a journey to

and from a worship event among lay Buddhists³⁶ and one on a long distance journey using a public coach and minibus.^{37 51}

The outbreak at a worship event was reported by Shen et al³⁶ who conducted a retrospective epidemiological investigation with an analytical component (rated as medium methodological quality). Thirty one of the 300 participants tested positive for SARS-CoV-2 of whom seven were likely to have been infected by close contact transmission during the religious event. The other 23 cases had travelled to the event in the same bus as the primary case and were thought to have been mainly infected during the bus journey, throughout

RESEARCH

Table 2 | Summary of included studies, in chronological order by setting: department store, singing events, meat processing plant, fitness facility, courtroom, and office

Reference (quality rating)	Transmission event, setting, date	No of cases	Outcome and exposure assessment	Potential for other transmission routes	Potential for airborne transmission >2 m*	Modifying factors
Jiang et al ⁴⁵ (low)	Department store, China, January 2020	Twenty four cases, with 12 secondary cases considered for long distance transmission	No genomic sequencing. Epidemiological data, surveillance video, assessment of ventilation conditions	Close contact, fomite transmission, or transmission from outside event all possible	Unclear airborne transmission across different sections of the store	Not applicable
Hamner et al, ¹ Miller et al ⁵² (low)	Singing event, USA, March 2020	Fifty two: 32 confirmed cases, 20 probable cases	No genomic sequencing. Telephone interviews	Close contact or transmission from outside event possible for some cases. Fomite transmission unlikely	Possible airborne transmission >2 m for some cases, owing to high secondary attack rate (2.5 hours)	Insufficient air replacement. Increased aerosol emission—singing
Charlotte et al ⁴⁸ (low)	Singing event, France, March 2020	Nineteen: seven confirmed cases, 12 probable cases	No genomic sequencing. Questionnaire and telephone interviews	Close contact possible for some cases. Fomite transmission unlikely. Transmission from outside event possible for at least two cases	Possible airborne transmission >2 m for some cases, owing to high secondary attack rate (2 hours)	Insufficient air replacement. Increased aerosol emission—singing
Gunther et al ⁴¹ (medium)	Meat processing plant, Germany, May-June 2020	Thirty one confirmed cases	Genomic sequencing. On-site visit (work condition and ventilation system) and information provided by employer on housing, commuting, and workplaces of employees	Close contact and fomite transmission possible for some cases. Transmission from outside event unlikely	Possible airborne transmission for some cases on the production line, up to 12 m from the primary case	Insufficient air replacement. Directional air flow from air circulation system. Increased aerosol emission—physical work (unclear)
Groves et al ⁴² (low)	Fitness facility, USA, June 2020	Twenty one confirmed cases, with 10 secondary cases considered for long distance transmission	No genomic sequencing. Questionnaire and on-site assessment	Close contact possible for some cases. Fomite transmission unclear. Transmission from outside event unlikely	Possible airborne transmission >2 m for some cases, owing to high secondary attack rate (1 hour)	Insufficient air replacement. Directional air flow from air fan. Increased aerosol emission—shouting
Katellaris et al ⁴⁶ (high)	Singing event, Australia, July 2020	Thirteen confirmed cases	Genomic sequencing. Interviews with cases, video recording, on-site visit (ventilation system)	Close contact or fomite transmission unlikely (except for five cases in same household). Transmission from outside event unlikely	Possible airborne transmission with secondary cases seated 1-15 m from the primary case (1 hour)	Insufficient air replacement. Increased aerosol emission—singing
Vernez et al ⁴³ (low)	Courtroom, Switzerland, September 2020	Five confirmed cases	No genomic sequencing. Court records, contact tracing data, and field measurements	Close contact cannot be ruled out, especially for the two secondary cases at 1.5 m from the primary case. Fomite transmission unlikely. Transmission from outside event likely for one secondary case	Possible long distance airborne transmission for three secondary cases (1.5-3 m; 3 hours)	Insufficient air replacement
Shah et al ⁴⁷ (medium)	Five singing events, Netherlands, September-October 2020	Fifty: 48 confirmed cases and two probable cases	Genomic sequencing for seven cases. Phone and email correspondence, questionnaires, epidemiological data, aerosol transmission model	Close contact possible for some cases. Fomite transmission unlikely (except for one event). Transmission from outside event possible for some cases, but unlikely in others	Possible airborne transmission >1.5 m for some cases (1 hour to 2.5 hours)	Increased aerosol emission—singing. Directional air flow (unclear). Insufficient air replacement (unclear)
Sarti et al ⁴⁴ (low)	Office, Italy, November 2020	Five confirmed cases	No genomic sequencing. Telephone interviews	Close contact, fomite transmission, or transmission from outside event possible	Unclear airborne transmission between coworkers	Not applicable

The review's assessment of likelihood of airborne transmission of SARS-CoV-2 over distances >2 m is based on likelihood of it occurring in some, but not necessarily all, transmission events.

*Exposure distance and time are stated when known; if not stated they are categorised as not clear or not specified.

which no one wore face coverings. Those travelling on the bus with the primary case were 11 times more likely to develop covid-19 compared with the other participants (relative risk 11.4, 95% confidence interval 5.1 to 25.4; $P < 0.01$) and 42 times more likely compared with those travelling in the other bus (42.2, 2.6 to 679.3; $P < 0.01$). Close contact transmission, fomite transmission, and transmission from outside the event cannot be ruled out for some of the cases but are unlikely to have accounted for all 23 secondary cases.

The second outbreak, reported by Luo et al³⁷ (rated as low methodological quality) with additional environmental investigations conducted by Ou et al,⁵¹ involved one primary case (symptom onset occurred on the day of the event) who had travelled without wearing a face covering on a coach for 2.5 hours with 48 other individuals and then on a minibus for one hour with 12 other individuals. Nine secondary cases were identified, resulting in a secondary attack rate of 15% (95% confidence interval 6% to 24%), with most seated >2 m from the primary case: up to 4.5 m based

Fig 2 | Quality assessment. *Assessments using quality criteria checklist (QCC) for primary research (see supplementary material 1). †Critical questions: 2 on selection bias, 3 on group comparability, 6 on description of exposure/assessment of transmission routes, and 7 on validity of outcome measurements

on one report³⁷ and up to 9.5 m based on the other report.⁵¹ Genomic sequencing was not performed and, based on symptom onset dates, it is plausible that more than one primary case was present, reducing our confidence in the distances reported. However, even taking into account all potential primary cases, it is possible that airborne transmission occurred for some secondary cases seated >2 m from a primary case. Some passengers wore face coverings, but none of the secondary cases did.

In both outbreaks, insufficient air replacement and directional airflow from the heating system were hypothesised as promoting long distance airborne transmission, supported by tracer gas experiments in the buses involved in one of the outbreaks.⁵¹

Apartment blocks

Three outbreaks of covid-19 in three separate residential apartment blocks were identified. The study by Lin et al³⁸ (rated as low methodological quality) investigated an outbreak involving nine people who tested positive for SARS-CoV-2 in three flats of a 29 storey apartment block in China. The nine cases, identified between 27 January and 13 February 2020, lived in flats that shared drain and sewer pipes connected via an exhaust pipe to the roof. Except for

cases in the same household, close contact and fomite transmission were ruled out based on interviews with the cases and partial video analysis (lift only). Some but not all of the cases reported wearing face coverings in the communal areas of the building.

The two other outbreaks were in South Korea. The first, reported by Hwang et al³⁹ (rated as low methodological quality), occurred in August 2020 in an apartment block of 267 flats and involved 10 cases from seven households located around two ventilation ducts (eight cases around one, two around another). The second outbreak, reported by Han et al⁴⁰ (rated as low methodological quality), occurred in January 2021 in a complex of 260 flats, in which cases located in three flats along the same drainpipe and ventilation duct could not be explained by close contact or fomite transmission. For both outbreaks, transmission routes were mainly investigated through interviews with cases, and therefore recall bias (no video analysis) was possible. All cases reported wearing face coverings in the communal areas of the buildings.

For all three outbreaks, long distance airborne transmission between flats through vertical air ducts or floor drains was deemed possible for at least some of the secondary cases, although environmental investigation (tracer gas experiment) to support this

hypothesis was conducted in only one³⁸ of the three studies. In two of the three studies,^{38 40} the ventilation ducts were found to be malfunctioning, which could have contributed to transmission risk. However, only one of these studies³⁹ tested all residents and only one conducted whole genome sequencing,⁴⁰ which reduces confidence in the results.

Other indoor settings

The other outbreaks identified in this review occurred in a food processing factory,⁴¹ fitness facility,⁴² courtroom,⁴³ office,⁴⁴ and department store.⁴⁵

Gunther et al⁴¹ (rated as medium methodological quality) reported on an outbreak in a meat processing plant in Germany in May and June 2020 in which 31 out of the 140 workers on the same shift had tested positive for SARS-CoV-2 and were part of the same genomic cluster. Although close contact or fomite transmission in other areas of the processing plant and outside the factory (some workers shared accommodation and carpools) was possible for some cases, the spatial distribution of the cases suggested that transmission was likely to have occurred on the processing line at distances up to 12 m from the primary case who was asymptomatic. The authors hypothesised that factors such as increased respiratory rates (from physically demanding work), lack of air replacement, and continuous recirculation of cooled unfiltered air might have promoted long distance airborne transmission, but these were not investigated further. Some covid-19 measures were in place, including increased distance between workers and use of single layer face coverings, but adherence was not assessed as part of the study.

Groves et al⁴² (rated as low methodological quality) reported on an outbreak involving two fitness instructors at classes taught in three different facilities in June and July 2020, although the investigation suggested that close contact and fomite transmission were likely to have occurred in all classes but one. The class in which long distance airborne transmission might have happened was a one hour static cycling class in which bikes were placed at least 1.8 m apart, with doors and windows closed and three large fans directed towards the class participants. The instructor, who had shouted instructions while facing the participants, was identified as being the primary case (with symptom onset the next day) and all 10 class participants had tested positive for SARS-CoV-2 three to six days after the class. Face coverings had not been used during the class.

In an outbreak in a courtroom in Switzerland reported by Vernez et al⁴³ (study rated as low methodological quality), five out of the 10 participants at a three hour hearing held on the 30 September 2020 tested positive for SARS-CoV-2. The use of face coverings was mandatory in the building, but not when seated, and social distancing measures were in place, with a minimum of 1.5 m between each seat. Long distance airborne transmission (1.5-3 m) was likely to have happened between a primary case (with symptom onset on that day) and three secondary cases, although

close contact or fomite transmission after the hearing or in the bathroom cannot be ruled out. The hypothesis that a lack of air replacement (doors and windows were closed and there was no mechanical ventilation) might have promoted long distance airborne transmission was supported by field measurements and modelling.

Sarti et al⁴⁴ (rated as low methodological quality) reported on an outbreak in an office in Italy in which five of six coworkers were identified as cases. One of the five coworkers was identified as the primary case, and transmission happened before symptom onset. The sixth coworker, who was not infected, was not present in the office for the two days before symptom onset of the primary case. This transmission event happened in November and December 2020 when mitigation measures were in place, including social distancing, acrylic panels between desks, hand hygiene, and use of a face covering except when seated at a desk. The office was not well ventilated (no air conditioning and windows were closed), which could have promoted long distance airborne transmission. On the basis of the investigation, however, close contact, fomite transmission, and transmission from outside the event cannot be ruled out, so it is unclear as to whether long distance airborne transmission was the most likely route.

Jiang et al⁴⁵ (rated as low methodological quality) reported on an outbreak linked to a department store that occurred in January 2020 in Tianjin, China, involving 24 cases (six staff and 18 customers). Airborne transmission was considered as the most likely route of transmission between a primary case and 12 secondary cases, which might have been promoted by a lack of air replacement (doors were closed) and high density of people in the store. As genomic sequencing of SARS-CoV-2 was not performed, however, transmission from outside this event cannot be ruled out and, based on symptom onset dates, it is possible that several primary cases were present. On the basis of this investigation, it is unclear whether long distance airborne transmission had occurred in the store.

Singing events

In addition to transmission events associated with specific settings, four epidemiological investigations reporting on outbreaks linked to singing events were identified.

Katellaris et al⁴⁶ (rated as high methodological quality) reported on an outbreak in Sydney, Australia, linked to a series of four church services held between 15 and 17 July 2020. The probable primary case, a choir member, had sung at each of these one hour services, and 12 secondary cases were identified (2.4% secondary attack rate across the four services), who had sat in the same section of the church, between 1 m and 15 m from the primary case. Viral genomic sequencing of the primary case and 10 secondary cases showed a single genomic cluster, suggesting that transmission had occurred during the church services.

The second epidemiological investigation⁴⁷ (rated as medium methodological quality; preprint) reported on five singing events held between September and October 2020 in the Netherlands. At the time, national recommendations were in place to reduce covid-19 transmission, and although singing in groups was allowed, physical distancing (>1.5 m) and ventilation were recommended. Each singing event had between nine and 21 attendees, and attack rates of between 53% and 74% were observed. Fomite transmission was deemed unlikely in all but one event, but close contact transmission was considered possible for some of the secondary cases in three of the five events. However, owing to the high secondary attack rates, it is possible that at least some of the secondary cases had been infected via long distance airborne transmission and, even though ventilation through open doors or windows was reported for all events, air exchange rates were likely to have been low in at least three of the five events.

The two other outbreaks occurred in March 2020—that is, during the early stage of the pandemic when no mitigation measures were in place. One of them (70% attack rate, including probable cases) happened in France during a two hour choral rehearsal in a narrow, indoor, non-ventilated space⁴⁸ (study rated as low methodological quality). The second outbreak (87% secondary attack rate, including probable cases) after a 2.5 hour choral rehearsal on 10 March 2020 in Washington (USA) was initially reported by Hamner et al¹ (rated as low methodological quality) and further discussed by Miller et al.⁵² For both outbreaks, close contact and fomite transmission were only assessed through interviews and cannot be fully ruled out. The high secondary attack rate, however, suggests that long distance airborne transmission might have occurred for at least some of the cases.

The results from the four studies suggest that long distance airborne transmission was likely to have occurred for at least some of the transmission events, and that singing may have increased the amount of aerosol generated by the primary cases, which is consistent with modelling results reported by some of these authors.^{52 53}

Summary and critical analysis of results

Seven of the outbreaks identified^{1 34 36-38 45 48} occurred in the early stage of the pandemic (January-March 2020) when knowledge of covid-19 was limited, especially the incubation period and the extent of asymptomatic or presymptomatic transmission. As a result, most of these studies only conducted symptomatic testing and considered potential secondary cases to be participants with symptom onset soon after the potential exposure event, including the next day. In addition, for the studies conducted in January 2020 in China and in March 2020 in Europe or the US, it is possible that community transmission was higher than perceived at the time.

Therefore, in an outbreak such as the one reported by Luo et al³⁷ where no genomic sequencing was

conducted and three of the nine secondary cases developed symptoms or tested positive for SARS-CoV-2 one or two days after exposure, it is plausible that more than one primary case was present and that transmission occurred through means other than long distance airborne transmission. In two of the studies reporting on singing events,^{1 48} genomic sequencing and asymptomatic testing were not carried out and some of the secondary cases developed symptoms in the days after exposure but because of the high attack rates reported for these outbreaks, it is possible that long distance airborne transmission had happened for at least some of the transmission events. Long distance airborne transmission was also considered possible for two other early studies as a result of detailed epidemiological investigations.^{34 36} However, the plausibility of long distance airborne transmission for the outbreak in the department store was unclear as other transmission routes could not be ruled out.⁴⁵

Among the other studies, four^{33 35 41 46} provided convincing evidence for long distance airborne transmission as a result of detailed epidemiological investigations combined with genomic sequencing. Eichler et al³² also conducted genomic sequencing but their reporting of the epidemiological investigation was not sufficiently exhaustive to exclude other transmission routes (close contact or fomite) for the only secondary cases who could have been infected by long distance airborne transmission. The investigations by Shah et al,⁴⁷ Hwang et al,³⁹ Groves et al,⁴² Han et al,⁴⁰ and Vernez et al⁴³ suggested that long distance airborne transmission was possible for at least some of the transmission events (close contact or fomite could not be fully ruled out), but stronger conclusions could not be drawn owing to methodological limitations (including the absence of genomic sequencing and risk of selection bias). Finally, the likelihood of long distance airborne transmission was unclear in the outbreak in the office reported by Sarti et al⁴⁴ as, despite the covid-19 measures in place, close contact and fomite transmission could not be completely ruled out on the basis of the investigation.

Eleven of the 18 studies reported on the use of face coverings.^{33 35-44} Overall, the information provided was limited, and two of these studies only mentioned that face coverings were compulsory in the settings of interest (quarantine hotel³³ and food processing factory⁴¹) without reporting on adherence or behaviour (eg, whether workers wore face coverings correctly for the duration of their shift). Based on this limited information, we found no evidence of long distance airborne transmission where participants were known to have worn face coverings for the duration of exposure.

Only one of the outbreaks³³ identified occurred at a time when covid-19 vaccines were available, although in this outbreak the primary and secondary cases were not vaccinated.

Grading of the evidence

Table 3 provides the grading of the evidence for each of the primary outcomes: SARS-CoV-2 infection via

airborne transmission at a distance >2 m, insufficient air replacement (modifying factor), directional air flow (modifying factor), and increased aerosol emission when singing, speaking loudly, or doing intense physical work (modifying factor). Assessment of modifying factors was considered not applicable for the two outbreaks where the likelihood of long distance airborne transmission had been judged as unclear.

For all four outcomes, the evidence was judged as having methodological limitations owing to study design and to be at serious risk of imprecision owing to small numbers of participants as well as some risk of bias in exposure or outcome assessment, or both. However, the risks of inconsistency and indirectness were judged as not serious as the results were consistent across studies conducted in a range of settings and with different populations and provide evidence of direct relevance to the public health question of interest. The risk of publication bias was judged to be serious for the outcome of SARS-CoV-2 infection through airborne transmission at a distance >2 m and for the modifying factor of activities associated with increased emission of aerosols, but not serious for the modifying factors of insufficient air replacement and directional air flow. As a result, the certainty of evidence was judged as very low for all outcomes.

Because of high heterogeneity between studies, the additional outcomes of time spent in the transmission setting and distance over which airborne transmission was thought to have occurred could not be summarised or graded using the GRADE framework. Exposure timings ranged from five minutes to three hours, and distances were up to 15 m.

Discussion

Evidence from the outbreak investigations discussed in this review suggests that airborne transmission of SARS-CoV-2 from an infectious individual to others located >2 m away can occur in different indoor non-healthcare settings. The results of this review show that when long distance transmission occurred, one or more factors were thought to have contributed. Modifying factors such as insufficient air replacement and singing are likely to result in an increased concentration of infectious respiratory particles within the indoor space, whereas factors such as directional air flow are likely to allow viable virus to travel further in a certain direction, which could potentially infect someone downstream of a primary case. The results of this review therefore confirm the importance of the role of ventilation to mitigate the risk of long distance aerosol transmission.⁵⁴⁻⁵⁷

A total of eight events (from four studies) in which singing may have contributed to long distance airborne transmission were identified.^{1 46-48} These results are in line with experimental and modelling studies that have reported on singing and aerosol generation, suggesting that more virus-containing respiratory particles tend to be emitted when singing compared with speaking or breathing.^{53 58} More generally, the quantity of respiratory particles emitted increases with

loudness of vocalisation,^{59 60} which was thought to have contributed to long distance aerosol transmission in a fitness facility.⁴²

In 13 out of 18 studies identified,^{33-37 41-48} suspected primary cases were asymptomatic, presymptomatic, or near the time of symptom onset when transmission occurred. This finding is consistent with wider evidence that people with asymptomatic or presymptomatic SARS-CoV-2 infection can contribute to the community spread of covid-19,⁶¹⁻⁶³ including from long distance airborne transmission.

Although the evidence on face coverings was limited, no outbreaks in which participants had been wearing face coverings for the duration of the exposure were identified. Evidence suggests that face coverings can reduce the number of respiratory particles emitted from the nose and mouth.⁶⁴ However, it is not possible to deduce from the evidence assessed in this review if wearing a face covering can prevent or reduce the risk of long distance transmission of SARS-CoV-2.

Most of the outbreaks we identified occurred at a time when population immunity was limited, either naturally acquired or vaccine mediated. This limits the applicability of our findings to the current context, although there is evidence that transmission of SARS-CoV-2 after vaccination does occur.⁶⁵ While the lack of evidence identified in vaccinated populations may to some extent reflect the successes of vaccine rollout, there may also be a time lag in publication of outbreak reports since vaccine programmes were initiated. There may also be less interest in publishing reports on SARS-CoV-2 associated outbreaks over time.

The evidence from our rapid systematic review was deemed to be of very low certainty based on 18 studies. The relatively small number of studies identified could suggest that outbreaks related to long distance airborne transmission are rare, although also likely to result from difficulties in identifying such events or to under-reporting—for example, in countries without sufficient contact tracing. It can also be partly explained by the level of detail needed to assess transmission routes. Indeed, even outbreak investigations that follow reporting guidelines such as the Outbreak Reports and Intervention studies Of Nosocomial infection (ORION) statement published by the Canada Communicable Disease Report⁶⁶ are not necessarily thorough enough to be able to fully rule out other transmission routes. As a result, several outbreaks in which long distance airborne transmission may have happened were excluded on full text, including a few reports on clusters in aeroplanes that did not properly consider transmission routes during boarding and disembarking.⁶⁷⁻⁷⁰ Finally, the wider challenges of the pandemic should be acknowledged, including the limited resources in public health teams to conduct detailed epidemiological investigations.

The outcomes were rated as being of very low certainty using the GRADE framework, although this reflects the principles of GRADE rather than a lack of quality of the included studies because in traditional evidence hierarchies, outbreak investigations are

Table 3 | Summary of findings using Grading of Recommendations, Assessment, Development, and Evaluation approach

Outcome	Effect	No of studies	Certainty in the evidence
SARS-CoV-2 infection through airborne transmission over a distance >2 m	Sixteen studies suggested that long distance airborne transmission was the main transmission route for at least some of the transmission events in the reported outbreaks. Unclear in two studies	18	Very low owing to methodological limitations of the studies and serious risk of imprecision and publication bias
Modifying factor: insufficient air replacement	Fourteen studies suggested that insufficient air replacement had increased the likelihood of long distance airborne transmission. Unclear in two studies	16	Very low owing to methodological limitations of the studies and serious risk of imprecision
Modifying factor: directional air flow	Eleven studies suggested that directional air flow might have increased the likelihood of long distance airborne transmission. Unclear in one study	12	Very low owing to methodological limitations of the studies and serious risk of imprecision
Modifying factor: activities associated with increased emission of aerosols	Five studies (reporting on nine events) suggested that singing and speaking loudly might have increased the likelihood of long distance airborne transmission. Unclear in one study (intense physical work)	6	Very low owing to methodological limitations of the studies and serious risk of imprecision and publication bias

classed as a low level of evidence. However, some of the included studies were well conducted investigations of covid-19 outbreaks and their contribution to this particular research question should not be underestimated—they provide critical insight where other types of study are just not feasible.⁷¹ The GRADE framework was developed to inform clinical practice where randomised controlled trials are feasible, and linear causal pathways are more often the norm. Public health research does not always fit easily within this framework and the question of what level of public health evidence is sufficient to support decision making for a novel infection warrants further consideration.

Comparison with other studies

These findings are an important addition to the wider body of evidence that supports the biological plausibility of airborne transmission as a potentially important route of transmission in certain scenarios. The wider evidence includes experimental evidence from animal studies⁷² as well as experimental studies that have shown that SARS-CoV-2 can remain viable in artificially generated aerosols for up to 16 hours, and that the stability and viability depends on environmental factors such as temperature, humidity, and exposure to sunlight.²² Similarly, biological monitoring studies have shown that SARS-CoV-2 RNA can be detected in exhaled breath and environmental air samples, but the evidence on viable virus remains limited to a few studies that mostly detected infectious virus in air samples collected at <2 m from the infectious individual.²²⁻²⁴ These experimental and biological studies provide evidence that SARS-CoV-2 can be viable in aerosols and therefore support the epidemiological evidence from this rapid review, and from others^{22,23} that suggest that airborne transmission can happen in some settings.

Strengths and limitations of this review

This rapid systematic review critically assessed the likelihood of long distance airborne transmission of SARS-CoV-2 using only direct real world evidence from observational studies from indoor non-healthcare settings. The application of inclusion criteria that focused the critical appraisal on those studies, which involved comprehensive investigations, is a key

strength of our approach: some of these studies not only included epidemiological data, but also genomic analysis, video surveillance, analysis of seating arrangements, and environmental hypothesis testing.

The main limitation of selecting studies of only real world human-to-human transmission events is that scenarios where transmission has not occurred were not included, and likewise where transmission events have not been detected by contact tracing systems, which could be seen as a form of publication bias. All the evidence is from retrospective epidemiological investigations of outbreaks and therefore this review cannot make inferences on the extent to which long distance airborne transmission occurs or the contribution it may have on community rates of transmission: these remain critical questions for policy and practice. In addition, most of the outbreaks occurred before vaccine rollouts and it is unclear how these results apply to populations with a high level of immunity to infection. Finally, and as with all reviews assessing evidence related to covid-19, this rapid review is limited by the fact that the evidence assessed is from an emerging specialty.

Future work and policy implications

Well conducted outbreak investigations continue to be needed to assess the potential for long distance airborne transmission in vaccinated populations, and with more transmissible SARS-CoV-2 variants such as omicron. To assess transmission routes, such outbreak investigations should deploy robust and mixed methods, ranging from genomic analysis to environmental assessment, and they should be conducted as early as possible to reduce recall bias.

The results from this rapid systematic review highlight the need to ensure measures to mitigate SARS-CoV-2 long distance transmission in indoor settings, especially in poorly ventilated spaces. Identification of poorly ventilated public spaces should be undertaken and improvements made. Other factors such as directional air flow or singing that could increase the risk for long distance airborne transmission should also be considered in risk mitigation.

A need also exists to develop a new framework, or to adapt the existing GRADE framework, to support a pragmatic and consistent approach to the collation,

interpretation, and synthesis of epidemiological investigations, especially when other types of studies are not feasible. The question of what level of public health evidence is sufficient to support decision making for a novel infection warrants further consideration.

Conclusion

This rapid review found evidence suggesting that long distance (>2 m) airborne transmission of SARS-CoV-2 might happen in indoor non-healthcare settings, and that it can occur from people who are asymptomatic or presymptomatic. All transmission events identified occurred alongside factors believed to have contributed to this type of transmission, including lack of air replacement (absence or little ventilation with fresh air), directional air flow (mainly through air circulation systems), and activities such as singing that increased aerosol emission. In the review, we found no evidence of long distance airborne transmission occurring without one or more of these factors present.

Based on the results from this review, indoor non-healthcare settings that might be at risk of long distance airborne transmission include hospitality settings such as restaurants, public transport, and workplaces with inadequate ventilation, as well as settings where activities resulting in increased aerosol emission, such as singing or speaking loudly are carried out.

These results highlight the importance of assessing ventilation, especially in indoor spaces where people meet others from outside their household. Particular attention should be given to ventilation in settings with activities that might increase the number of respiratory particles, for example, singing. Where ventilation is assessed to be inadequate, improvements should be made.

We thank colleagues within the UK Health Security Agency for their support into specific aspects of this review, especially Jason Kwasi Sarfo-Annin, Bethany Walters, and Marialena Trivella. JCP is supported by a British Heart Foundation accelerator award (AA/18/7/34219) and works in a unit that is supported by the University of Bristol and UK Medical Research Council (MC_UU_00011/6) and was also supported by a secondment to the COVID-19 Rapid Evidence Service.

Contributors: DD and JCP contributed equally. JCP, RC, NPS, and DD designed the review, with input from EOC and AB. NPS conducted the literature searches and citation analysis. JCP, DD, and IT conducted the screening and data extraction. DD and JCP conducted the critical appraisal, interpreted the findings, and drafted the manuscript, with further input from RC, EOC, and AB. RC supervised the study and is the study guarantor. All authors had direct access to the data, or access was provided as requested. The corresponding author attests that all listed authors meet authorship criteria and that no others meeting the criteria have been omitted.

Funding: No specific funding.

Competing interests: All authors have completed the ICMJE uniform disclosure form at www.icmje.org/disclosure-of-interest/ and declare: no support from any organisation for the submitted work; AB reports grant funding from UK Research and Innovation (UKRI) and from PROTECT (National Core Study on Transmission and the Environment); no other relationships or activities that could appear to have influenced the submitted work.

Ethical approval: Not required.

Data sharing: Data are from published research and therefore are in the public domain. Extracted data are available in supplementary material 2.

The manuscript's guarantor (RC) affirms that the manuscript is an honest, accurate, and transparent account of the study being

reported; that no important aspects of the study have been omitted; and that any discrepancies from the study as planned (and, if relevant, registered) have been explained.

Dissemination to participants and related patient and public communities: This paper will be shared widely within the UK Health Security Agency and used to inform relevant guidance. It will also be shared with relevant stakeholders, policy makers, and other public health agencies within the United Kingdom and internationally. Further dissemination will include our website <https://ukhsalibrary.koha-ptfs.co.uk/covid19rapidreviews/> and through colleagues working in covid-19 evidence synthesis.

Review of Fungal Outbreaks and Infection Prevention in Healthcare Settings During Construction and Renovation

Hajime Kanamori,^{1,2} William A. Rutala,^{1,2} Emily E. Sickbert-Bennett,^{1,2} and David J. Weber^{1,2}

¹Hospital Epidemiology, University of North Carolina Health Care, and ²Division of Infectious Diseases, University of North Carolina School of Medicine, Chapel Hill

Hospital construction and renovation activities are an ever-constant phenomenon in healthcare facilities, causing dust contamination and possible dispersal of fungal spores. We reviewed fungal outbreaks that occurred during construction and renovation over the last 4 decades as well as current infection prevention strategies and control measures. Fungal outbreaks still occur in healthcare settings, especially among patients with hematological malignancies and those who are immunocompromised. The causative pathogens of these outbreaks were usually *Aspergillus* species, but Zygomycetes and other fungi were occasionally reported. *Aspergillus* most commonly caused pulmonary infection. The overall mortality of construction/renovation-associated fungal infection was approximately 50%. The minimal concentration of fungal spores by air sampling for acquisition of fungal infections remains to be determined. Performing infection control risk assessments and implementing the recommended control measures is essential to prevent healthcare-associated fungal outbreaks during construction and renovation.

Keywords. fungal outbreaks; *Aspergillus*; healthcare-associated infections; construction; renovation.

Numerous fungal outbreaks have occurred in healthcare settings and have been a serious threat to immunocompromised hosts [1]. Construction and renovation activities can cause serious dust contamination and disperse large amounts of fungal spores, and construction activity has been reported to be an independent risk factor for invasive fungal infections [1,2]. A previous review revealed that construction or renovation activities within the hospital or in surrounding areas accounted for approximately half of the sources of healthcare-associated *Aspergillus* outbreaks [2]. Hospital construction and renovation activities are an ever-constant phenomenon [2], and the cost of hospital construction is expected to be nearly \$200 billion dollars by 2015 in the United

States [3]. It is estimated that 5000 deaths due to construction-related infections occur each year in healthcare settings [4].

The goal of this review article was to (1) examine fungal outbreaks that were related to hospital construction, renovation, and/or demolition over the last 4 decades; and (2) offer infection prevention and control measures in healthcare facilities based on previous experiences, evidence, and guidelines.

SEARCH AND SELECTION CRITERIA

To select relevant articles, we searched the published literature in PubMed using the following keywords [All Fields]: (aspergillosis OR *Aspergillus* OR Zygomycetes OR Mucor OR mycoses OR mycosis OR fungi) AND (hospital OR healthcare OR nosocomial) AND (construction OR renovation) AND (outbreak OR contamination OR infection OR prevention OR control). From 1974 through 2014, 158 references were carefully reviewed. Additional reports were also identified through the references cited. Finally, 49 studies [5–53] were

Received 10 February 2015; accepted 4 April 2015; electronically published 13 April 2015.

selected for the analysis, including all cases of outbreaks that were related to hospital construction, renovation, or demolition. We excluded non-English publications, reported cases of contaminations or *Candida* species only, and reports that did not include human infections. We used each author's definition in the selected articles to classify construction, renovation, demolition, and excavation. Definitive outbreaks (pseudo-outbreaks were not included) are summarized in Table 1.

FUNGAL OUTBREAKS ASSOCIATED WITH CONSTRUCTION AND RENOVATION AT EACH 5-YEAR TIME PERIOD

The trend of outbreaks that were related to construction, renovation, and demolition by 5-year period of publication from 1970 to the present is shown in Figure 1. The first report was published in 1976 [5], and the reported cases of outbreaks increased gradually. There were 7–10 articles of outbreaks associated with construction, renovation, and demolition in each 5-year period during 1985–2009; however, in the last period, 2010–2014, there were only 3 published studies that had been conducted before 2010. This reduction in reported outbreaks may represent improved infection control that resulted in fewer outbreaks or publication bias (by authors or journals) given the large number of previously published outbreaks.

SETTINGS WHERE FUNGAL OUTBREAKS AND INFECTIONS OCCURRED, AND PATIENT POPULATIONS AT RISK

Healthcare-associated fungal outbreaks have been reported throughout the world [2]. In this review of English-language studies that focused on construction and renovation, the United States accounted for 47% (23/49 articles), followed by European countries, including the United Kingdom (8%), Italy (8%), and France (8%). University hospitals were the most common (35%) settings. Tertiary care hospitals and university hospitals have often implemented the most medically advanced treatment in a given era (eg, cancer chemotherapy, immunosuppressive therapy, and transplant), which likely accounts for the overrepresentation of academic centers because of their highly susceptible patient populations.

Susceptible populations for healthcare-associated *Aspergillus* infections included patients with the following characteristics: hematological malignancies, allogeneic hematopoietic stem cell transplant (HSCT), solid organ transplant (renal and liver), high-dose steroid therapy, neonates, other malignancies, chronic lung disease, residing in intensive care units (ICUs), and thoracic surgery [2]. The main risk factors for healthcare-associated mucormycosis were prolonged steroid therapy, solid organ transplant, diabetes mellitus, prematurity, and hematological malignancies [54].

In this review, hematologic malignancies or bone marrow transplant accounted for 53% of reports by underlying diseases, and construction-related fungal infections occurred infrequently among rheumatology patients, patients after surgery, premature infants, and nephrology and dialysis patients (Table 2).

FEATURES OF FUNGAL OUTBREAKS AND INFECTIONS AND THOSE CAUSATIVE PATHOGENS

The primary infection site was mainly lower respiratory tract in healthcare-associated *Aspergillus* outbreaks as air was the major transmission route of fungal spore, whereas surgical site infections and skin infections were rarely described [2]. Of the 41 articles reporting *Aspergillus* infection only, the major site of *Aspergillus* infection was lung only (19 articles [46%]), followed by lung with other sites (8 articles [20%]), skin/wound (3 articles [7%]), sinus with other sites (1 article), eye (1 article), and disseminated (1 article). An outbreak of *Aspergillus fumigatus* endophthalmitis after cataract surgery during construction has been described [32]. The causative pathogens of fungal outbreaks and infections were usually *Aspergillus* species, including *A. fumigatus*, *Aspergillus flavus*, *Aspergillus terreus*, and *Aspergillus niger*, but occasionally Zygomycetes and other fungi, which was similar to a previously published article [55]. Six construction-related cases of healthcare-associated pulmonary mucormycosis due to *Mucor indicus* or *Cunninghamella bertholletiae* have been reported [9, 34], although it was difficult to differentiate healthcare-acquired from community-acquired mucormycosis, as most of those infections in hospitalized patients are sporadic in nature [56].

Furthermore, there were 4 articles of pseudo-outbreaks associated with construction and renovation, including a pseudo-epidemic of *Sporothrix cyanescens* pneumonia due to bronchoscopy material contaminated by dust created during renovation of the bronchoscopy suite [57]; pseudo-fungemia of *Aspergillus* species and *Penicillium* species from contamination of plates that had been inadvertently left open to air on a workbench area connected to locations outside the laboratory during renovation [58]; pseudo-epidemic of *A. niger* cultures traced to specimen contamination in the laboratory during construction [59]; and pseudo-outbreak of *Aspergillus sydowii* keratitis due to environmental contamination of culture media following construction in an ophthalmology ward [60].

Invasive aspergillosis is an independent predictor of mortality, and the overall case-fatality rate among the published reports was 58%, ranging from 25% in cutaneous cases to 88% in disseminated or central nervous system cases [61, 62]. Death attributable to mucormycosis differed from 50% to 100% by each report [54]. This review revealed that the overall mortality of fungal outbreaks and infections associated with construction

Table 1. Characteristics of Fungal Outbreaks and Infections Associated With Construction, Renovation, and Demolition

Author, Year	Patient Population	No. of Patient Infected	No. of Patient Deaths	Type of Infection (Site)	Type of Fungi	Reservoir or Source	Airborne Fungal Level(s)	Molecular Typing	Control Measures
Aisner, 1976 [5]	Cancer patients	8	Unknown	<i>Aspergillus</i> infection (lung, pharyngeal, or maxillary sinus)	<i>Aspergillus</i> spp. (predominantly <i>A. niger</i> , <i>A. flavus</i> , <i>A. fumigatus</i>)	Fireproofing material sprayed wet during construction	Unknown	Unknown	Unknown
Arnou, 1978 [6]	Immunosuppression (renal transplant)	3	1	<i>Aspergillus</i> infection (lung)	<i>A. fumigatus</i> , <i>Aspergillus</i> sp.	Renovation, spores on dust from false ceiling tiles above transplant unit	Airborne spores >200 cfu below renovation	Unknown	Impermeable plastic barriers, immunosuppressed patients moved to other floors, horizontal surfaces, vacuumed, damp mopped, and dusted
Sarubbi, 1982 [8]	Hospitalized patients (acute nonlymphocytic leukemia for 1 infected)	1	1	Invasive <i>Aspergillus</i> infection (lung)	<i>A. flavus</i>	Construction, defective ventilation and air filtration	8 <i>A. flavus</i> /positive room, control 1 <i>A. flavus</i> /positive room-settle plates	Unknown	Pre-filters and filters in ventilation system replaced
Lentino, 1982 [7]	Immunosuppressed patients with renal allograft recipients or hematologic malignancy	10	4	Invasive <i>Aspergillus</i> infection (lung)	<i>Aspergillus</i> sp.	Road construction for access to the new hospital, contaminated window air conditioners in renal transplantation ward	400–2800 <i>Aspergillus</i> spores/cm ² from air conditioner filter	Unknown	Unknown
Krasinski, 1985 [9]	Premature infants	2	2	Fungal infection (lung)	<i>Aspergillus</i> sp., Zygomycetes, <i>Rhizopus indicus</i>	Renovation of adjacent special care unit and demolition of wall, mold in dust above a false ceiling	0.88 fungi per hour per settle plate compared to 0.22 fungi per hour per settle plate in construction free area	Unknown	Patients moved from area of construction, additional dampers placed in air ducts, impervious dust barriers erected, area above false ceiling and ventilation ducts vacuumed, replaced HEPA filters, air ducts and environmental surfaces disinfected
Opal, 1986 [10]	Immunocompromised (lymphoreticular malignancy, high-dose corticosteroid therapy or disseminated carcinoma)	11	11	<i>Aspergillus</i> infection (disseminated)	<i>A. flavus</i> , <i>A. fumigatus</i> , <i>A. niger</i> , <i>Aspergillus</i> sp.	Hospital renovation and construction	5.9 ± 0.7 <i>Aspergillus</i> /m ³ inside construction site compared to 1.2 <i>Aspergillus</i> /m ³ outside construction site	Unknown	Copper-8 quinolinolate, airtight plastic and dry wall barriers about the construction site, HEPA filters in patients room, and negative pressure in construction area
Barnes, 1989 [14]	Children undergoing BMT	6	6	Invasive <i>Aspergillus</i> infection (lung)	Unknown	Building work installing a laminar air flow system to the unit	133 cfu/m ³ of <i>A. fumigatus</i> in the BMT unit during building work	Unknown	Laminar air flow isolation
Humphreys, 1991 [19]	Severe patients in the ITU	2	2	Invasive <i>Aspergillus</i> infection (lung)	<i>A. fumigatus</i> , <i>A. flavus</i>	Building work in an area adjacent to the ITU, disturbance of spores in fibrous insulation material above the perforated metal ceiling	Sampling after building work completed, but no molds isolated	Unknown	Improved hospital design, satisfactory ventilation, thorough regular cleaning of environmental surfaces, and relocation of patients

Table 1 continued.

Author, Year	Patient Population	No. of Patient Infected	No. of Patient Deaths	Type of Infection (Site)	Type of Fungi	Reservoir or Source	Airborne Fungal Level(s)	Molecular Typing	Control Measures
Brincker, 1991 [18]	Acute leukemia	10	4	<i>Aspergillus</i> infection (lung)	Unknown	Indoor building renovation, increased spores in ward locations with heavy traffic of patients and staff	At least 11.2 <i>Aspergillus</i> per 24h-settle plate	Unknown	Unknown
Flynn, 1993 [20]	BMT recipients, acute myeloid leukemia, or disseminated choriocarcinoma	4	4	<i>Aspergillus</i> infection (lung)	<i>A. terreus</i>	Hospital renovation, entry of fungal organisms from corridors, stairwells, elevator, shafts serving the ICU and renovation areas due to the negative air pressure gradient	Fungal spores >71/m ³ at elevator shafts during renovation	Unknown	Reestablished positive pressure and unidirectional airflow
Iwen, 1994 [22]	Neutropenic patients who underwent high-dose chemotherapy	5	Unknown	Invasive <i>Aspergillus</i> infection (unknown)	<i>A. fumigatus</i> , <i>A. flavus</i>	Hospital construction, increase in molds in the air occurred in the patient rooms and corridor adjacent to construction staging area, windows in the adjacent corridor as the most likely source of mold contamination	0.14 cfu fungi per hour per settle plate (before construction) to 0.40 cfu fungi per hour per settle plate (after construction)	Unknown	Special care unit closed to incoming patients, window casements, plumbing penetrations, electrical outlets, and other sources for potential air leaks visually examined and sealed, HEPA filters replaced, each room terminally cleaned with subsequent follow-up testing by air-settling plates
Buffington, 1994 [21]	Acute leukemia or aplastic anemia	7	6	Invasive <i>Aspergillus</i> infection (unknown)	<i>A. flavus</i> , <i>A. fumigatus</i> , <i>Aspergillus</i> sp.	Construction activity, staff and visitors frequently walking through breezeway by the construction	Unknown	Randomly amplified polymorphic DNA (6 different pattern, similar pattern banding from case patient, healthcare worker, and environmental source)	Laminar air flow rooms with HEPA filters, air intake ducts decontaminated with formaldehyde vapor
Loudon, 1994 [23]	Hematologic malignancies (acute lymphoblastic leukemia, acute myeloid leukemia, lymphoma, Hodgkin's disease)	7	5	Invasive <i>Aspergillus</i> infection (lung)	<i>A. fumigatus</i> , <i>A. flavus</i>	Extensive building work was ongoing on the ground floor beneath the hematology unit, <i>Aspergillus</i> for showerhead	Unknown	Silver staining of sodium dodecyl sulphate-immunoblot fingerprinting, and random amplification of polymorphic DNA (3 cases indistinguishable)	Itraconazole prophylaxis

Table 1 continued.

Author, Year	Patient Population	No. of Patient Infected	No. of Patient Deaths	Type of Infection (Site)	Type of Fungi	Reservoir or Source	Airborne Fungal Level(s)	Molecular Typing	Control Measures
Anderson, 1996 [25]	Immunocompromised pediatric patients with leukemia or neuroblastoma	6	Unknown	Nosocomial <i>Aspergillus</i> infection (lung, blood, pericardial fluid, or cardiac vegetation)	<i>A. fumigatus</i> , <i>A. terreus</i> , <i>A. flavus</i> , <i>A. niger</i> , <i>Aspergillus</i> sp.	Defective disposal conduit door and dispersal of contaminated aerosol from the ward vacuum cleaner	62 <i>Aspergillus</i> /m ³ close to vacuum cleaner during use	Unknown	Disposal door sealed, vacuum cleaner replaced by a machine of higher efficiency, itraconazole prophylaxis
Loo, 1996 [28]	Patients with leukemia or BMT	36	17	Nosocomial <i>Aspergillus</i> infection (lung, sinus)	<i>A. flavus</i> , <i>A. fumigatus</i> , <i>A. niger</i>	Archaic ventilation system in hospital which could not filter the <i>Aspergillus</i> spores that were disturbed and dispersed to patient-care areas during construction activity	6.77 <i>Aspergillus</i> sp./m ³ during the epidemic period	Unknown	Portable HEPA filter air purifier units, application of copper-8-quinolinate formulation, windows sealed, existing perforated ceiling tiles replaced with the easy-to-clean, non-perforated tiles, vinyl-faced aluminum tiles, horizontal dust-accumulating blinds replaced with vinyl, opaque, roller shades, ventilation systems meticulously maintained, patient rooms cleaned regularly, patients moved to another area of the hospital and housed in single rooms with doors closed
Thio, 2000 [35]	Patients with leukemia or BMT	21	6	Invasive <i>Aspergillus</i> infection (sinus and other)	<i>A. flavus</i>	Construction of a new building adjacent to the oncology center, negative pressure in the oncology unit	0.8–18 <i>A. flavus</i> /1,000L	Randomly amplified polymorphic DNA (2 of 5 patient samples and 5 environmental samples identical)	Use of wet buffing to clean all floors, N95 masks to protect neutropenic patients outside filtered areas, portable HEPA at entrance, change of traffic patterns into the unit, windows and exterior walls resealed, doors to patient rooms kept closed, hospital construction policy developed, closing central stairwell
Lai, 2001 [37]	Patients undergoing BMT and neutropenia	2	2	Invasive <i>Aspergillus</i> infection (lung)	<i>Aspergillus</i> sp., <i>A. flavus</i>	Construction below the unit, but no link to the construction by air sampling	0.5–5.9/0 <i>Aspergillus</i> cfu/m ³ , 5.9–23.6/0.4–> 11.6 other filamentous fungi cfu/m ³ (precleaning/postcleaning)	Unknown	BMT unit closed, air intake ducts cleaned, HEPA filters replaced, double plastic coverings across the entryways to construction sites, stairwell sealed with negative pressure, carpeting replaced by vinyl flooring, prophylactic amphotericin B
Burwen, 2001 [36]	Neutropenic patients in hematology-oncology ward	6	Unknown	Invasive <i>Aspergillus</i> infection (lung, blood, ear tissue, and other)	<i>A. flavus</i>	Internal construction on a new west wing adjacent to the hematology-oncology ward and renovation of patients' room	Unknown	Randomly amplified polymorphic DNA (patient isolate matched an environmental isolates matched)	Unknown

Table 1 continued.

Author, Year	Patient Population	No. of Patient Infected	No. of Patient Deaths	Type of Infection (Site)	Type of Fungi	Reservoir or Source	Airborne Fungal Level(s)	Molecular Typing	Control Measures
Oren, 2001 [38]	Acute leukemia	31	8	Invasive <i>Aspergillus</i> infection (lung)	<i>Aspergillus</i> sp.	Extensive hospital construction and indoor renovation	15 <i>Aspergillus</i> /m ³ at construction site	Unknown	Amphotericin B prophylaxis, and HEPA system
Read, 2002 [39]	Neutropenic patients with hematologic malignancy	113	Unknown	Nosocomial invasive <i>Aspergillus</i> infection (lung)	<i>A. fumigatus</i> , <i>A. terreus</i> , <i>A. flavus</i>	Hospital construction (low-intensity construction and high-intensity construction)	5–29 fungi/m ³ in outdoor air during low-intensity construction, 1–71 fungi/m ³ in outdoor air during high-intensity construction and 1–2 fungi/m ³ in indoor air	Unknown	Physical barriers using floor-to-ceiling dry wall or plastic barriers, protected environment with laminar air-flow rooms, HEPA filter, use of high-efficiency filtration masks for patients when leaving rooms
Yonemori, 2002 [40]	Acute leukemia	4	0	Invasive fungal infection (lung)	Unknown	Demolition and excavation near new building	65 fungi/m ³ at construction area; 10 fungi/m ³ in patient rooms	Unknown	Windows sealed, use of portable open horizontal laminar-air-flow apparatuses placed at bedside of neutropenic patients, itraconazole prophylaxis
Panackal, 2003 [42]	Renal transplant recipients	4	4	Invasive <i>Aspergillus</i> infection (unknown)	<i>A. fumigatus</i>	Inappropriate barriers between construction site and ward, frequent trafficking of staff between the construction and patient care areas, few respiratory protection	Unknown	Restriction fragment length polymorphism (genotype matched between 2 patients and 2 environmental isolates, but no match between environmental and clinical isolate)	Recommend application of CDC guideline such as: appropriate placement of impermeable barriers, the use of HEPA filters in HVAC, N95 respirator use for patients in contaminated areas, preventing traffic between construction and patient care areas, and elevator for exclusive use of construction workers and debris removal
Ahmad Sarji, 2006 [44]	Child patients with leukemia and other malignancies undergoing chemotherapy	14	9	Fungal infection (lung, blood, sinus, liver, spleen, kidney, skin)	<i>Candida</i> sp., <i>Aspergillus</i> sp., <i>Fusarium</i> sp., <i>Chrysosporium</i> sp., <i>Mycellium</i> sp., <i>Monilia</i> sp., <i>Phaeclomyces</i> sp.	Soil disturbance at adjacent building construction work	659 fungi /m ³ at treatment room	Unknown	Identifying high-risk patients, anti-fungal prophylaxis
Berthelot, 2006 [45]	Highly immunocompromised patients with hematological malignancies	15	8	Invasive <i>Aspergillus</i> infection (lung)	<i>A. flavus</i> , <i>A. fumigatus</i>	Hospital building work and demolition	3.7% - 15.2% (frequency of environmental samples containing <i>A. fumigatus</i> per year)	Unknown	Use of temporary barriers during work, watering of soil during demolition work, reduction of pedestrian traffic in construction areas, maintaining negative pressure, and wearing of high-efficiency filtration masks by immunosuppressed patients

Table 1 continued.

Author, Year	Patient Population	No. of Patient Infected	No. of Patient Deaths	Type of Infection (Site)	Type of Fungi	Reservoir or Source	Airborne Fungal Level(s)	Molecular Typing	Control Measures
Pini, 2008 [50]	Acute leukemia	7	Unknown	Invasive <i>Aspergillus</i> infection (lung)	<i>A. fumigatus</i> , <i>Aspergillus</i> sp.	Renovation work	2.98 <i>A. fumigatus</i> /m ³ corridor between the wards, 0.09 <i>A. fumigatus</i> /m ³ in restricted access rooms	Unknown	Multiple-bed rooms without HEPA filtration but restricted access to visitors and other particular behavioral measures (ban on plants, flowers, and opening windows)
Chang, 2008 [49]	Leukemia, multiple myeloma, and high-grade lymphoma	6	2	Nosocomial invasive <i>Aspergillus</i> infection (lung, mediastinum)	<i>A. fumigatus</i>	Hospital construction in and around the vicinity of the day oncology building	No fungal growth by air sampling in the inpatient facility, day-oncology and pharmacy	Unknown	Unit relocation, impermeable barriers at construction site, face-masking and voriconazole prophylaxis among high-risk patients
Chabrol, 2010 [51]	Acute leukemia	25	6	Invasive <i>Aspergillus</i> infection (lung, sinus, brain, disseminated)	<i>A. fumigatus</i> , <i>A. flavus</i> , <i>A. terreus</i>	Construction or renovation work	1–10 <i>Aspergillus</i> /m ³ (during building work)	Unknown	HEPA filters without any laminar air flow room, and prophylaxis with voriconazole or caspofungin
Pokala, 2014 [53]	Children with acute leukemia	50	10	Invasive fungal diseases (lung, sinus, and other)	<i>Scedosporium</i> sp., <i>Rhizopus</i> sp., <i>Phoma</i> sp., <i>Exosporium</i> sp., <i>Bipolaris</i> sp., <i>Fusarium</i> sp., <i>Aspergillus</i> sp., <i>Candida</i> sp.	Major renovation with excavation of the grounds for construction of a new tower connected to the existing buildings	Unknown	Unknown	Windows of the existing adjacent building re-sealed, education for construction crews, air handling systems optimized using HEPA filters, use of N-95 respirator, valet parking service for all oncology patients immediately adjacent to the hospital entrance, fluconazole or voriconazole prophylaxis

Abbreviations: BMT, bone marrow transplant; CDC, Centers for Disease Control and Prevention; CFU, colony-forming unit; HEPA, high-efficiency particulate air; HVAC, heating, ventilation, and air conditioning; ICU, intensive care unit; ITU, intensive therapy unit.

Figure 1. Trend of fungal outbreaks and infections associated with construction, renovation, and demolition.

and renovation among the published reports was 48%, ranging from 12.5% after surgery to 67% in rheumatology patients, premature infants, or nephrology and dialysis patients (Table 2). Thus, the mortality of fungal outbreaks and infections was substantially high but varied greatly according to underlying conditions and infection types.

RESERVOIRS AND SOURCES OF FUNGI OUTBREAKS AND INFECTIONS ASSOCIATED WITH CONSTRUCTION AND RENOVATION

Construction was the most common type of source in this review (38 articles [78%]), followed by renovation (19), demolition (4), and excavation (3). The data on reservoirs and sources are summarized in Table 1. Environmental sources in construction-related settings were described as follows: inflow of unfiltered outside air, backflow of contaminated air, air

filters, fireproofing materials, air conditioners, duct systems, and dust above false ceilings [55], thereby enabling fungal spores to be aerosolized and disseminated throughout hospital areas. *Aspergillus* species can also be isolated from hospital water samples and be involved in invasive aspergillosis [52, 63, 64]. However, it remains unclear how *Aspergillus* species isolated from hospital water contribute to nosocomial waterborne *Aspergillus* infections, and there are no criteria for determining water contamination levels that have been correlated with a risk of fungal infections.

LABORATORY TESTING, AIR SAMPLING, AND MOLECULAR TYPING IN INVESTIGATION OF FUNGAL OUTBREAKS AND INFECTIONS

In the special settings of construction and renovation, several studies described the monitoring of *Aspergillus* species using quantitative polymerase chain reaction (PCR) of air samples [65, 66] or serum *Aspergillus* galactomannan in pediatric patients with allogeneic stem cell transplant [67]. Although *Aspergillus* infections were finally diagnosed at autopsy in many articles reviewed, the diagnosis of invasive aspergillosis during a patient's lifetime remains difficult. Clinical signs and radiological findings for *Aspergillus* infections can be nonspecific, and in less invasive testing methods, there are diagnostic limitations for conventional culture methods and serum biomarkers (eg, galactomannan and [1→3]-β-D-glucan assays) due to the low sensitivities and for clinical implementation of PCR assays because of the potential environmental contamination of *Aspergillus* DNA [68–72]. Recently, detection of *Aspergillus* antigen by the lateral-flow device as a point-of-care test [73] or *Aspergillus* secondary metabolite signature in breath by thermal desorption–gas chromatography/mass spectrometry [72] may be promising, but further investigation is needed.

Air sampling may be used to measure airborne fungal levels inside and outside of hospitals before, during, and after

Table 2. Fungal Infections and Associated Mortality by Each Underlying Disease During Construction, Renovation, or Demolition

Underlying Diseases	No. of Articles Published	No. of Patients Infected	No. of Patients Died	Mortality, No. ^a (%)
Hematologic malignancies or bone marrow transplant	26	414	148	131/288 (45.5)
Other malignancies, transplant, and/or immunosuppressed patients	13	105	38	38/60 (63.3)
Patients in intensive care unit	3	8	2	2/4 (50)
Rheumatology patients	2	6	4	4/6 (66.7)
After surgery	2	8	1	1/8 (12.5)
Premature infant	2	3	2	2/3 (66.7)
Nephrology and dialysis patients	1	3	2	2/3 (66.7)
Total	49	547	197	180/372 (48.4)

^a Articles in which the number of patients infected or died was unknown were excluded for mortality calculation.

Table 3. Bundle of Key Methods for Preventing Filamentous Fungal Infections Associated With Renovation/Construction Activities

1. Hospital epidemiology (infection control) should be notified by plant engineering prior to any renovation/construction activities in the healthcare facility.
2. Conduct an ICRA for all renovation/construction activities: implement recommended prevention strategies as guided by the ICRA.
3. Focus prevention efforts on control of airborne dissemination of fungal spores (eg, barriers, containment, air handling, portable HEPA filters).
4. Consider impact of renovation/construction on the involved hospital unit plus adjacent units on the same floor, and hospital units on floors above and below the renovation/construction activities.
5. Maintain surveillance for healthcare-associated filamentous fungal infections during renovation/construction. Investigate any cases to see if they are related to renovation/construction and determine if prevention efforts need to be revised.
6. Visit renovation/construction sites regularly to assure compliance with recommended prevention activities.

Abbreviations: HEPA, high-efficiency particulate air; ICRA, infection control risk assessment.

construction by identifying viable airborne fungal spores [1]. Air sampling may be useful in inspection of ventilation performance, maintenance, and cleaning of airflow systems, construction activities, and epidemiologic investigation and research purposes, but microbiologic air sampling and environmental culture are not routinely recommended [55]. Although air sampling has been performed in many studies, there are no standardized methods that are comparable in terms of performance, data collection and analysis, and interpretation (eg, type of air samplers, sampling sites and time, air volume, airflow rate, ecological condition [1]). In addition, there are only limited studies showing a direct relationship between fungal spore concentration by air sampling and human fungal infections in healthcare settings during construction and renovation [37]. In fact, airborne fungal levels varied greatly, and even <1 colony-forming unit (CFU)/m³ could be associated with an *Aspergillus* outbreak among immunocompromised patients [2]. In this review focused on construction and renovation, 22 of 49 (45%) articles conducted air sampling, and airborne fungal levels ranged from 1 to 659 CFU/m³. Several investigators have provided a time series over several years in which they assessed a relationship between healthcare-associated filamentous fungal infections and construction and renovation [45, 52, 53, 74]. In some cases, an increase in fungal infections with an increase in fungal spores occurred during the time period of renovation and construction [14, 22, 28]. Although renovation and construction can be associated with outbreaks, the correlation is

imperfect (ie, outbreaks may occur without renovation/construction, whereas renovation/construction may occur without an outbreak). An article reported fungal infections despite no fungal growth by air sampling [49]. Thus, the minimal airborne concentration of spores needed for acquisition of fungal infections remains to be determined.

Unlike most bacterial outbreaks in healthcare settings, multiple fungal strains can cause construction-related outbreaks because *Aspergillus* species are ubiquitous in nature [75]. In addition, the incubation period of invasive aspergillosis remains unclear, and thus it is impossible to definitively conclude that *Aspergillus* infections resulted from construction activities. Notably, a recent whole-genome sequencing analysis of serial *A. fumigatus* clinical isolates showed dynamic alterations in the genome within its host [76]. In this review, only 5 (10%) articles applied molecular typing, mostly random amplified polymorphic DNA (4 articles), to their investigations. Furthermore, if molecular typing is performed and reveals multiple distinguishable fungal strains within a patient cluster, the possibility of a nosocomial outbreak cannot be excluded as invasive fungal cases could be caused by a variety of unrelated strains [2]. Therefore, the value of *Aspergillus* typing to facilitate epidemiologic investigations remains undetermined. The lack of genotypic matches between the environmental and clinical isolates may be related to the genetic diversity of *Aspergillus* species in the environment.

INFECTION PREVENTION AND CONTROL MEASURES IN SPECIAL HEALTHCARE SETTINGS OF CONSTRUCTION AND RENOVATION

Infection prevention and control measures used to prevent and terminate outbreaks are summarized in Table 1. Recent guidelines regarding infection prevention and control in construction and renovation activities have been published [77–79]. A multidisciplinary coordination team and elaborate planning are essential to prevent airborne fungal infections before/during/after construction and renovation activities in healthcare facilities [78]. The environmental surveillance for immunocompromised patients and high-risk units during construction and renovation are also recommended by several guidelines [77, 80]. A bundle of preventive measures for fungal infections associated with renovation/construction activities is summarized in Table 3. Construction activities can be safely conducted if a bundle of preventive measures is employed with cooperation and coordination among team members who are involved in infection prevention and control for construction projects [81]. It is important for infection control departments to ensure that hospital engineering staff notify them of the planned work activities and seek advice from them preemptively for all hospital

construction and renovation. Furthermore, education of construction workers, engineers controlling indoor air quality and ventilation, and healthcare personnel caring for high-risk patients is necessary to mitigate dust and moisture intrusion from construction sites into patients' areas. Regular monitoring and feedback on compliance with infection control guidelines in and around construction site are also critical [78].

The risk assessment before construction and renovation is implemented to identify potential exposures of susceptible patients to dust and moisture for prevention of airborne infections and to mitigate potential risks [78]. The infection control risk assessment (ICRA) is a multidisciplinary, organizational, documented process using the risk matrix based on construction project types (eg, type A: small noninvasive and inspection; type D: major demolition and construction) and patient risk groups (eg, low risk: office areas and public areas; highest risk: ICUs, oncology, and transplant units). The matched matrix helps to determine the class of infection control precautions that should be followed. Details of the ICRA are available at http://www.ashe.org/advocacy/organizations/CDC/pdfs/assessment_icra.pdf. Infection control risk mitigation recommendations are developed as specific measures for obviating transmission of airborne biological contaminants in construction activities.

Protective measures include relocating high-risk patients, wet cleaning, sealing off the construction site and avoiding unnecessary traffic, and using air filtration adequately [49, 77]. The Centers for Disease Control and Prevention guideline recommends high-efficiency particulate air (HEPA) for high-risk patients as the HEPA filter system can reduce fungal spore counts from the environment of healthcare facilities during construction and renovation and may help prevent fungal outbreaks in combination with other environmental control measures [1, 77]. However, a meta-analysis revealed no significant improvement of HEPA filtration in the prevention of death among patients with hematological malignancies and severe neutropenia, although there were possible publication bias and limitations that no studies were blinded or had control subjects [82]. Further investigations are needed to clarify whether specific control measures contribute to preventing healthcare-associated fungal infections in construction and renovation.

Because antifungal prophylaxis is recommended by the Infectious Diseases Society of America for immunosuppressed patients, including neutropenic patients and HSCT recipients, under certain conditions [83], physicians are likely to administer antifungal prophylaxis among those patients, whether or not construction and renovation are ongoing. Although the practical use of antifungal drugs for prophylaxis is beyond the scope of this review, pharmacokinetics/pharmacodynamics, spectrums, interactions, and adverse effects should be considered in administering antifungal drugs properly. Several previous

studies described the usefulness of antifungal prophylaxis during construction and renovation [49, 51], but no randomized controlled studies exist in such a special condition. On the other hand, voriconazole prophylaxis did not prevent healthcare-associated environmental mold infections among approximately 40% of pediatric patients with leukemia who had received this prophylaxis and had exposure to hospital construction with excavation that was related to the increased risk of developing mold infections despite the recommended prospective measures, suggesting the need for monitoring compliance with infection preventive strategies [53].

CONCLUSIONS

We reviewed outbreaks and infections with medically important mycotic agents during construction and renovation over the last 4 decades, and summarized current infection prevention and control strategies. Construction-related fungal cases among recently published articles seem to be in decline, presumably due to introduction of guidelines and policies regarding infection prevention and control and dissemination of antifungal prophylaxis, but fungal outbreaks and infections under special circumstances still continue to occur in healthcare settings, especially among patients with hematological malignancies and those who are immunocompromised. Further research is required to address the unresolved issues on air sampling and molecular typing for investigation of sources, and specific control measures. It is important for infectious disease physicians and infection preventionists in collaboration with building contractors and other associated departments to appropriately implement risk assessment and mitigation measures and prevent healthcare-associated fungal outbreaks and infections.

Supplementary Data

Supplementary materials are available at *Clinical Infectious Diseases* online (<http://cid.oxfordjournals.org>). Supplementary materials consist of data provided by the author that are published to benefit the reader. The posted materials are not copyedited. **The reported rate reflects the sum-total of resistance cases calculated from GEMINI I and II (n=1/716, through 144 weeks), STAT (n=0/131, through 52 weeks), and D2ARLING (n=0/106, through 24 weeks).⁵⁻⁷

†GEMINI I and II are two identical 148-week, phase III, randomised, double-blind, multicentre, parallel-group, non-inferiority, controlled clinical trials testing the efficacy of DTG/3TC in treatment-naïve patients. Participants with screening HIV-1 RNA ≤500,000 copies/mL were randomised 1:1 to once-daily DTG/3TC (n=716, pooled) or DTG + TDF/FTC (n=717, pooled). The primary endpoint of each GEMINI study was the proportion of participants with plasma HIV-1 RNA <50 copies/mL at Week 48 (ITT-E population, snapshot algorithm).¹³

‡STAT is a phase IIb, open-label, 48-week, single-arm pilot study evaluating the feasibility, efficacy, and safety of DTG/3TC in 131 newly diagnosed HIV-1 infected adults as a first line regimen. The primary endpoint was the proportion of participants with plasma HIV-1 RNA <50 copies/mL at Week 24.⁶

§D2ARLING is a randomised, open-label, phase IV study designed to assess the efficacy and safety of DTG/3TC in treatment-naïve people with HIV with no available baseline HIV-1 resistance testing. Participants were randomised in a 1:1 ratio to receive DTG/3TC (n=106) or DTG + TDF/XTC (n=108). The primary endpoint was the proportion of participants with plasma HIV-1 RNA <50 copies/mL at Week 48. Results at week 24 of the study.

|| The reported rate reflects the sum-total of resistance cases calculated from TANGO (n=0/369, through 196 weeks) and SALSA (n=0/246, through 48 weeks).^{8,9}

¶TANGO is a randomised, open-label, trial testing the efficacy of DOVATO in virologically suppressed patients. Participants were randomised in a 1:1 ratio to receive DOVATO (n=369) or continue with TAF-containing regimens (n=372) for up to 200 weeks. At Week 148, 298 of those on TAF-based regimens switched to DOVATO. The primary efficacy endpoint was the proportion of subjects with plasma HIV-1 RNA ≥50 copies/mL (virologic non-response) as per the FDA Snapshot category at Week 48 (adjusted for randomisation stratification factor).^{8,13}

#SALSA is a phase III, randomised, open-label, non-inferiority clinical trial evaluating the efficacy and safety of switching to DTG/3TC compared with continuing current antiretroviral regimens in virologically suppressed adults with HIV. Eligible participants were randomised 1:1 to switch to once-daily DTG/3TC (n=246) or continue current antiretroviral regimens (n=247). The primary endpoint was the proportion of subjects with plasma HIV-1 RNA ≥50 copies/mL at Week 48 (ITT-E population, snapshot algorithm).⁹

Recognition of aerosol transmission of infectious agents: a commentary

Raymond Tellier¹, Yuguo Li², Benjamin J. Cowling³ and Julian W. Tang^{4,5*}

Abstract

Although short-range large-droplet transmission is possible for most respiratory infectious agents, deciding on whether the same agent is also airborne has a potentially huge impact on the types (and costs) of infection control interventions that are required.

The concept and definition of aerosols is also discussed, as is the concept of large droplet transmission, and airborne transmission which is meant by most authors to be synonymous with aerosol transmission, although some use the term to mean either large droplet or aerosol transmission.

However, these terms are often used confusingly when discussing specific infection control interventions for individual pathogens that are accepted to be mostly transmitted by the airborne (aerosol) route (e.g. tuberculosis, measles and chickenpox). It is therefore important to clarify such terminology, where a particular intervention, like the type of personal protective equipment (PPE) to be used, is deemed adequate to intervene for this potential mode of transmission, i.e. at an N95 rather than surgical mask level requirement.

With this in mind, this review considers the commonly used term of 'aerosol transmission' in the context of some infectious agents that are well-recognized to be transmissible via the airborne route. It also discusses other agents, like influenza virus, where the potential for airborne transmission is much more dependent on various host, viral and environmental factors, and where its potential for aerosol transmission may be underestimated.

Background

The classification of an infectious agent as airborne and therefore ‘aerosol-transmissible’ has significant implications for how healthcare workers (HCWs) need to manage patients infected with such agents and what sort of personal protective equipment (PPE) they will need to wear. Such PPE is usually more costly for airborne agents (i.e. aerosol-transmissible) than for those that are only transmitted by large droplets or direct contact because of two key properties of aerosols: a) their propensity to follow air flows, which requires a tight seal of the PPE around the airways, and b) for bioaerosols, their small size, which calls for an enhanced filtering capacity.

Several recent articles and/or guidance, based on clinical and epidemiological data, have highlighted the potential for aerosol transmission for Middle-East Respiratory Syndrome-associated coronavirus (MERS-CoV) [1, 2] and Ebola virus [3, 4]. Some responses to the latter have attempted to put these theoretical risks in a more practical light [4], and this nicely illustrates the quandary of how to classify such emerging or re-emerging pathogens into either the large droplet (short-range) versus airborne (short and possibly long-range) transmission categories. However, this delineation is not black and white, as there is also the potential for pathogens under both classifications to be potentially transmitted by aerosols between people at close range (i.e. within 1 m).

Definitions

Strictly speaking, ‘aerosols’ refer to particles in suspension in a gas, such as small droplets in air. There have been numerous publications classifying droplets using particle sizes over the years [5–10]. For example it is generally accepted that: i) small particles of $< 5\text{--}10\text{ }\mu\text{m}$ aerodynamic diameter that follow airflow streamlines are potentially capable of short and long range transmission; particles of $< 5\text{ }\mu\text{m}$ readily penetrates the airways all the way down to the alveolar space, and particles of $< 10\text{ }\mu\text{m}$ readily penetrates below the glottis (7) ii) large droplets of diameters $> 20\text{ }\mu\text{m}$ refer to those that follow a more ballistic trajectory (i.e. falling mostly under the influence of gravity), where the droplets are too large to follow inhalation airflow streamlines. For these particle sizes, for example, surgical masks would be effective, as they will act as a direct physical barrier to droplets of this size that are too large to be inhaled into the respiratory tract around the sides of the mask (which are not close-fitting); iii) ‘intermediate particles’ of diameters $10\text{--}20\text{ }\mu\text{m}$, will share some properties of both small and large droplets, to some extent, but settle more quickly than particles $< 10\text{ }\mu\text{m}$ and potentially carry a smaller infectious dose than large ($> 20\text{ }\mu\text{m}$) droplets.

‘Aerosols’ would also include ‘droplet nuclei’ which are small particles with an aerodynamic diameter of $10\text{ }\mu\text{m}$ or less, typically produced through the process of rapid

desiccation of exhaled respiratory droplets [5, 6]. However, in some situations, such as where there are strong ambient air cross-flows, for example, larger droplets can behave like aerosols with the potential to transmit infection via this route (see next section below).

Several properties can be inferred from this, for example the penetration of the lower respiratory tract (LRT), as at greater than $10\text{ }\mu\text{m}$ diameter, penetration below the glottis rapidly diminishes, as does any potential for initiating an infection at that site. Similarly, any such potential for depositing and initiating an LRT infection is less likely above a droplet diameter of $20\text{ }\mu\text{m}$, as such large particles will probably impact onto respiratory epithelial mucosal surfaces or be trapped by cilia before reaching the LRT [6].

The Infectious Diseases Society of America (IDSA) has proposed a scheme that is essentially equivalent [7], defining “respirable particles” as having a diameter of $10\text{ }\mu\text{m}$ or less; and “inspirable particles” as having a diameter between $10\text{ }\mu\text{m}$ and $100\text{ }\mu\text{m}$, nearly all of which are deposited in the upper airways. Some authors have proposed the term “fine aerosols”, consisting of particles of $5\text{ }\mu\text{m}$ or less, but this has been in part dictated by constraints from measurement instruments [8]. Several authors lump together transmission by either large droplets or aerosol-sized particles as “airborne transmission” [9], or use “aerosol transmission” to describe pathogens that can cause disease via inspirable particles of any size [10].

However, we think that it is important to maintain a distinction between particles of $< 10\text{ }\mu\text{m}$ and larger particles, because of their significant qualitative differences including suspension time, penetration of different regions of the airways and requirements for different PPE. In this commentary, we use the common convention of “airborne transmission” to mean transmission by aerosol-size particles of $< 10\text{ }\mu\text{m}$.

If the infected patients produce infectious droplets of varying sizes by breathing, coughing or sneezing, transmission between individuals by both short-range large droplets and airborne small droplet nuclei are both possible, depending on the distance from the patient source. Figure 1 illustrates these potential routes of short and long-range airborne transmission, as well as the downstream settling of such droplets onto surfaces (fomites). From such fomites, they may be touched and transported by hands to be self-inoculated into mucosal membranes e.g. in the eyes, nose and mouth) to cause infection, depending on the survival characteristics of individual pathogens on such surfaces, and the susceptibility (related to available, compatible cell receptors) of the different exposed tissues to infection by these pathogens.

For example, when the infectious dose (the number of infectious agents required to cause disease) of an organism is low, and where large numbers of pathogen-laden droplets are produced in crowded conditions with poor

ventilation (in hospital waiting rooms, in lecture theatres, on public transport, etc.), explosive outbreaks can still occur, even with pathogens whose airborne transmission capacity is controversial, e.g. the spread of influenza in a grounded plane where multiple secondary cases were observed in the absence of any ventilation [11].

The more mechanistic approaches (i.e. arguing from the more fundamental physical and dynamic behavior of small versus larger particle and droplet sizes in the absence of any biological interactions) to classifying which pathogens are likely to transmit via the airborne route have been published in various ways over the years [12–17], but may have to be considered in combination with epidemiological and environmental data to make a convincing argument about the potential for the airborne transmissibility of any particular agent – and the number of possible potential exposure scenarios is virtually unlimited).

The importance of ambient airflows and the of aerosols

One should note that “aerosol” is essentially a relative and not an absolute term. A larger droplet can remain airborne for longer if ambient airflows can sustain this suspension for longer, e.g. in some strong cross-flow or natural ventilation environments, where ventilation-induced airflows can propagate suspended pathogens effectively enough to cause infection at a considerable distance away from the source.

One of the standard rules (Stoke's Law) applied in engineering calculations to estimate the suspension times of droplets falling under gravity with air resistance, was derived assuming several conditions including that the ambient air is still [13–17]. So actual suspension times will be far higher where there are significant cross-flows, which is often the case in healthcare environments, e.g. with doors opening, bed and equipment movement, and people walking back and forth, constantly. Conversely, suspension times, even for smaller droplet nuclei, can be greatly reduced if they encounter a significant downdraft (e.g. if they pass under a ceiling supply vent). In addition, the degree of airway penetration, for different particle sizes, also depends on the flow rate.

In the field of dentistry and orthopedics, where high-powered electric tools are used, even bloodborne viruses (such as human immunodeficiency virus – HIV, hepatitis B and hepatitis B viruses) can become airborne when they are contained in high velocity blood splatter generated by these instruments [18, 19]. Yet, whether they can cause efficient transmission via this route is more debatable. This illustrates another point, that although some pathogens can be airborne in certain situations, they may not necessarily transmit infection and cause disease via this route.

Outline

Over time, for a pathogen with a truly predominant airborne transmission route, eventually sufficient numbers of published studies will demonstrate its true nature [13]. If there are ongoing contradictory findings in multiple studies (as with influenza virus), it may be more likely that the various transmission routes (direct/indirect contact, short-range droplet, long-, and even short-range airborne droplet nuclei) may predominate in different settings [16, 20], making the airborne route for that particular pathogen more of an opportunistic pathway, rather than the norm [21]. Several examples may make this clearer.

The selected pathogens and supporting literature summarized below are for illustrative purposes only, to demonstrate how specific studies have impacted the way we consider such infectious agents as potentially airborne and ‘aerosol-transmissible’. It is not intended to be a systematic review, but rather to show how our thinking may change with additional studies on each pathogen, and how the acceptance of “aerosol transmission” for different pathogens did not always followed a consistent approach.

Results and discussion

Chickenpox

Chickenpox is a febrile, vesicular rash illness caused by varicella zoster virus (VZV), a lipid-enveloped, double-stranded DNA virus, and a member of the *Herpesviridae* family.

For chickenpox, the evidence appears to be mainly epidemiological and clinical, though this has appeared to be sufficient to classify varicella zoster virus (VZV) as an airborne agent. Studies on VZV have shown that the virus is clearly able to travel long distances (i.e. up to tens of meters away from the index case, to spread between isolation rooms and other ward areas connected by corridors, or within a household) to cause secondary infections and/or settle elsewhere in the environment [22–24]. In addition, Tang et al. [25] showed that airborne VZV could leak out of isolation rooms transported by induced environmental airflows to infect a susceptible HCW, most likely via the direct inhalation route.

Measles

Measles (also known as rubeola) is a febrile, rash illness caused by the measles virus, a lipid-enveloped, single-stranded, negative-sense RNA virus, and a member of the *Paramyxoviridae* family.

For measles several studies examined a more mechanistic airflow dynamical explanation (i.e. based upon the fundamental physics and behaviour of airborne particles) for the main transmission route involved in several measles outbreaks [26], including that of Riley and colleagues who used the concept of ‘quanta’ of infection [27]. Later, two other outbreaks in outpatient clinics included retrospective

airflow dynamics analysis, providing more evidence for the transmissibility of measles via the airborne route [28, 29].

Tuberculosis

Tuberculosis is a localized or systemic, but most often respiratory bacterial illness caused by mycobacteria belonging to the *Mycobacterium tuberculosis* complex.

For tuberculosis (TB), definitive experimental evidence of airborne transmission being necessary and sufficient to cause disease was provided in a series of guinea-pig experiments [30, 31], which has been repeated more recently in a slightly different clinical context [32]. Numerous other outbreak reports have confirmed the transmissibility of TB via the airborne route [33–35], and interventions specifically targeting the airborne transmission route have proven effective in reducing TB transmission [36].

Smallpox

Smallpox is a now eradicated, febrile, vesicular rash and disseminated illness, caused by a complex, double-stranded DNA orthopoxvirus (*Poxviridae* family), which can present clinically in two forms, as variola major or variola minor.

For smallpox, a recent comprehensive, retrospective analysis of the literature by Milton has suggested an important contribution of the airborne transmission route for this infection [37]. Although various air-sampling and animal transmission studies were also reviewed, Milton also emphasized clinical epidemiological studies where non-airborne transmission routes alone could not account for all the observed smallpox cases.

At least one well-documented hospital outbreak, involving 17 cases of smallpox, could only be explained by assuming the aerosol spread of the virus from the index case, over several floors. Retrospective smoke tracer experiments further demonstrated that airborne virus could easily spread to patients on different floors via open windows and connecting corridors and stairwells in a pattern roughly replicating the location of cases [38].

Emerging coronaviruses: Severe acute respiratory syndrome (SARS), middle-east respiratory syndrome (MERS)

Coronaviruses are lipid-enveloped, single-stranded positive sense RNA viruses, belong to the genus *Coronavirus* and include several relatively benign, seasonal, common cold viruses (229E, OC43, NL63, HKU-1). They also include two new more virulent coronaviruses: severe acute respiratory syndrome coronavirus (SARS-CoV), which emerged in the human population in 2003; and Middle-East Respiratory Syndrome coronavirus (MERS-CoV), which emerged in humans during 2012.

For SARS-CoV, several thorough epidemiological studies that include retrospective airflow tracer investigations are

consistent with the hypothesis of an airborne transmission route [39–41]. Air-sampling studies have also demonstrated the presence of SARS-CoV nucleic acid (RNA) in air, though they did not test viability using viral culture [42].

Although several studies compared and contrasted SARS and MERS from clinical and epidemiological angles [43–45], the predominant transmission mode was not discussed in detail, if at all. Several other studies do mention the potential for airborne transmission, when comparing potential routes of infection, but mainly in relation to super-spreading events or “aerosolizing procedures” such as broncho-alveolar lavage, and/or a potential route to take into consideration for precautionary infection control measures [46–48]. However, from the various published studies, for both MERS and SARS, it is arguable that a proportion of transmission occurs through the airborne route, although this may vary in different situations (e.g. depending on host, and environmental factors). The contribution from asymptomatic cases is also uncertain [49].

For both SARS and MERS, LRT samples offer the best diagnostic yield, often in the absence of any detectable virus in upper respiratory tract (URT) samples [50–52]. Furthermore, infected, symptomatic patients tend to develop severe LRT infections rather than URT disease. Both of these aspects indicate that this is an airborne agent that has to penetrate directly into the LRT to preferentially replicate there before causing disease.

For MERS-CoV specifically, a recent study demonstrated the absence of expression of dipeptidyl peptidase 4 (DPP4), the identified receptor used by the virus, in the cells of the human URT. The search for an alternate receptor was negative [53]. Thus, the human URT would seem little or non-permissive for MERS-CoV replication, indicating that successful infection can only result from the penetration into the LRT via direct inhalation of appropriately sized ‘droplet nuclei’-like particles. This makes any MERS-CoV transmission leading to MERS disease conditional on the presence of virus-containing droplets small enough to be inhaled into the LRT where the virus can replicate.

Influenza

Influenza is a seasonal, often febrile respiratory illness, caused by several species of influenza viruses. These are lipid-enveloped, single-stranded, negative-sense, segmented RNA viruses belonging to the *Orthomyxoviridae* family. Currently, influenza is the only common seasonal respiratory virus for which licensed antiviral drugs and vaccines are available.

For human influenza viruses, the question of airborne versus large droplet transmission is perhaps most controversial [54–57]. In experimental inoculation experiments on human volunteers, aerosolized influenza

viruses are infectious at a dose much lower than by nasal instillation [58]. The likely answer is that both routes are possible and that the importance and significance of each route will vary in different situations [16, 20, 21].

For example, tighter control of the environment may reduce or prevent airborne transmission by: 1) isolating infectious patients in a single-bed, negative pressure isolation room [25]; 2) controlling environmental relative humidity to reduce airborne influenza survival [59]; 3) reducing exposure from aerosols produced by patients through coughing, sneezing or breathing with the use of personal protective equipment (wearing a mask) on the patient (to reduce source emission) and/or the healthcare worker (to reduce recipient exposure) [60]; 4) carefully controlling the use and exposure to any respiratory assist devices (high-flow oxygen masks, nebulizers) by only allowing their use in designated, containment areas or rooms [61]. The airflows being expelled from the side vents of oxygen masks and nebulisers will contain a mixture of patient exhaled air (which could be carrying airborne pathogens) and incoming high flow oxygen or air carrying nebulized drugs. These vented airflows could then act as potential sources of airborne pathogens.

Numerous studies have shown the emission of influenza RNA from the exhaled breath of naturally influenza-infected human subjects [62–66] and have detected influenza RNA in environmental air [67–69]. More recently, some of these studies have shown the absence of [70], or significantly reduced numbers of viable viruses in air-samples with high influenza RNA levels (as tested by PCR) [66, 71, 72]. The low number of infectious particles detected is currently difficult to interpret as culture methods are inherently less sensitive than molecular methods such as PCR, and the actual operation of air-sampling itself, through shear-stress related damage to the virions, also causes a drop in infectivity in the collected samples. This may lead to underestimates of the amount of live virus in these environmental aerosols.

An additional variable to consider is that some animal studies have reported that different strains of influenza virus may vary widely in their capacity for aerosol transmission [73].

In some earlier articles that discuss the predominant mode of influenza virus transmission [74–78], these same questions are addressed with mixed conclusions. Most of the evidence described to support their views was more clinical and epidemiological, and included some animal and human volunteer studies, rather than physical and mechanistic. Yet, this mixed picture of transmission in different circumstances is probably the most realistic.

It is noteworthy that several infections currently accepted as airborne-transmitted, such as measles, chickenpox or TB present, in their classical form, an unmistakable and pathognomonic clinical picture. In

contrast the clinical picture of influenza virus infection has a large overlap with that of other respiratory viruses, and mixed outbreaks have been documented [79]. Thus, a prevalent misconception in the field has been to study ‘respiratory viruses’ as a group. However, given that these viruses belong to different genera and families, have different chemical and physical properties and differing viral characteristics, it is unwise and inaccurate to assume that any conclusions about one virus can be applied to another, e.g. in a Cochrane review of 59 published studies on interventions to reduce the spread of respiratory viruses, there were actually only two studies specifically about influenza viruses [80]. As the authors themselves pointed out, no conclusion specific to influenza viruses was possible.

While many airborne infections are highly contagious, this is not, strictly speaking, part of the definition. Even so, the lower contagiousness of influenza compared to, say, measles has been invoked as an argument against a significant contribution of airborne transmission. Yet, it should be noted that a feature of influenza virus infections is that the incubation time (typically 1–2 days) is much shorter than its duration of shedding. This allows for the possibility that a susceptible person will be exposed during an outbreak to several different infectious cases belonging to more than one generation in the outbreak. This multiple exposure and telescoping of generations may result in an underestimate of influenza virus transmissibility, as fewer secondary cases will be assigned to a known index case, when in fact the number of secondary cases per index could be much higher. For example, it is known that in some settings a single index case can infect a large number of people, e.g. 38 in an outbreak on an Alaska Airlines flight [11].

Ebola

Ebola is a viral hemorrhagic fever associated with a very high mortality, caused by the Ebola viruses; these are enveloped single-strand, negative-sense RNA viruses comprising five species within the family *Filoviridae*. Four Ebola species have been implicated in human diseases; the most widespread outbreak, also the most recent, was caused by Ebola Zaire in West Africa in 2013–2016. The transmission of Ebola viruses has been reviewed in depth by Osterholm et al. [4]. These authors noted the broad tissue tropism, as well as the high viral load reached during illness and the low infectious dose, from which it appears inescapable that more than one mode of transmission is possible.

Regarding aerosol transmission, concerns are raised by several documented instances of transmission of Ebola Zaire in laboratory settings between animals without direct contact [81, 82] (also reviewed in [4]). Experimental infections of Rhesus monkeys by Ebola Zaire using aerosol infection has been shown to be highly effective [83, 84] and

this experimental procedure has in fact been used as infectious challenge in Ebola vaccine studies [85, 86]. Rhesus monkeys infected by aerosol exposure reliably developed disseminated, fatal infection essentially similar to that caused by parenteral infection with the addition of involvement of the respiratory tract. Autopsies showed pathological findings in the respiratory tract and respiratory lymphoid system in animals infected by the aerosol route that are not found in animals infected parenterally [83, 84].

Such respiratory pathological lesions have not been reported in human autopsies of Ebola cases, but as noted by Osterholm et al. [4], there have been few human autopsies of Ebola cases, arguably too few to confidently rule out any possibility of disease acquired by the aerosol route. The precautionary principle would therefore dictate that aerosol precautions be used for the care of infected patients, and especially considering that infection of the respiratory tract in such patients is not necessary to create an aerosol hazard: Ebola viruses reach a very high titer in blood or other bodily fluids during the illness [87, 88] and aerosolization of blood or other fluids would create a significant airborne transmission hazard.

Conclusions

In summary, despite the various mechanistic arguments about which organisms can be potentially airborne and therefore aerosol-transmissible, ultimately, the main deciding factor appears to be how many studies using various differing approaches: empirical (clinical, epidemiological), and/or experimental (e.g. using animal models), and/or mechanistic (using airflow tracers and air-sampling) methods, reach the same consensus opinion. Over time, the scientific community will eventually form an impression of the predominant transmission route for that specific agent, even if the conclusion is one of mixed transmission routes, with different routes predominating depending on the specific situations. This is the case for influenza viruses, and is likely the most realistic.

Some bacterial and viral infections that have more than one mode of transmission are also *anisotropic*, like anthrax, plague, tularemia and smallpox: the severity of the disease varies depending on the mode of transmission [37, 89]. Older experimental infection experiments on volunteers suggest that this is the case for influenza, with transmission by aerosols being associated with a more severe illness [14, 90], and some more recent field observations are consistent with this concept [57]. For anisotropic agents, even if a mode of transmission (e.g. aerosols) accounts for only a minority of cases, interruption of that route of transmission may be required if it accounts for the most severe cases.

Abbreviations

LRT: lower respiratory tract; MERS-CoV: Middle East Respiratory Syndrome-associated coronavirus; PCR: polymerase chain reaction; RNA: ribonucleic

acid; SARS-CoV: severe acute respiratory syndrome-associated coronavirus; TB: tuberculosis; URT: upper respiratory tract; VZV: varicella zoster virus

The physics of human breathing: flow, timing, volume, and pressure parameters for normal, on-demand, and ventilator respiration

Joachim D. Pleil^{1,*}, M. Ariel Geer Wallace², Michael D. Davis³, Christopher M. Matty⁴

Abstract

Normal breathing for healthy humans is taken for granted; it occurs without conscious effort using ambient (1-atmosphere) pressure with 21% oxygen (O₂) concentration. The body automatically adjusts for stress, exercise, altitude, and mild disease by increasing the volume and frequency of breathing. Longer term adaptations for exercise and altitude include increases in red blood cell counts and higher concentrations of capillaries in muscle tissue. When more challenging external environmental conditions or pulmonary illnesses exceed the capability for these adaptations, the human system requires technology to maintain sufficient ventilation to preserve life. On the environmental side there are two conditions to be addressed: toxicity of the surrounding atmosphere and changes in external pressure and O₂ concentration. On the medical side, mechanisms for assisting breathing include O₂ supplementation at ambient pressure, positive pressure/flow without additional O₂, or a combination of both. This overview describes the various technologies applied to maintaining a safe breathing environment. Topics for environmental intervention include filter-based and flowing air-supply masks for toxic environments (occupational and laboratory protection), and on-demand gas supply systems for firefighters, self-contained underwater breathing apparatus (SCUBA) divers, and altitude (high performance aircraft, spacecraft) applications. The topics for medical intervention include nasal cannula, continuous positive airway pressure (CPAP), and medical ventilators. The primary purpose of this article is to provide a basic understanding of normal human breathing and the adaptation of breathing in different environments using available technologies.

OVERVIEW

The topic of human breathing mechanics and support has come to the forefront of public awareness due to the current COVID-19 crisis. Wearing hospital masks or improvised facial

* address correspondence to: pleil@unc.edu.

coverings was broadly implemented to protect against spreading infectious aerosols (Pleil et al. 2020a, Eikenberry et al. 2020). At the outset of the pandemic, the news media reported on the availability and use of medical ventilators as well as oxygen (O₂) supplementation via less invasive nasal cannulas or masks to help patients recover from pulmonary disease (Kliff 2020, Ranney et al. 2020). Additionally, breathing protection, supplementation, and therapy appear in the media with respect to firefighters battling wildfires, pilots flying high-performance military aircraft, recreational self-contained underwater breathing apparatus (SCUBA) and professional divers, and medical and laboratory researchers.

This commentary describes normal breathing functionality and strives to put human breathing into context with the modern technologies used to extend the safety envelope beyond sea-level pressure and O₂ concentration to support life in situations ranging from extreme pressures in diving, to low pressures in aviation. Herein we discuss all manner of human breathing parameters and how different support systems work. The article describes the current understanding of the physics of breathing and the processes for distributing O₂ from the air to the human tissues, organs, and the brain.

The discussions are grouped by the level of intervention; consider that a simple hospital mask only serves to filter particles but does not affect O₂ concentration, gas flow, or ambient pressure, whereas a hospital ventilator can take complete control of the human breathing system and dictate timing, flow, volume, and level of oxygen. Between these extremes are applications that address specific parameters. Some common examples are flow-through masks that receive clean air flow from outside to protect the wearer from an indoor contaminated environment, the nasal cannula that provides additional ambient air enriched with O₂ for a patient with respiratory distress, the standard respirator that protects the wearer from organic volatile chemicals, and various “on-demand” mask systems that replace ambient air using a separate source.

The mission of this commentary is to provide a basic understanding of human breathing under different scenarios and to present a baseline of breathing parameters that are required to maintain human life. Examples and data are drawn directly from the authors’ research and expertise, as well as being supplemented with the peer-reviewed literature. This article expands on the understanding of the physics parameters of pressure, flow, volume, and timing under different conditions encountered by humans to further the concepts of breath research beyond the chemistry of metabolism (Pleil et al. 2020b).

NORMAL BREATHING

Humans descended from the superfamily Hominoidea (10–20 million years ago); the earliest fossil records for hominids (earliest direct ancestors) date back 4–5 million years (Andrews 1992), and modern homo sapiens date back approximately 200,000 years (Stringer 2016). Over 2.3 billion years ago, early cyanobacteria began emitting O₂ via photosynthesis (Kasting and Siefert 2002). Considering that the earth’s atmosphere stabilized at ~21% O₂ and ~78% nitrogen (N₂) about 550 million years ago (Berner 1999), it is safe to say that modern humans evolved to efficiently use this atmosphere for “normal” breathing (Liem 1988).

Normal breathing is defined here as the movement of air in and out of the lungs in an environment with infinite volume and stable external pressure. Normal breathing is an autonomous function performed without conscious effort, although humans can take conscious control for actions such as breath-holding, talking, singing, swimming, and exercise. The physics of normal breathing are based on differential pressure between the lungs and the ambient atmosphere. As the diaphragm and ribcage expand and contract due to muscle action, air flows in and out to balance pressure. During inhalation, the fresh oxygenated air flows into branching progressively smaller airways to ultimately inflate the alveoli (small membranous air sacs) and exchange O₂ for carbon dioxide (CO₂), a waste product of cellular energy production. CO₂ is expelled upon exhalation and the cycle begins anew. Humans do not absorb all of the inhaled O₂ for metabolism; inhaled air contains 21% O₂ while exhaled breath contains approximately 16% O₂ and 5% CO₂.

Oxygen transport

Oxygen transport begins at the mouth/nose, continues into the lungs, consisting of progressively smaller branching airways, ending in alveoli or air sacs where oxygen is transferred to the red blood cells. It is then delivered to the systemic blood flow and ultimately into the various cells by capillaries and diffusion. The first effects of reduced O₂ are felt by the brain; in fact, even minor reductions (mild hypoxia) can manifest as disorientation, confusion, and reduced higher executive function. Longer term O₂ deprivation can also cause organ damage, especially to the heart and kidneys, but practically, the brain is the organ of primary concern. In a recent National Aeronautics and Space Administration (NASA) Pilot Breathing Assessment (PBA) study of jet fighter pilots, detailed analyses of breathing response, spirometry, and blood oxygenation have shown that there are losses in O₂ transport along the way from the face to the organs despite 100% O₂ in the breathing gas (NASA PBA Report 2020). A study of environmental contamination has shown that pulmonary function can be lost even when the O₂ content and pressure in the air are nominal (sea level) due to pulmonary inflammation (Stiegel et al. 2017). As an example, Figure 1 shows the conceptual model for O₂ transport related to jet aircraft life support systems.

Breathing frequency, tidal volume, and pulmonary pressure

At complete rest, the typical adult male exchanges approximately 0.5 L (500 mL; 400 mL for female) of air per breath (tidal volume) at a rate of 12 times per minute, resulting in a minute ventilation rate of about 6 L of air per minute. Certainly, there are individual variations due to size, age, gender, and health-state, but these parameters are considered robust default values. Of note is that the first 0.15 L (150 mL) volume of each breath, referred to as the tracheal dead volume, does not participate in O₂/CO₂ exchange but only fills the trachea and branching airways. In calm, at-rest breathing, the body generates a modest ± 3 mmHg pressure swing to create inhalation and exhalation flow. For context, imagine one is blowing up a balloon or drinking a thick milkshake through a straw; there is a maximum amount of positive or negative pressure one can exert, after which the activity fails. According to the literature, the diaphragm and related thoracic muscles can exert maximum exhalation pressures of 44 to 88 mmHg and maximum inhalation pressures of negative 29 to 74 mmHg (Lausted et al. 2006, Evans and Whitelaw 2009). As such, normal

at-rest breathing only requires minimal muscle effort compared to the maximum possible exertion.

The human body is highly adaptable and as metabolic need increases for activity, exercise, and warmth, the cardio-pulmonary (heart-lung) system has mechanisms to increase blood flow and O₂ perfusion. Heart rate, respiration rate, and tidal volume increase to provide the necessary cellular resources to support energy production. With moderate exercise, normal adults can sustain 30 breaths/minute with 3.5 L/breath, and depending on fitness, age, and other health factors, individuals can adapt to higher needs for O₂ perfusion. Pulmonary function tests (PFTs) measure the absolute maximum for a single breath (forced vital capacity, FVC) in the range of 4 to 5.5 L/breath, but such levels are not sustainable, and so this limits human activity. Again, normal at-rest breathing only uses a small amount of the total resources possible.

Table 1 shows the normal breathing parameters for healthy adults. Certainly, individuals can vary greatly depending on cardiovascular fitness, anxiety, inflammatory status, genotype, and phenotype. The values in the table are illustrative and show the potential adaptability of the human system to increased workload. Notably, all measurements of breathing require masks or other devices to measure flows and pressures, and so there is a caveat that these numbers are not exactly “normal breathing.” However, modern measurement technology has evolved to minimize pressure drops and flow restrictions so that such measurements can be taken at face-value. The values in the table are considered “nominal” in that they are generally accepted by the medical community and found in various public websites (e.g., Wikipedia, Mayo Clinic, and Johns Hopkins). Certainly, ranges or slightly different values may also be found, including adjustments for gender or physical size, but the values in Table 1 represent a consensus for normal breathing for healthy adults. More detailed statistical analyses of human breathing have been published by the U.S. Environmental Protection Agency (EPA 2011).

Figure 2 below shows pulmonary function testing with laboratory instrumentation and a handheld device that can be used in the field (US EPA and NASA).

Oxygen saturation

The amount of O₂ in the blood, or blood O₂ saturation level, is defined as the fraction of O₂-saturated hemoglobin in red blood cells compared to the total amount of hemoglobin. Invasive medical tests can be used to measure arterial blood gases (ABG) very accurately; however, standard practice is to estimate peripheral oxygen saturation (SpO₂) non-invasively with pulse oximetry using a colorimetric light sensor attached to a finger. SpO₂ between 95 and 100% is considered normal; readings between 90 and 95% are considered mildly hypoxic, and a level of 90% or below indicates a serious medical condition called hypoxemia that needs to be treated quickly. The human body can adapt slightly to lower levels of SpO₂, but generally this engenders feelings of fatigue and shortness of breath (Hoiland et al. 2016, Hardt et al. 2015).

Altitude adaptation

The default values mentioned above apply for sea-level atmospheric pressure and O₂ levels. However, as altitude increases, the percentage (mass fraction) of O₂ remains the same but the partial pressure decreases proportionally with total pressure, as such the number of O₂ molecules within each breath is proportionally lower. Humans have adapted to elevation as evidenced by major population centers at higher altitudes. In the short term, for visitors to higher altitudes, breathing frequency and tidal volume increase to provide more O₂ to the systems biology. Long-term and natural selection adaptations include the increase in red-blood cells, capillary density, and higher efficiencies in hemoglobin transport.

At sea-level, the partial pressure of oxygen (ppO₂) is 0.21 atmospheres and normal “at-rest” breathing results with O₂ blood perfusion levels of ~98%. At higher elevations, ppO₂ decreases; for context, Table 2 shows some examples for major cities, their populations, elevation, and ppO₂. For example, one of the biggest cities in the world, Mexico City, Mexico (population ~22 million), has an elevation of 7,350 feet, resulting in ppO₂ of 0.16 atm, which represents an O₂ density 60% of sea-level. Anecdotally, some newcomers to Mexico City experience some breathing discomfort, headache, mild hypoxia, and elevated respiration; however, they generally adapt within a few days. Likewise, while “altitude training” has served as an intermittent fad in endurance athletes, practical experience has shown that physiological adaptations from training at altitude generally revert to normal within a few days of returning to sea level conditions. As a comparison, Table 2 shows the typical commercial airliner, which cruises at ~36,000 to 40,000 feet altitude with cabin pressurization set to an equivalent altitude of about 8,000 feet (0.16 ppO₂ atm) as mandated in the U.S. by Federal Regulation 14 CFR 25.831 (Federal Aviation Administration (FAA) 2002); as such, the typical airliner cabin ppO₂ is close to that of Mexico City. The FAA general aviation guidelines further require supplemental O₂ supply if cabin pressure drops to 12,500 feet equivalent (0.13 ppO₂ atm) for more than 30 minutes and always above 14,000 feet cabin altitude (0.12 ppO₂ atm).

Table 2 also includes two mountains: Denali, Alaska, USA, and Mt. Everest, Nepal for additional context. Climbers of Denali (elevation ~20,000 feet) can adapt to the summit altitude with prior aerobic training and acclimation over a few weeks’ time. Very few climbers of Mt. Everest (summit elevation ~29,000 feet) have ever achieved summiting without supplemental O₂. The altitude tipping point for unassisted breathing in very fit individuals (mountain climbers) is around 26,000 feet. The values presented are for illustration only; they are gleaned from consensus of various Wikipedia and other internet sources, as well as published references (e.g., Peacock 1998, West 2000).

Concentration adaptation to CO₂ (artificial atmospheres)

Like the adaptations to activity and ambient pressure, the human body also has some leeway in adapting to different concentrations of O₂ and CO₂. In the previous section, we discussed changes brought about by pressure with constant percentages of constituent gases. Here, we consider only standard pressure, but with different concentrations of CO₂ resulting from the buildup from exhalations.

When breathing normally, humans inhale fresh air with 21% O₂ along with a negligible amount of ambient CO₂ (0.04%), and exhale ~16% O₂ and ~5% CO₂. Medically, ambient concentrations above 19.5% O₂ are considered safe, but there are reported minor adverse effects (e.g., headache, irritability, and confusion) from inhalation of CO₂ starting at ~1,000 ppm (0.1%), with increasing adverse effects up to ~20,000 ppm (2%) concentration. Beyond this level, it becomes more difficult for the body to expel metabolic waste CO₂, and CO₂ concentrations of 100,000 ppm and above can cause loss of consciousness and asphyxiation (National Research Council 2007). Because O₂ and CO₂ in a confined space represent a zero-sum (add up to 20.95% in dry air), excess CO₂ ultimately displaces available O₂. Studies have shown that humans can tolerate more CO₂ for short periods of time, but from a public health perspective, humans in general are not well-adapted to chronic (indoor) exposures to CO₂ beyond 0.1%. Various studies of CO₂ inhalation effects are available in the literature (e.g., Shriram et al. 2019, National Research Council 2007, Satish et al. 2012), and recently the use of CO₂ breath measurements (capnography) has been discussed (Pleil and Christensen 2021).

Consumption of O₂ and production of CO₂ (artificial atmospheres)

Unlike open air breathing, the act of breathing in confined space environments consumes the available O₂ and increases the CO₂ concentration. As such, sustaining normal breathing in closed environments requires some form of ventilation to stabilize the gas mixture. Fully sealed spaces such as submarines, spacecraft, underwater habitats, and hyperbaric/hyperoxic chambers, have engineering systems that continually scrub exhaled CO₂ and add replacement O₂ as needed. More porous environments such as aircraft, cars, large office buildings, crowded auditoriums, and large ships rely on external air exchange via passive or pumped ventilation from the surrounding environment to balance O₂ and CO₂ levels. In the special cases of aircraft flying at altitude and hyperbaric chambers, the supplemental air must be pressurized as well.

In general, artificial atmospheres cannot cost-effectively maintain a perfect ambient atmosphere with 20.95% O₂ and 0.041% CO₂. Depending on ventilation, indoor spaces with human occupancy always have lower O₂ and higher CO₂ than outdoor air. The acceptable American Society of Heating and Air-Conditioning Engineers (ASHRAE) standard for CO₂ in offices is 800 ppm (0.08%); however, levels as high as 4,000 to 5,000 ppm (0.4 to 0.5%) have been measured (Zhang et al. 2017). Measurements in cars stopped in traffic using recirculated conditioned air have shown CO₂ levels reaching 2,500 ppm (0.25%) in a few minutes and continuing to rise (Angelova et al. 2019). In many cases, the practical tradeoff is temperature control vs. CO₂ buildup.

Enclosed spaces such as spacecraft, the International Space Station (ISS) or military submarines always rely on totally artificial atmospheres and maintain a tightly controlled atmospheric gas mixture. Therefore, CO₂ levels in these enclosed spaces are higher than the ambient CO₂ concentration on earth (0.3 mmHg, 400 ppm, or 0.04% of Earth's atmosphere). CO₂ levels in spacecraft typically range from 2.3 to 5.4 mmHg, with the highest recording of 14.9 mmHg on Apollo 13 (Law et al. 2014). NASA's spacecraft maximum allowable concentrations (SMACs) for CO₂ for 1-h and 24-h exposure were set at 13,000 ppm, but

recently the CO₂ SMAC was removed and acceptable levels for CO₂ in spacecraft are currently under review (National Research Council 2007, NASA 2020).

CO₂ levels of more than 10,000 ppm have been reported in nuclear-powered submarines. The U.S. Navy's emergency and continuous exposure guidance levels for CO₂ were evaluated in 2007. The 1-h and 24-h emergency exposure guidance levels of 40,000 ppm were proposed to be lowered to 30,000 ppm and 15,000 ppm, respectively, compared to the National Research Council (NRC) inhalation exposure recommendation of 25,000 ppm for both 1-h and 24-h exposure levels. The 90-day continuous exposure guidance level of 5,000 ppm was proposed to be increased to 7,000 ppm, compared to the 8,000 ppm NRC recommendation (National Research Council 2007).

At complete rest at sea level, a single human consumes approximately 8.6 m³ of air per day of which 5% is exhaled as metabolic CO₂, producing approximately 785 gm of CO₂. According to the U.S. EPA's Exposure Factors Handbook (EPA 2011), an adult male of normal weight with moderate activity for 16 hours and rest for 8 hours consumes ~22.8 m³ of air per day with 99th percentile of 23.7 m³. For calculations, this is generally rounded to 24 m³ or 1 m³ per hour as the default assumption and equates to an exhalation of approximately 2.2 kg of CO₂ per day.

Using the ISS as an example with ~950 m³ interior volume, a crew of seven astronauts (with moderate activity) is expected to produce a volume of 8.4 m³ of CO₂ gas per day. Left uncontrolled, the ISS atmosphere would reach 0.09% CO₂ concentration in 24 hours. Empirically, this does not happen in the ISS environment presumably because the astronauts are not working against gravity and produce only about 1 kg CO₂ per day. Regardless, the closed environment requires removal of CO₂ and supplementation of O₂. As such, the environmental control systems onboard the ISS remove approximately 7 kg of CO₂ each day to maintain a viable atmosphere and continually replenish the air with O₂ that is produced via hydrolysis of water. Figure 3 illustrates space mission environments with the individual space suit, the "shirtsleeve" environment inside the ISS, and an exterior shot of the loneliness of the self-contained human ISS habitat. Within the individual suit, and the whole of the ISS, CO₂ is regularly removed and O₂ is added to maintain a sustainable atmosphere (photos from NASA archives).

Normal breathing in contaminated air environments

There are many situations where there is sufficient O₂ in the air, but contaminants including particulate matter (PM) and dusts, virulent aerosols, gas-phase carcinogens, and adverse odors can make the breathing air unsafe. Typically, these are occupational hazards that require specific respirators or masks; however, now in the era of the COVID-19 pandemic, the general public is also routinely wearing masks to help prevent the spread of the disease (Pleil et al. 2020a).

Respirators: Breathing protection comes in different forms depending on the expected contaminants. The most common occupational respirators are designed to scrub toxic gases and vapors generally using half-face or full-face masks with adsorbent (chemical) or molecular sieve cartridges. Although there is always some small flow restriction from

such cartridges, generally the respirators are very close to normal breathing. Typically, the additional pressure required for inhalation across modern activated carbon filters (ACF) is in the range from 1.5 to 3 mmHg. As such, normal breathing with typical respirators requires ~4.5 to 6 mmHg pulmonary pressure, which is well below the upper limits that are around 40 mmHg (Balanay and Lungu 2016).

Hospital masks: Many environments need only protection against aerosols and particles; for these scenarios, different levels of physical filter materials are used. Standard medical protection masks like the well-known N-95 mask have a tight fit on the face using a double mesh/cloth layer that forces all air through the filter material. In these masks, the inhalation restriction is ~ 0.025 mmHg, which is negligible compared to normal at rest breathing (Skaria and Smaldone 2014). More conventional hospital (paper/polypropylene) masks are loose-fitting and rely more on aerosol and particle kinetics rather than direct filtration; these masks, like improvised facial coverings (bandanas and scarves), have no measurable pressure drops.

Free-flow air supplies: In some confined-space scenarios, outside air is pumped directly into a face shield or mask in the breathing zone at a rate high enough to continually displace the microenvironmental air. There is no pressure drop experienced by the worker; in fact, this style of respiratory protection provides a secondary benefit in that the free-flowing external air provides cooling as well. Such air supplies are common in occupational settings, including aircraft systems maintenance and chemical laboratories.

Figure 4 shows some examples of common protective masks that all support safe “normal” breathing. They include simple facial coverings, face shields, as well as half- and full-face respirators.

Normal breathing with medical O₂ enrichment

In some cases, individuals with moderate lung or heart disease require additional O₂ to maintain oxygenation; this could be a temporary recovery solution in the hospital, or a longer-term solution for ambulatory outpatient maintenance. This “O₂ therapy” can be low- or high-flow. In low-flow O₂ therapy, a small tube provides O₂ enriched flow to a nasal cannula or mask from a cylinder or a portable O₂ generator at up to 15 L per minute (LPM). Of note, low-flow O₂ therapy can only deliver up to ~80% fraction of inspired oxygen. In high-flow O₂ therapy, flows of more than 15 LPM are delivered to a mask or nasal cannula, typically through larger bore tubing. In low- and high-flow O₂ therapy applications, the flow rates and O₂ concentrations delivered are tailored to the needs of the patient.

A common current practice uses high-flow nasal cannula (HFNC) to delivery respiratory support. HFNC can deliver up to 60 LPM and range up to 100% O₂ (Ward 2013, Helviz and Einav 2018). HFNC is a non-invasive alternative to mask-based O₂ therapy and mechanical ventilation; the supplementation remains in the realm of normal breathing in the sense that there is no measured forcing pressure.

Normal breathing in spacesuits and other sealed protective gear

The most esoteric situations for normal breathing involve protective gear that allows independent movement, yet still seals the person completely off from the external environment. The best examples are spacesuits and certain types of HazMat suits. In these configurations, clean air is provided into the suit, especially around the head, without a sealed mask on the face. CO₂ is constantly scrubbed and replaced with an equivalent amount of O₂ in periodic bursts to maintain a viable atmosphere; the most recent advances in space suit design can be found in the literature (e.g., Goldfarb and Hodgson, 2001, Southern and Moisey, 2019).

Extreme adaptation

There are some people that are adapted or trained for extreme situations focused on breath holding and breathing control. The largest groups are found in the free-diving community and in certain types of meditation. The normal healthy human can hold their breath between 30 to 60 seconds. With some practice and coaching, breath hold times can be quickly improved to about 2 minutes or more. Free divers, without prior oxygen loading, can routinely hold their breath for 10 minutes or more and dive unassisted to 300 feet depth, corresponding to about 10 atmospheres pressure. These extreme activities carry risks for acute injury to tissues and airways, as well as for permanent damage or even death. The book “Deep: Freediving, Renegade Science, and What the Ocean Tells Us about Ourselves” describes extreme adaptation not only for humans but also for creatures in the depths of the ocean (Nestor 2014). The human record for breath holding with O₂ loading is 24 minutes 37 seconds achieved by Budimir Šobat in Sisak, Croatia in March 2021; new attempts are ongoing ([Guinnessworldrecords.com](https://www.guinnessworldrecords.com)).

ON-DEMAND BREATHING

There are scenarios in human breathing experience that require more than just adaptation or passive filtration, but instead employ non-rebreathing devices to bring clean air directly to the nose/mouth. These systems operate through “on-demand” mechanics; as the person begins to inhale, the slight pressure drop opens a valve, which in turn triggers delivery of an airstream for inhalation. As the person begins to exhale, the pressure increases, shuts off the inhalation valve and flow, and opens the exhalation valve to allow air out. This type of system has the advantage of conserving resources by only providing air when needed. The challenge is to respond properly with the correct flow, concentration, speed, timing, and volume required to sustain life. All on-demand breathing systems work at the ambient pressure (or maybe a tiny bit higher) that surrounds the human.

SCUBA open-circuit breathing

The first practical applications for “on-demand” breathing were for underwater exploration and recreation. Termed self-contained underwater breathing apparatus (SCUBA), this engineering advance replaced the hardhat suits that were tethered to large surface compressors and pumped with air continuously at high flow rates. With SCUBA gear, the diver could now bring along his own breathing gas in a compressed air cylinder and be completely independent of the surface. Although Jacques Cousteau (of underwater filming

fame) is credited for developing the Aqua-Lung (twin hose scuba equipment) in France for commercial and recreational diving circa 1945 (Richardson 1999), the original concept of the on-demand regulator and use in a diving suit was developed and patented by Benoît Rouquayrol in 1860 (Siermontowski et al. 2016).

Standard SCUBA uses open-circuit breathing wherein the inlet side from the air supply is pressurized and sealed but the outlet (exhalation) side is expelled directly into the water by a diaphragm valve. The basic configuration has a compressed gas cylinder with a two-stage on-demand regulator system that includes a first stage, which regulates the raw cylinder pressure down to a more practical intermediate pressure proportional to depth, and a second stage (typically held by the mouth) that supplies gas from the reference pressure on-demand to the user. The lips provide the seal; standard SCUBA is mouth breathing only and the nose is sealed into the diving mask airspace to allow the sinus volume to equalize to the breathing pressure. Normal swimming goggles cannot be used as they do not allow pressure equalization of the airspace. A variant is the full-face mask that combines visual and breathing needs. This arrangement seals from the forehead around the face down to the chin which allows both mouth and nose breathing, as well as radio communication.

The most important issue with breathing underwater is the wide range of positive pressures encountered. Each additional 33 feet (10 meters) of seawater depth adds one atmosphere of pressure. Typical recreational (vacation) diving has a maximum of 130 feet (40 meters) and is defined as “no-decompression” diving in that it is possible to ascend to the surface in an emergency without obligatory decompression stops. In general, descents and ascents are done slowly to allow the body, especially sinuses and ear channels, to come to equilibrium with the water pressure, and to allow the dissolved gasses in body tissues time to dissipate. Each breath is delivered at the pressure at that depth; so, when breathing at a depth of 33 feet for example, there are twice as many O₂ molecules per L as at the surface. This is not an advantage for conserving volume, however. The body triggers the breathing response based on the build-up of blood CO₂, and so the additional O₂ is not helpful for metabolism. As such, at 33 feet depth (2 atm), one uses the available air in the cylinder twice as fast as at the surface; at 66 feet depth (3 atm) air is used three times as fast, etc. (Loske 2013).

The standard recreational SCUBA tank is referred to as an “Aluminum 80,” which refers to the material and cubic volume of air in cubic feet when pressurized to 3,000 psi. Standard SCUBA breathing for an individual is defined as a surface air consumption (SAC) rate. This depends mostly on the proficiency of the diver; new divers may have anxiety or difficulty with buoyancy control and breathe up to 1 cubic foot per minute (cfm), whereas experienced divers that are calmer and more efficient underwater may have SAC rates of 0.5 cfm or lower. SAC rate, depth, and tank volume are used to estimate the time available for an individual to remain underwater safely. A new diver with a SAC rate of 1 cfm and an Aluminum 80 can expect no more than ~30 minutes of diving on a reef at 33 feet depth and still maintain a safety margin of ~500 to 800 psi residual volume upon surfacing. Experienced divers generally dive recreational profiles for an hour or more with an Aluminum 80, depending on depth. It is common for recreational SCUBA divers to use O₂ enriched mixtures, commonly referred to as “Nitrox”, to increase the partial pressure of O₂ and thus lower the partial pressure of N₂ in the breathing gas. Common Nitrox

mixes range from 28–36% O₂. Use of Nitrox generally allows recreational divers to stay down longer with lower accumulated N₂ in their tissues, due to the proportionally lower N₂ fraction in the breathing gas.

Beyond recreational SCUBA diving there is a complex realm of technical diving using multiple tanks, gas mixtures, long dives, and depths down to 300 feet or more. The most common groups of tech-divers are shipwreck explorers, cave divers, and divers supporting industrial work such as undersea telecommunications, undersea construction, and mining for fossil fuels. Becoming certified in different aspects of technical diving requires years of training, and unlike recreational diving, carries much higher risk. Because human metabolism dissolves N₂ into the bloodstream, increased N₂ is dissolved into the blood and body tissues at the elevated pressures associated with diving. If the diver were to immediately return to the surface, this dissolved N₂ would rapidly come out of solution in the body's blood and tissues, causing a painful and potentially dangerous condition commonly known as "the bends" or decompression sickness (DCS). DCS is commonly called "the bends" because emerging gas often first manifests as pain and immobility in the body's joints, leading the sufferer to "bend" themselves in an attempt to alleviate this joint pain. In order to avoid DCS, divers who spend longer times at depth must "decompress" toward the end of the dive, making periodic stops as they ascend to allow the dissolved gasses to dissipate from their tissues at a manageable rate. Because diving at depth for prolonged periods of time requires proportionally longer decompression times, industrial divers will often live "at pressure" continuously for several months at a time, living, eating, and sleeping in a pressurized vessel matched to the working pressure of their diving environment. This so-called "Saturation Diving" allows divers to work effectively at significant depths of 300 feet or more for months at a time. At the end of this period, saturation divers undergo multiple days of decompression at steadily declining pressures before they can return to the ambient surface environment.

While O₂ is crucial to the human metabolic process, too much O₂ is toxic to humans, and elevated O₂ from pressurized breathing at depth carries significant risk of O₂ toxicity. Symptoms of O₂ toxicity include sudden seizure, convulsion, and sudden loss of consciousness. For obvious reasons, these symptoms, if experienced while diving underwater, can be extremely dangerous or even immediately fatal. Thus, significant care must be taken by divers to account for the elevated pressure of O₂ that they are breathing. Pure O₂ can become toxic to a human at depths as shallow as 6 meters/19.6 feet, while a typical atmospheric air mixture of 21% O₂ can become toxic below 66 meters/216.5 feet.

Tech-divers customize their gear to particular dive scenarios. For long dives above ~120 feet, the typical configuration may be twin back-mounted Steel 120 tanks providing a total of 240 cfm air. Deep dives from 120 to ~300 feet require multiple tanks and specific gas mixtures depending on depth. Typically, these divers use air as a travel gas from the surface down to ~120 feet and then below that level switch to an oxygen-helium-nitrogen (O₂-He-N₂) "trimix" that has reduced O₂ concentration at 10 to 20%, 50% He, and balance N₂. For very deep commercial applications (below 330 feet), divers may use a mixture of 79–90% He and 10–21% O₂ "heliox," which eliminates the N₂ component entirely. These mixtures are carefully chosen such that the effective ppO₂ at depth does not risk becoming toxic to the

user. At 330 feet depth, the body experiences ~11 atmospheres of pressure, so each breath has 11 times as many O₂ molecules as the same breath on the surface. With a concentration of 10% O₂, heliox provides the equivalent of 1.1 ppO₂ atm O₂. O₂ concentration can be adjusted below 10% to accommodate deeper dives without excess risk of O₂ toxicity. The deepest commercial dives replace some of the He with hydrogen (H) and may have as little as 2% O₂ (Loske 2013). Upon returning to the surface, it is common to switch back to travel gas (air) at 120 feet, ascend very slowly with decompression stops at 90, 60, and 30 feet, and then switch to an O₂ enriched mixture (80%) for the final decompression stop at ~20 feet. It is common for technical divers to carry four or more tanks on a single open-water or wreck dive and to stage tanks along the way in caves to use on the return.

The diving industry has many additional mixtures of gases available or custom mixed. The recreational diver may be familiar with “Nitrox” or “EANx” which are O₂-N₂ blends with 32/68 or 36/64 ratios. These are designed for long-term shallow diving (above 100 feet depth). The lower level of N₂ reduces the risk of developing nitrogen narcosis and decompression illness. Nitrox is a popular choice for vacation SCUBA in warm climates.

SCUBA closed-circuit breathing

During open circuit breathing, exhaled breath is wasted by exhaling directly into the water. Consider that humans breathe out most of the O₂ they inhale; at the surface they breathe in 21% and exhale 16% O₂ and 5% CO₂. At depth, this wastage increases proportionally because the mass amount of O₂ metabolized into CO₂ stays the same. The advent of closed-circuit breathing technology recovers the exhalation volume, scrubs out the metabolic CO₂, adds O₂ as needed, and recycles this air back into the breathing circuit. This extends the time underwater by a factor of five or more depending on the configuration. An additional advantage is that there are no expended bubbles, which is important in overhead environments (wrecks and caves) where debris could be dislodged and obscure visibility. Rebreathers are also very quiet, which offers obvious advantages for observing wildlife or in military applications where stealth is important. The one caveat to closed-circuit breathing is the high complexity of the system and numerous potential points of failure, including loss of CO₂ removal, flooding or poisoning of the scrubber, O₂ sensor error, or battery brownout.

Firefighting SCBA gear

The standard turnout gear for firefighters provides protection against heat, abrasion, and airborne toxicity. Breathing gas is provided by a self-contained breathing apparatus (SCBA), which is similar to SCUBA gear in operation. Unlike SCUBA, however, the tanks tend to be smaller and constructed with reinforced carbon fiber wrapped around a thin-walled aluminum shell to reduce weight. As compensation, the tanks are filled to ~4,500 psi and contain 45 cubic feet of air. Another difference is that the regulator/mask assembly is simplified because it works against constant ambient pressure rather than the wide pressure ranges found underwater. However, in contrast to diving in neutral buoyancy, firefighting activity is very strenuous. The protective and breathing gear weigh more than 60 lbs without the advantage of water buoyancy, and the firefighters drag heavy hoses, climb ladders, wield axes, and sometimes carry victims out of buildings. As such, SCBA gear needs to accommodate much higher demands as firefighters generally work near their aerobic

threshold. A standard 45 cfm tank is specified for a maximum work cycle of 30 minutes, which is approximately 3-times the “at rest” air demand. For safety, firefighters typically work for 10–20 minute bouts with 5 minute interim periods for recovery to exchange air cylinders (Kesler et al. 2018).

Firefighter masks seal the whole face and use the open-circuit breathing design described above. Rebreather technology (closed circuit design) that requires a small pure O₂ cylinder is considered too risky for live-fire environments.

High-performance aircraft (military jetfighters)

Healthy humans can easily and safely breathe ambient air to ~8,000 feet elevation even with moderate exercise. Above that, the reduced ppO₂ becomes noticeable, and depending on acclimatization and aerobic demand, the breathing air needs to be enriched with O₂ in accordance with altitude. As discussed above, commercial aircraft are pressurized to the equivalent of 8,000 feet elevation for this reason. External air is compressed using jet engine (turbine) bleed air and a constant internal cabin environment is maintained. Passengers breathe normally, although a subset may experience ear pain on ascent and descent.

Cabin pressure—In contrast to commercial aviation, high performance military aircraft generally have only one or two occupants, and so it is more effective to provide breathing air directly with a mask/regulator system much like it is done for divers and firefighters. The main difference from SCUBA or firefighting activity is that the surroundings are at sub-ambient pressures, and aircraft altitude ranges up to ~50,000 feet where the ambient pressure is 0.11 atm, with a ppO₂ of 0.023 atm. Although high performance aircraft do not expose the pilot to the actual ambient pressure, in U.S. fighter jets, the cabin pressure is adjusted based on an altitude schedule. From sea level to 8,000 feet, the cabin pressure is ambient, from 8,000 to 23,000 feet the air pressure is held constant, and above 23,000 feet, the cabin pressure is maintained to be 5 psi higher than the ambient pressure. As such, the cabin pressure schedule provides some amount of safety up to 23,000 feet in that the pilot could breathe cabin air if necessary; however, above this altitude O₂ supplementation is absolutely required. In general, military regulations always require pilots to wear their breathing gear, regardless of altitude in the event of cabin pressure loss.

Oxygen schedule—There are basically two mask/regulator/supply systems used in high performance aircraft in U.S. jetfighter aircraft, pure O₂ “pressure demand” and mixed gas “diluter demand”; other possible systems are beyond the scope of this article. In short, the system either provides pure O₂ regardless of altitude or air enriched with some level of O₂ adjusted for cabin pressure. From a mechanical perspective, it is simplest to supply pure O₂ all the time, but at lower altitudes it is not necessary and may engender oxidative stress in the pilot. In addition, this method of delivery wastes a fair amount of O₂, especially at lower altitudes. A more conservative approach is to adjust the breathing air to provide a ppO₂ close to sea level and only increase the relative concentration to accommodate lower cabin pressures as altitude increases. Referred to as “diluter demand”, this method is more technically complex, but does a better job at providing only as much O₂ as needed by the pilot, and thus also conserves O₂ resources. Figure 5 shows representative pictures of

respiratory protection/supplementation for scuba, firefighting, aircraft maintenance and jet pilots drawn from the authors' field studies.

Breathing system disruptions (BSDs)

One of the most difficult challenges to breathing when using on-demand technology occurs with respect to mechanical delays in valve and regulator response. Termed "breathing system disruptions" (BSDs), these have different (but related) indications. The most common is referred to as "hysteresis" wherein the combination of very brief delays between inhalation, the start of gas flow, and delayed shut-off for exhalation create excess pressure demands on the human. As most of the breathing systems previously discussed use mechanically triggered valves, this is a normal characteristic of on-demand systems, and generally, divers, firefighters and pilots adapt quickly, and mild hysteresis is not noticed. When adapting to such delays results in conscious effort, maintenance is required.

A second BSD indication is "pressure no flow", a more severe condition wherein the regulator and/or mask valves malfunction to the extent that breathing is interrupted noticeably. This is more likely in SCUBA and high-performance jets systems where the system is referenced to varying external pressures. This has been found particularly important in jet fighters where supply pressure, cabin pressure, and mask pressure all interact. A related phenomenon called "free flow" occurs more often in SCUBA diving wherein pressure balance is lost when the second-stage regulator exhalation valve fails and remains open.

The most subtle of the BSDs occur due to high frequency pressure pulses. A recent study of pilot on-demand breathing showed that adaptive pressure controls can "chatter" or "modulate" and at times have a frequency spectrum similar to that of human breathing. Even modest cycling in mask pressure during inhalation (decrease) or during exhalation (increase) may overwhelm the pressures capable of the human system (NASA PBA Report 2020).

Dissolved inert gases

There are additional physics wrinkles in breathing pressurized air based on the thermodynamics of gases dissolved into the body tissues. These are primarily of concern for SCUBA diving where the ambient pressure varies severely, adding one full atmosphere for every 33 feet of depth, but could also affect high-performance aircraft operation, especially during rapid decompression of the cockpit.

Under higher pressures, inert gases (mostly N₂) slowly dissolve into the blood and tissues; because these inert gases are not metabolized like O₂, they can only leave the system in a reverse process as pressure is reduced. If the ambient pressure drops too quickly, interstitial bubbles can form that may damage the surrounding tissues, leading to DCS. Mild DCS can cause fatigue and malaise while more severe cases can affect the lungs and central nervous system, requiring treatment at a recompression facility (Newton et al. 2001). In SCUBA diving, DCS is avoided by slow ascents, and intermittent decompression stops based on dive tables designed to minimize bubble formation. However, more than 50% of DCS cases occur after no-decompression dives, and factors such as hypothermia, fatigue, dehydration,

alcohol, health conditions, and older age can contribute to the risk of developing DCS (Newton et al. 2001).

Inert gas narcosis is another issue that can affect the human system. As inert gases (typically N₂) dissolve into cellular membranes, especially those of the central nervous system, they can disrupt the normal function of neurological signaling analogous to anesthesia or alcohol inebriation, leading to symptoms of light-headedness, euphoria, poor judgement, overconfidence, hallucinations, and possibly loss of consciousness. Narcosis typically happens when diving at deeper depths and during rapid descents. This is a physical effect that quickly resolves upon relief of positive pressure (Rocco et al. 2019).

As discussed in the SCUBA section above, He is sometimes used as an inert balance gas to offset nitrogen narcosis and bubble formation. Although less likely to cause DCS or narcosis, He has six times the thermal conductivity of N₂ and so has a noticeable systemic cooling effect, removing body heat during exhalation.

POSITIVE PRESSURE VENTILATOR BREATHING

The most invasive level of breathing support technology is used when the pulmonary system cannot sustain adequate ventilation. Medical ventilators literally breathe for the patient. They can be used invasively or non-invasively. Non-invasive ventilation (NIV) is relatively simple as ventilation is provided through a mask that is sealed to the nose and mouth externally. When NIV only provides one continuous pressure setting to a spontaneously breathing patient, this is called continuous positive airway pressure (CPAP); when there is one pressure for inhalation (IPAP) and a lower pressure for exhalation (EPAP) a respiratory rate is provided; this is called bi-level positive airway pressure (BiPAP), since there is a different pressure during inhalation and exhalation. NIV is indicated to help patients who can protect their own airway but need assistance oxygenating and/or ventilating. However, hospital ventilators as used in intensive care units (ICUs) commonly require the patient to be intubated wherein a breathing tube is inserted through the mouth or neck and into the trachea. During this invasive ventilation, the tubing is sealed off and the system periodically inflates the lungs. Breathing frequency and parameters to regulate tidal volume are set specifically for each patient.

Indications for controlled invasive mechanical ventilation

The criteria used to decide to place a spontaneously breathing patient on mechanical ventilation varies, particularly for patients with chronic respiratory diseases, but is typically based on the following five criteria related to breathing stress:

1. Inability to protect one's airway
2. Respiration rate is increasing beyond 30 breaths/minute
3. O₂ saturation rate is no longer maintained above 90% despite supplementation above 60% O₂
4. Blood is trending towards acidic, dropping below pH 7.20
5. ppCO₂ exceeds 50 mmHg

Certainly, there are more immediate conditions that require ventilation, including trauma from chest injuries, collapsed lung, heart failure, head injury/coma, and severe pulmonary infection. Ventilators are also used during surgery to maintain breathing under anesthesia and in postoperative recovery.

During the early stages of the COVID-19 pandemic, ventilators were the primary mechanism to preserve life and maintain oxygenation and ventilation in the setting of acute respiratory distress syndrome while the patient's immune system geared up to fight the infection. Since then, antiviral treatments and other early interventions such as nasal cannulas and early prone positioning have reduced the need for invasive ventilation. Figure 6 shows two examples of patients on hospital ventilator equipment; the left panel shows a BiPAP system that provides positive pressure when needed and the right panel shows a patient in an ICU.

Methods for controlled invasive mechanical ventilation

Modern mechanical ventilators are programmable and feedback-regulated to achieve appropriate life support. They have various functions, including volumetric cycling, pressure cycling, flow cycling, and combinations of all three, and are controllable for O₂ concentration, frequency of breathing, and inspiratory flow rate. Traditional adult positive pressure ventilators are typically set for 10–30 breaths/minute, but neonatal ventilators are often used with high frequency (300–1200 breaths/min) coupled with low volumes referred to as high-frequency oscillatory ventilation (HFOV) to accommodate complex respiratory diseases of premature infants with small tidal volumes.

Typically, controlled ventilation starts with 60% O₂, which may be reduced over time as the patient stabilizes to avoid potential complications from oxidative stress. Modern ventilators can accommodate spontaneous breathing response as the patient improves and ultimately return to an “on-demand” hybrid mode.

Ventilator parameter settings

Adjustable ventilator settings differ with mode and patient demand but generally include the following adjustable parameters and their normal settings (in parentheses):

1. Respiratory rate (12–20 breaths/min)
2. Tidal volume (500 mL, or 4–8 mL/kg body mass, depending upon disease pathophysiology)
3. Trigger sensitivity (adjustable for spontaneous breathing response)
4. Flow rate (adjustable from 60 to 100 L/min)
5. Pressure profile - waveform
6. Inspiratory/expiratory (I/E) time ratio (1/2)
7. O₂ concentration (21–100%)
8. Positive End Expiratory Pressure (PEEP, 5–10 cmH₂O)

These parameters are set based on the patient's health state, physical size, age, and ventilation needs to approximate "normal breathing" as discussed previously. Based on health state, there are accommodations for restrictions in the airway (lower flow rates), there may be lower tidal volumes with respectively higher frequency used to adapt for trauma or disease, and there may be a decrease in the I/E ratio from 1/2 to 1/4 to allow for longer exhalation in response to compromised pulmonary flexibility. The waveform parameter is a relatively new concept and may be adjusted to adapt to the patient's particular physiology.

SUMMARY

Human breathing is a complex function that occurs automatically to provide O₂ needed by cells and tissues. Although humans have evolved to breathe 1-atmosphere with 21% O₂, the human systems biology is adaptable to the immediate environment (altitude, pressure, and CO₂). Humans can quickly adapt to small changes in external conditions or O₂ demand unconsciously and can also consciously modify breathing for singing, swimming, breath holding, and coughing. However, if something goes awry, lack of pulmonary ventilation becomes life threatening in a few minutes.

Technology has been developed to protect humans from inhaling contaminants in the air, to provide adequate air flow and concentrations for flight, travel, and sport activities, and for medical supplementation of O₂ within the construct of normal breathing for trauma or disease intervention. Although much of contemporary breathing research involves the chemistry and metabolism of breathing, the physics of breathing described herein is also an important factor in the preservation of human life.

ACKNOWLEDGEMENTS

The authors thank their colleagues in the breath research community, especially those from the International Association of Breath Research (IABR) and the Scientific Board of the Journal of Breath Research (JBR) for inspiration and expertise throughout this project. We especially thank James Dimond and Lauren Carter from JBR for their encouragement and support, John Graf, Marta Shelton, David Alexander and Clinton Cragg from NASA for their expertise in hyperbaric life support, and Kenneth Fent from NIOSH and Gavin Horn from the University of Illinois for insights in firefighter respiration.

Abstract

Background: Nosocomial infection of health-care workers (HCWs) during outbreaks of respiratory infections (e.g. Influenza A H1N1 (2009)) is a significant concern for public health policy makers. World Health Organization (WHO)-defined 'aerosol generating procedures' (AGPs) are thought to increase the risk of aerosol transmission to HCWs, but there are presently insufficient data to quantify risk accurately or establish a hierarchy of risk-prone procedures.

Methodology/Principal Findings: This study measured the amount of H1N1 (2009) RNA in aerosols in the vicinity of H1N1 positive patients undergoing AGPs to help quantify the potential risk of transmission to HCWs. There were 99 sampling occasions (windows) producing a total of 198 May stages for analysis in the size ranges 0.86–7.3 μm . Considering stages 2 (4–7.3 μm) and 3 (0.86–4 μm) as comprising one sample, viral RNA was detected in 14 (14.1%) air samples from 10 (25.6%) patients. Twenty three air samples were collected while potential AGPs were being performed of which 6 (26.1%) contained viral RNA; in contrast, 76 May samples were collected when no WHO 2009 defined AGP was being performed of which 8 (10.5%) contained viral RNA (unadjusted OR = 2.84 (95% CI 1.11–7.24) adjusted OR = 4.31 (0.83–22.5)).

Conclusions/Significance: With our small sample size we found that AGPs do not significantly increase the probability of sampling an H1N1 (2009) positive aerosol (OR (95% CI) = 4.31 (0.83–22.5)). Although the probability of detecting positive H1N1 (2009) positive aerosols when performing various AGPs on intensive care patients above the baseline rate (i.e. in the absence of AGPs) did not reach significance, there was a trend towards hierarchy of AGPs, placing bronchoscopy and respiratory and airway suctioning above baseline (background) values. Further, larger studies are required but these preliminary findings may be of benefit to infection control teams.

Introduction

In 2003, at least 284 healthcare workers (HCWs) were infected with SARS-Coronavirus during the severe acute respiratory

syndrome epidemic [1]. Nosocomial infection was the primary accelerator of infection accounting for 72% of cases in Toronto and 55% of probable cases in Taiwan [2,3]. Aerosol generating procedures (AGPs) performed on infected patients were implicated

as the source of outbreaks among Health Care Workers (HCWs), however no direct evidence for this mode of transmission was demonstrated. [4].

Several medical procedures have been reported to generate aerosols and to increase the risk of pathogen transmission [5]. In response to these concerns the World Health Organization (WHO) produced guidelines on infection control procedures and personal protective equipment in 2007, which were refined in 2009 (Table 1) [6,7]. The guidelines incorporated the available data relating to the infective potential of AGPs but many of the studies contained methodological flaws that precluded the use of their conclusions to draw recommendations, and it was accepted that the level of understanding of the aerobiology of AGPs may evolve. In particular the risks associated with individual AGPs have not been quantified nor has a risk hierarchy been established.

Despite their scientific limitations these guidelines have been used to plan infection control during subsequent pandemics. In addition, controversy remains about the importance of aerosol transmission of influenza in the absence of AGPs [8,9,10]. This ongoing uncertainty was reflected in the diverse approaches adopted by different countries in relation to the recommendations for the use of surgical face masks (SFM) and respirators by HCWs during the 2009 pandemic [11,12,13].

WHO guidance states that standard and droplet precautions (i.e. SFMs) should be adopted when working in direct contact with infected patients and high level respiratory protective equipment (minimum of an FFP2/N95 class respirator) should be worn only in the vicinity of infected patients when AGPs are performed [5,6]. As a result, this infection control strategy was adopted in all U.K. NHS organisations [14].

Infectious pathogens may be contained in aerosols which are generally recognised to be <5 µm in aerodynamic diameter, remain suspended for periods of time and travel significant distances. Safety in the presence of infectious aerosols requires respiratory protective equipment (UK standard - FFP3 respirators) to protect exposed HCWs [14]. During human influenza infection, virus emission occurs via coughing and sneezing, which produce a 'respiratory spray' containing particles in a size continuum from <1 to >500 µm [15].

The initial outbreak and subsequent worldwide spread of influenza A (H1N1) 2009 provided an opportunity to perform air sampling to define the viral RNA copy number, and size of aerosols that an AGP (defined by WHO) produces and the relative burden compared to freely respiring patients.

Methods

Objectives

The primary objectives of this study were to:

- 1) Establish if World Health Organization defined 'aerosol generating procedures' produce infectious aerosols.
- 2) If detectable clouds are produced then determine infectious aerosol concentration and particle size.
- 3) To use this information to inform infection control practice.

Participants

Air was sampled around hospitalised patients with suspected or proven lower respiratory tract infection located either in pandemic H1N1 (2009) isolation rooms (single occupancy rooms) or cohort areas (wards in which numerous patients suspected or confirmed as being H1N1 positive were placed away from other patients). Sampling was performed in 5 different hospitals located around England, U.K. This study was performed from October 2009 to January 2011. Peak sampling times corresponded to known periods of heightened H1N1 (2009) activity. Potential recruits were identified in participating units by local principal investigators who informed the sampling team. The sampling team was deployed to units with the highest level of overall activity. Patient inclusion criteria were defined as new chest X-Ray changes (e.g. consolidation, alveolar infiltrates or atelectasis) in the presence of one or more of the following: central temperature ≥38°C (38.5°C in children) or ≤36°C, white blood cell count <4000 cells/mm² or >12,000 cells/mm², positive microbiology or virology from respiratory secretions and mucopurulent secretions from the respiratory tract (Figure 1). During air sampling, investigators recorded any clinical interventions performed, as well as temperature, relative humidity, time and location of air sample, activity levels, patient sex, age, diagnostic specimen type, results and time since admission. Using these data, two consultant physicians (JP & MB), blinded to the air sampling data and the H1N1 status of the patients, independently coded interventions as AGPs if they met 2007 and 2009 WHO definitions (Table 1). Any disagreements were discussed until a consensus was reached. Baseline samples were those taken during interventions not meeting the WHO definitions of an AGP or taken at least 30 minutes after a WHO defined AGP had been completed. All recruits had at least one baseline sampling event, but incidence of

WHO defined AGPs was rarer and investigators attempted to capture as many of these as possible.

Description of Procedures or Investigations Undertaken

Glass May 3-stage impingers (produced at HPA, Porton Down), operating at 55 litres per minute and placed at 1 meter height within 1 meter of the patients head, were used to collect air samples for a maximum of 40 minutes [16]. Baseline samples were taken for 10 minutes. Air was collected into 15 mls of sterile, nuclease free, molecular grade, phosphate buffered saline. The May 3-stage impinger fractionates air particles into 3 aerodynamic size ranges, stage 1 collects particles $>7.3 \mu\text{m}$, stage 2 collects particles in the range $4-7.3 \mu\text{m}$ and stage 3 collects particles $0.86-4 \mu\text{m}$. Liquid air samples were transported to the laboratory frozen on dry ice and stored at -20°C until analysis.

The sampling team and all staff/visitors were wearing FFP3 respirators in cohort areas and isolation rooms during the 2009/2010 pandemic. In addition, the sampling team, and a proportion of the staff/visitors were vaccinated against the pandemic strain and the majority of other patients in the intensive care units were on closed ventilator circuits. This means that it is unlikely that the influenza aerosols could have been generated by anyone other than the patient on whom the AGP was being performed. In the case of baseline samples there was often some form of non-AGP classified activity ongoing (e.g. activity associated with chest physiotherapy or respiratory care), and as such these samples do

not represent 'control' samples where no activity was taking place, they merely represent air samples taken when no activity that could be defined as an AGP was taking place.

Sample Processing and Analysis Methodology

On arrival at the laboratory samples were stored at -20°C prior to RNA extraction. Each sample was concentrated into $<500\text{ }\mu\text{l}$ using 30 kD macroseph centrifugal devices (5000 g for 1.5 hours at 4°C). Any viral RNA present within the resulting concentrate was extracted using the Qiagen QIAamp viral RNA spin protocol (Qiagen, U.K.) and eluted into $2\times 30\text{ }\mu\text{l}$ volumes of elution buffer which were subsequently pooled. Samples were frozen at -20°C and defrosted prior to use in the qRT-PCR assay.

A pan-influenza A qRT-PCR assay, based on the pan-influenza segment 7 assay developed by Spackman *et al.* (2002), was used to detect the presence of any influenza A RNA within the samples [17]. The primer, probe concentrations and RNA template volumes were re-optimised from the conditions originally described. The hydrolysis probe was also adapted to use a black hole quencher (BHQ) rather than Carboxytetramethylrhodamine (TAMRA) increasing assay sensitivity. A standard curve was also added to the assay to allow quantification of influenza RNA within the samples. This was prepared using 2009 pandemic nH1N1 A/Cal/04/09 influenza virus. RNA extracted from a live virus preparation was performed using the QIAamp viral RNA mini kit (Qiagen). The full-length influenza segment 7 was amplified by RT-PCR using RT primer Uni12 and PCR primers Bm-M-1 and BM-M-1027 R as described in Hoffman *et al.* (2001) [17]. The amplicon was purified from a 1% (w/v) agarose gel using the QIAquick gel extraction kit (Qiagen), cloned into pCR 2.1 TOPO vector and heat-shocked into *E. Coli* TOP10 cells, as described in the TOPO TA cloning kit (Invitrogen), to construct pCR 2.1 TOPO-CalM. The influenza A/Cal/04/09 segment 7 insert within pCR 2.1 TOPO-CalM was confirmed by sequencing using M13 forward and reverse priming sites that flanked the insert (data not shown). The H1N1 A/Cal/04/09 segment 7 sequence was then amplified from pCR2.1 TOPO-CalM by PCR using primers MCalFwd1 (5'-AGCTAGG-CATGCGCGGCCGAGCAAAAGCAGGTAG-3') and MCal-Rev1 (5'-AGCTAGGCATGCTAATACGACTCACTATAGGGAG-TAGAAACAAGGTAGTTTTT-3') which contained a T7 RNA polymerase promoter sequence (highlighted in italics). A negative sense T7 RNA transcript of the Cal/04/09 M segment sequence was generated from the PCR amplicon, with the amplicon subsequently removed by DNase digestion, using the Megascript T7 kit (Ambion). DNase digestion of the amplicon template was confirmed by agarose gel electrophoresis. The RNA transcript was purified using an RNeasy mini kit (Qiagen) RNA clean-up protocol and the copy number calculated following determination of the RNA transcript concentration with a Nanodrop ND100 spectrophotometer.

All qRT-PCR reactions were performed on 96-well plates using the superscript III platinum one-step quantitative RT-PCR kit (Invitrogen) and run on the Applied Biosystems 7900 real-time PCR system. Each 96-well plate consisted of a standard curve (prepared from a ten-fold dilution series of the nH1N1 A/Cal/04/09 M segment RNA transcript in H_2O) which also acted as the assay positive control, a non-template negative control (molecular grade water) and RNA from processed air samples. All controls and samples were run in duplicate. qRT-PCR reactions consisted of $12.5\text{ }\mu\text{l}$ $2\times$ Buffer, $1.25\text{ }\mu\text{l}$ M+25 oligo (AGA TGA GTC TTC TAA CCG AGG TCG) (300 nM final concentration), $1.25\text{ }\mu\text{l}$ M-

125 oligo (TGC AAA AAC ATC TTC AAG TCT CTG) (300 nM final concentration), $0.5\text{ }\mu\text{l}$ Rox, $0.5\text{ }\mu\text{l}$ Taq/superscript enzyme, $0.25\text{ }\mu\text{l}$ M+65 probe (FAM-TCA GGC CCC CTC AAA GCC GA-BHQ) (250 nM final concentration) and $8.75\text{ }\mu\text{l}$ of either sample RNA, standard curve RNA or negative control (dH_2O) to reach a final volume of $25\text{ }\mu\text{l}$. The Influenza qRT-PCR Cycling Conditions were 50°C for 30 minutes, 95°C for 10 minutes, followed by 50 cycles of 95°C for 15 seconds and 60°C for 60 seconds. The number of virus copies/litre were for each sample was then determined using the standard curve (R^2 values were typically 0.94).

Ethics

The study was approved by Oxfordshire Local Research Ethics Committee (REC reference 09/H0604/119) and the requirement for informed consent was waived. The committee agreed that this study did not constitute intrusive research because it involved only the processing of non-identifiable data. The committee felt that the provisions of the Mental Capacity Act did not apply to this study. The committee welcomed the statements by the researchers that they would always seek the views of patients, parents and/or relatives prior to starting to take air samples and that they would respond to concerns after the sampling had started. The committee is constituted in accordance with the Governance Arrangements for Research Ethics Committees (July 2001) and complies fully with the Standard Operating Procedures for Research Ethics Committees in the U.K.

Statistical Methods

Statistical analysis was performed with Stata software (version 11.0; Stata Corp., College Station, TX, USA). Only patients confirmed as influenza A H1N1 (2009) RT-PCR positive from respiratory tract samples were considered in the statistical analysis. Univariable logistic regression models were used to examine the relationship between propensity to produce a positive H1N1 aerosol sample and a number of potential risk factors. Wald tests were used to assess risk factor significance. A sample was considered to be positive for aerosolised influenza particles if either or both of May stages 2 and 3 ($0.86\text{--}7.3\text{ }\mu\text{m}$) indicated the presence of H1N1. Copy numbers from stages 2 and 3 were summed to give a total copy number for the sampling occasion. A random effect was included in the logistic models at subject level to account for potential correlation caused by repeated measurements on the same individual. In instances where a positive H1N1 sample was produced, univariable negative binomial regression models, corrected for sample duration, were used to examine the relationship between total copy number per litre per minute and potential risk factors. Only three participants gave more than one positive H1N1 sample and so a random subject-level effect was not used in the negative binomial regressions. Instead a robust standard error was used to adjust for potential correlation in these models.

Finally, the probability of obtaining a positive sample and the viral load obtained from positive samples were modelled to rank the 2007 and 2009 WHO procedure lists and chest physiotherapy and produce a hierarchy of procedures on the basis of potential risk. The classical definition of risk as equal to 'probability times consequence' was used and hence multiplied predictions from the logistic and negative binomial models together in order to obtain a risk measure which gives the expected value of copy number (l/min) associated with each procedure.

Results

A total of 57 patients were studied, however only 39 patients were later confirmed as influenza A H1N1 (2009) RT-PCR positive and were included in the statistical analysis.

Table 2 and 3 show the percentage of total RNA found in each stage of the May impinger (Table 2) and the % of RNA collected in each stage during each procedure (Table 3). These tables show that most of the RNA recovered from the baseline samples has been recovered in the $>7.3\ \mu\text{m}$ size range (53.6% of total RNA and 78.7% of the total RNA recovered from baseline samples). In contrast, the total amount of RNA recovered from all the bronchoscopy samples was only 7.1% (confounded by limited sample size) but 75.1% of this was collected in the stages $<7.3\ \mu\text{m}$. The situation is similar for respiratory and airway suctioning (3.0% total RNA of which 77.6% was in the $<7.3\ \mu\text{m}$ size range). Therefore the results indicate that AGPs as defined by the WHO 2009 definitions tend to produce aerosols of smaller particle sizes than baseline levels.

Figure 1 shows the patient inclusion process but as this paper is interested in the ability of AGPs to generate aerosols rather than respiratory droplets subsequent analysis deals with the results from the second and third stages (particle sizes $0.86\text{--}7.3\ \mu\text{m}$) of the May sampler, however full results can be seen as an online supplement. Tables 4 & 5 show H1N1 patient demographics together with other characteristics of their samples.

There were 99 sampling occasions (windows) producing a total of 198 May stages for analysis in the size ranges $0.86\text{--}7.3\ \mu\text{m}$ (Table 6). Forty-six air stage samples were collected while potential AGPs (according to WHO 2009 definitions – see Table 1) were being performed of which 9 (19.6%) contained viral RNA; in contrast, 152 May stage samples were collected when no WHO 2009 defined AGP was being performed of which 12 (7.9%) contained viral RNA (unadjusted OR = 2.84 (95% CI: 1.11–7.24) adjusted OR = 4.31 (0.83–22.5)).

There were 99 May stages for analysis in the $>7.3\ \mu\text{m}$ size range, 23 air stage samples were collected while potential WHO (2009) AGPs were being performed of which 3 (13.0%) contained viral RNA; 76 May stage samples were collected when no WHO (2009) AGP was being performed of which 9 (11.8%) contained viral RNA. This was not statistically significant (unadjusted OR = 1.06 (0.26–4.29)).

Results from the logistic regressions (Tables 4, 5, 6, 7, 8, 9) indicate that, after adjustment for repeated measurements, none of the variables we examined had a significant influence on the production of an H1N1 positive aerosol ($p < 0.05$) (Table 6). The value of the estimated odds ratio (OR) for the likelihood of producing PCR positive air samples in particle sizes ranges $0.86\text{--}7.3\ \mu\text{m}$ in the presence of a WHO (2009) AGP was 4.31 (0.83–22.5). The categorical variable for WHO (2009) AGP was itself not significant.

Subject-level random effects obtained from the null logistic model indicate that one individual in the study has a significantly higher propensity than average to produce a positive sample, and that others have a raised propensity. This, coupled with the lack of significant relationships given in Tables 4, 5, 6, 7, 8, 9, suggests that propensity to produce a positive sample is more related to unmeasured individual-level attributes than demographic or other measured characteristics. The variation caused by the unmeasured attributes is high as the subject-level random effects have wide confidence intervals. The Variance Partition Coefficient (VPC) for the null logistic model indicates that only 31% of the total variance in the propensity to produce a positive sample is due to differences between individuals, for example in age or hospital location, and hence 69% is due to differences within individuals, for example, stage in infection. Unfortunately we do not have enough data to analyse an individual through time to investigate this further.

Results from the negative binomial regression are also given in Tables 4, 5, 6, 7, 8, 9. Copy number per litre is significantly positively associated with cases aged 50–60 years (incident rate ratio [IRR] 8.85 compared to referent, (95% CI: 4.14–18.9)) and cases from hospital location no. 2 (IRR 6.21(2.49–15.5)). It is significantly negatively associated with days since diagnosis (IRR 0.84 (0.79–0.90)); days since last positive sample (IRR 0.84 (0.78–0.90)); and relative humidity (IRR 0.95 (0.91–0.98)). However, WHO (2009) AGP categorisation itself was found to have no association with copy number, suggesting that some AGPs are associated with high copy numbers and others are associated with low copy numbers, as revealed by the IRR estimates for the various WHO (2009) AGP categories. These range from 0.15 to 5.41 (Table 6) but are, however, inconclusive because of the low numbers in each category. Our analysis of the influences on virus quantity in an aerosol is likely to be subject to confounding because of the low number of positive samples, and possible correlation between risk factors.

When the data are analysed with regard to the WHO (2007) AGP definitions there was a broad agreement with the results detailed above (Table 7). We also included procedures relating to chest physiotherapy in the analysis against AGP (2009) and AGP (2007) (Tables 8 & 9). The results suggest that chest physiotherapy is associated with an increased probability of aerosol production if included in the WHO (2009) AGP model (OR 3.06 (0.28–33.3)), but that aerosol titre is lower than baseline samples (IRR 0.23 (0.06–0.93)). To further establish the relationship between different AGPs the data were modelled to determine a hierarchy of procedures in terms of the potential risk of generating infectious aerosol (Table 10). We found that whilst most AGPs are associated with a higher probability of sampling an H1N1 positive aerosol they are also, with the exception of bronchoscopy, associated with lower copy numbers (1/min) than background samples and this lessens their overall risk (Tables 6, 7, 8, 9). Only bronchoscopy and

respiratory/airway suctioning were found to have a risk greater than that encountered in the baseline (background) samples.

Discussion

Evidence regarding the role of AGPs in the transmission of influenza in the hospital setting is limited. [5] The results from Table 2 indicate that smaller particles are preferentially produced during AGP procedures compared to baseline samples. However the total level of RNA recovered is higher during baseline samples, i.e. large particles containing higher quantities of RNA vs smaller particles containing smaller quantities of RNA. Due to the limitations of the sampling method it is impossible to quantify the total number of particles at each particle size – we only have an indication of the quantity of RNA collected in each particle size range. One might speculate (as others have done before) that a dispersed aerosol with a low concentration of influenza containing small particles might potentially be more of a transmission and morbidity risk than a few large particles containing significantly more total influenza. [5,19].

This study detected influenza virus RNA in 14/99 (14.1%) air-sampling windows in particles 0.86–7.3 μm from 10/39 (25.6%) patients in broad agreement with reports from different health care settings [20,21,22,23]. Of particular note is the fact that 19.6% of air specimens taken in the presence of a 2009 defined AGP (AGP 2009) revealed virus RNA infractions 0.86–7.3 μm , compared with only 7.9% in non-AGP (2009) settings (unadjusted OR = 2.84 (95% CI: 1.11–7.24) adjusted OR = 4.31 (0.83–22.5)).

Data were analysed for the propensity of an air-sampling event to produce a positive air sample in the 0.86–7.3 μm aerodynamic size range. None of the variables investigated in this study significantly increased the probability of obtaining a positive air sample for either the 2007 or 2009 analysis. However, there will be variability in the potential for the air sampler to detect positive air samples due to a number of factors including room ventilations patterns, the air particles' initial velocities, temperature, relative humidity, and distance from source [24]. Even with this significant level of uncertainty and the low sample number we estimated an adjusted OR of 4.31 (0.83–22.5) for WHO (2009) AGP vs non WHO (2009) AGP settings ($p = 0.083$). Taken together with an unadjusted OR of 2.84, and in the context of the small study size, these findings suggest a true effect i.e. that AGPs as currently defined by 2009 WHO definitions increase the likelihood of generating infectious aerosols to the extent that this may be relevant in a clinical setting. However, we have almost certainly encountered a Type II statistical error due to small numbers. Further data are therefore required.

Analysis of the specific procedures shows that bronchoscopy is associated with the greatest probability of aerosol production (OR = 43.8(1.06–1809)), but both intubation and related proce-

dures (OR = 2.71 (0.15–49.1)), respiratory/airway suction (OR = 4.11 (0.50–34.0)) and chest physiotherapy (OR = 3.06 (0.28–33.3)) also show increased probability, although none of these results attained statistical significance.

The quantity of viral RNA is known to vary both between patients and within individual patients during the time-course of their illness. Patients early in the course of infection excrete higher titres of virus and thus might generate aerosols containing more viral RNA. [25] In our study only 31% of the total variance in the propensity to produce a positive sample is due to differences between individuals, and 69% is due to differences within individuals. Unfortunately, we did not have ethical committee approval to obtain respiratory tract specimens from patients; thus although we can determine H1N1 diagnostic status from specimens taken by the attending physician (the basis of recruitment into this study), we cannot correlate our air sample findings against patient virus concentrations. Many other studies have also noted high variability in the number of virus particles expelled by subjects infected with respiratory pathogens therefore this work is consistent with previous studies. [22,26,27,28,29].

The influenza RNA loading of a positive air sample is likely to be influenced by the source of the aerosol (i.e. the patient and the location within the patient where the aerosol is produced). In a recent paper by Johnson et al., 2011, it has been suggested that aerosols of different particle sizes can be produced from different areas of the respiratory tract when different activities are performed, such as coughing, breathing and talking [30]. Although not investigated in this study the results suggest that the aerosols detected in our study could have originated from different parts of the respiratory tract, which could account for the wide range of viral titres picked up. If the viral loading differs along the respiratory tract and between individuals, and the different procedures have differing abilities to produce an aerosol, then a wide range of viral titres would be expected. However it is also true that variability in the data can be caused by differences in impinger proximity, orientation, directional air flows, human activity (producing turbulent air conditions) and ventilation levels between sampling sites.

The results indicate (although small sample size prohibits firm conclusions) that performance of a bronchoscopy increases the viral copy number per litre in positive air samples by a factor of 4.37 (CI = 0.60–32.0). Intubation and related procedures and respiratory/airway suctioning show decreased IRRs (0.12 (0.03–0.5) and 0.35 (0.07–1.70), respectively). This is the first evidence to suggest that some AGPs (e.g. bronchoscopy) may confer a greater risk of transmission to HCWs than others.

In order to further understand the risk hierarchy, titre and probability of a positive sample have been used to construct a risk summary stratification table (Table 10). This table has been

produced simply as a method to summarise the results and modeled numbers are purely an indication of overall risk. However, this table shows that when probability of a positive air sample and the titre of an air sample are used to define risk, only bronchoscopy and the 2009 defined respiratory/airway suctioning carry a greater risk than the baseline samples. Positive baseline samples may be produced from residual aerosols left from previous AGPs, by some other unknown low level AGP, or by other H1N1 positive individuals coughing and sneezing in cohort areas.

The copy number of influenza virus recovered from a positive air sample is strongly influenced by hospital location ($p < 0.001$), age range ($p < 0.001$), day since diagnosis ($p < 0.001$), days since last positive diagnostic sample ($p < 0.001$), air sample volume ($p < 0.001$) and relative humidity ($p = 0.006$).

Hospital location number 2 had significantly higher viral concentrations recovered from positive air samples potentially because this hospital is a tertiary referral centre for respiratory illnesses which provided extracorporeal membrane oxygenation (ECMO) for adults during the H1N1 outbreak. In addition, most bronchoscopies were performed at this location and this hospital contained the patient with a higher than average propensity to produce a positive sample.

Age was shown to have a significant effect with patients aged between 50–60 years having the highest rate of H1N1 aerosol generation in contrast to what would be expected from previous studies [31,32]. This apparent age-related effect could be due to an outlying result; the patient with the significantly higher propensity than average to produce a positive air sample was in this group. A negative association between the copy number recovered and the number of days between diagnosis and sampling was found as would be expected. The significance of the relationship between high relative humidity and lower recovery of viral RNA correlated with previous studies [33].

Limitations

This study has several limitations. Firstly, we did not perform a biological assay to quantify the viability and infectious potential of this viral material. Although the influenza virus is capable of surviving in air in the indoor environment there are no data regarding the stability of pandemic H1N1 (2009) in aerosols. The successful culture of viable viruses from environmental samples is technically difficult and thus relatively insensitive as a bioassay of infectivity [21,22]. However, we believe that the detection of virus RNA in an aerosol within seconds of its generation, favours it being derived from viable viruses.

Secondly, even if an aerosol of the appropriate concentration does reach a health care worker and is inhaled, inhalation does not necessarily equate to infection. Infection depends upon infectious dose, route of inhalation (nose or mouth), tidal volume, breathing rate, timing and underlying susceptibility (immune status) [34]. It also depends upon particle size, for a particle to enter the distal lung it needs to be <5 µm for >10% deposition [35]. As we sampled in a wide range of different hospitals and it was very difficult to establish and get information about ventilation rates and patterns between hospitals and within different areas of the same hospital. In general isolation rooms had higher ventilation rates than ward cohort areas and in some cohort areas the opening of windows was the only form of ventilation evident. Obviously it was impossible to investigate fully all the areas we sampled due to time and logistical constraints in these busy environments. This study, therefore, can only give an indication of the levels of influenza RNA which a health-care worker could be exposed to.

Thirdly, estimating the aerosol infectious dose from previous studies is difficult due to the lack of studies in this area for health and ethical reasons [19,36]. However, Alford *et al.*, (1967) found that the aerosol infectious dose of influenza A2/Bethesda/10/63 was between 0.6–3 TCID₅₀, which equates roughly to 0.6–3 virus particles according to Teunis *et al.*, (2010). [19,37] The potential

exposure of HCW during AGPs can be roughly calculated using the aerosol concentration, breathing rate and exposure time. If we assume a female HCW breathing rate of 15 l/min during an AGP lasting 15 minutes then 225 litres of air will be inhaled during the procedure. [38] The modelled concentration of viral copy numbers found during the bronchoscopy positive air samples was 9,986 copies/litre/minute, suggesting that expected exposure would be 2246850 virus copies. This exposure is significantly greater than the 0.6–3 TCID₅₀ aerosol infectious dose reported by Alford *et al.*, in (1967). The study also shows that significant exposure to H1N1 aerosols (modelled copy number 2,285 copies/litre/minute) occurs in the absence of a recognized AGP in the vicinity. This study and that of Killingley *et al.*, suggest that exposure to aerosols of influenza may regularly occur during epidemics not just in ICUs or hospitals but in many other environments [20].

Fourthly, the May impinger does not collect particles <0.86 µm aerodynamic particle size, several studies have reported finding influenza RNA in air particles <1 µm, thus it is possible that some of the aerosolized RNA was missed [22,23].

Finally, this was a large and complex study involving collaborations between the laboratory, sampling teams and busy clinicians from five hospitals. Due to the limited resources, lack of time and ethical constraints full clinical information on patients was not available. It is likely that the patients will represent a full spectrum of clinical presentations. Some patients would be in the early course of the infection while others had been infected for weeks, therefore, no information on viral load immediately prior to air sampling was available. In addition, there are numerous technical difficulties associated with the recovery of influenza from the air with the potential that many additional positive air samples have been missed due to the reasons previously discussed.

Notwithstanding the constraints imposed by small numbers, our data indicate that some AGPs as defined by WHO in 2009 do

appear to be related to an increased likelihood of viral aerosol generation. The data are particularly clear for bronchoscopy and respiratory/airway suctioning. We conclude that AGPs have the potential to pose a threat of infection transmission to health care workers and that until further data are available, UK and WHO infection control policies for the use of high-filtration face pieces (respectively FFP3 and N95 respirators) during the performance of AGPs remain appropriate and should continue to be practiced according to local guidelines until more data are available.

Acknowledgments

The authors are the writing group on behalf of the Environmental monitoring of airborne samples (EASE) consortium. The authors would like to thank all members of the EASE consortium. The EASE study consortium have assisted in participant recruitment or have given logistical/scientific support to the project - these persons include Dr Alec Bonington, Dr Ian MacCartney, Dr Nick Sherwood, Dr Mark Bailey, Mr Thomas Pottage, Dr Peter McQuillan, Mrs Sara Speight, Dr Jimmy Walker, Dr Jane Greatorex, Nick Phin, Erika Duffel, Andrew Turner, Julian Sutton, Steve Shaw, Fiona Jefferies, Dr R Cusack, Dr Nick Parham and Miss Anna Davies.

The authors would like to acknowledge and thank all NHS and HPA staff that assisted during sampling in the hospital environment particularly all principle investigators. The views expressed in the publication are those of the authors and not necessarily those of the Department of Health, Health Protection Agency or any other funding body.

Summary

The potential aerosolised transmission of severe acute respiratory syndrome coronavirus-2 is of global concern. Airborne precaution personal protective equipment and preventative measures are universally mandated for medical procedures deemed to be aerosol generating. The implementation of these measures is having a huge impact on healthcare provision. There is currently a lack of quantitative evidence on the number and size of airborne particles produced during aerosol-generating procedures to inform risk assessments. To address this evidence gap, we conducted real-time, high-resolution environmental monitoring in ultraclean ventilation operating theatres during tracheal intubation and extubation sequences. Continuous sampling with an optical particle sizer allowed characterisation of aerosol generation within the zone between the patient and anaesthetist. Aerosol monitoring showed a very low background particle count (0.4 particles.l⁻¹) allowing resolution of transient increases in airborne particles associated with airway management. As a positive reference control, we quantitated the aerosol produced in the same setting by a volitional cough (average concentration, 732 (418) particles.l⁻¹, n = 38). Tracheal intubation including facemask ventilation produced very low quantities of aerosolised particles (average concentration, 1.4 (1.4) particles.l⁻¹, n = 14, p < 0.0001 vs. cough). Tracheal extubation, particularly when the patient coughed, produced a detectable aerosol (21 (18) l⁻¹, n = 10) which was 15-fold greater than intubation (p = 0.0004) but 35-fold less than a volitional cough (p < 0.0001). The study does not support the designation of elective tracheal intubation as an aerosol-generating procedure. Extubation generates more detectable aerosol than intubation but falls below the current criterion for designation as a high-risk aerosol-generating procedure. These novel findings from real-time aerosol detection in a routine healthcare setting provide a quantitative methodology for risk assessment that can be extended to other airway management techniques and clinical settings. They also indicate the need for reappraisal of what constitutes an aerosol-generating procedure and the associated precautions for routine anaesthetic airway management.

Introduction

The severe acute respiratory syndrome coronavirus-2 (SARS-CoV-2) and associated coronavirus disease 2019 (COVID-19) pandemic have had an unprecedented impact on global health and the world economy. Drastic interventions to limit transmission have been introduced worldwide, such as lockdowns, physical distancing and the use of personal protective equipment (PPE). Respiratory secretions have a high SARS-CoV-2 viral load and are believed to be the main source for person-to-person transmission [1, Cevik et al., preprint: doi.org/10.1101/2020.07.25.20162107]. Coughing and sneezing atomise respiratory secretions into particles with different aerodynamic properties according to size; particles greater than 20 µm in diameter are conventionally defined as droplets and tend to follow a ballistic trajectory. These droplets can either directly contact and infect a susceptible individual within close proximity or may settle on nearby surfaces (fomites) where viable virus can exist for up to 72 h [2, 3]. This direct droplet and indirect contact transmission are considered the predominant modes of spread of SARS-CoV-2, providing the rationale for physical distancing and hand hygiene as primary measures to reduce the incidence of COVID-19.

The extent to which SARS-CoV-2 is transmitted by the airborne route is a controversial topic [3–6]. Aerosolised particles (typically considered to be < 20 µm in diameter and particularly those of < 5 µm) may transmit infection by deposition on respiratory epithelium and can potentially transit the full extent of the respiratory tract. It is also feared that these small particles may remain airborne for long periods and may be carried far from the site of origin by air currents. The risks from aerosols and optimum methods of preventing transmission are under active debate [7–10]. To minimise airborne transmission of SARS-CoV-2 to healthcare workers, specific patient care activities have been designated as aerosol-generating procedures. Tracheal intubation and extubation, manual ventilation via facemask and respiratory tract suctioning are all designated as aerosol-generating procedures [11–13]. Many organisations, including the World Health Organization and the public health bodies of the UK, have recommended that those undertaking these aerosol-generating procedures wear airborne precaution PPE consisting of a fitted face-piece (FFP3 or NR95), a long sleeved, fluid-resistant gown, gloves and eye protection [1, 13].

The quantitative evidence base for these guidelines is weak and the relative magnitude of risk for each aerosol-generating procedure is unknown [3, 11]. The evidence for this designation is largely based on retrospective cohort

and case-controlled studies of transmission during the severe acute respiratory syndrome (SARS) pandemic in 2003 [12, 14]. A systematic review of these studies concluded that tracheal intubation was associated with a significant increase in risk of disease transmission but categorised the quality of available evidence as “very low quality based on GRADE” and identified that “a significant research gap exists in the epidemiology of the risk of transmission of acute respiratory infections from patients undergoing aerosol generating procedures to healthcare workers, and clinical studies should be carefully planned to address specific questions around the risks of transmission in these settings” [12]. An attempt to provide such evidence employed aerosol sampling traps placed in the vicinity of patients with H1N1 influenza during periods of hospital care, including some with aerosol-generating procedures, but this large study did not clearly demonstrate an increased risk above background of detecting virus RNA in the air [15]. There is still no quantitative evidence of increased aerosol generation from the designated aerosol-generating procedures, which likely relates to the challenge of obtaining such measurements in routine healthcare settings.

When considering the risk of transmission of SARS-CoV-2, it is helpful to reflect on the definition of an aerosol-generating procedure that has been expressly stated as “aerosol generating procedures are considered to have a greater likelihood of producing aerosols compared to coughing.” [16]. There is a comparatively large quantitative evidence base around aerosolised particle generation by coughing from laboratory-based investigations with sizes ranging from visible droplets to submicron particles [17–20]. Given the uncertain balance of potential risks and benefits associated with the protective strategies put in place to limit viral transmission, it is important to quantitatively assess the degree to which individual aerosol-generating procedures generate aerosolised particles. In this study, we have quantitated airborne particle emission in real-time during tracheal intubation and extubation, using particle analysis instruments in a working operating theatre environment and compared this with volitional coughs as a reference.

Methods

A prospective environmental monitoring study was conducted to quantitate the airborne particle size distribution and particle number concentration produced by aerosol-generating procedures in four operating theatres in a UK hospital (North Bristol NHS Trust). Institutional Review

Board approval for the study was given by the Faculty of Life Science and Science Research Ethics Committee at the University of Bristol. As this was an observational study, the anaesthetic and theatre team undertook their normal practice during airway management. The researchers were not involved in the delivery of anaesthetic care.

Observations were made within operating theatres with an ultraclean, laminar flow ventilation system (EXFLOW 32; Howorth Air Technology, Farnworth, UK) with high efficiency particulate air (HEPA) filtration. This ventilation system has a canopy 'clean zone' where surgical procedures are performed; the air circulation velocity is 0.2 m.s^{-1} at 1 m above the floor below the canopy and produces 500–650 air changes per hour. All aerosol recordings were performed under the canopy. Air temperature in theatres was set to 20°C and humidity between 40 and 60%.

A lightweight, portable Optical Particle Sizer (TSI Incorporated, model 3330, Shoreview, NM, USA) was used which samples air at 1 l.min^{-1} and detects particles by laser optical scattering. The optical particle sizer reports the particle number concentration and size distribution within the diameter range 300 nm to $10 \mu\text{m}$ with a time resolution of 1 s. It is widely used for aerosol studies both within laboratories and clean rooms to use in more demanding applications in the outside environment. It is calibrated by the manufacturer using polystyrene latex spheres and its performance conforms to the ISO standard 21501-4:2018. A sampling funnel was 3D printed (RAISE3D Pro2 Printer, 3DGBIRE, Chorley, UK) with a maximum diameter of 150 mm, cone height of 90 mm with a 10-mm exit port. A conductive silicone sampling tube of 2 m length and internal diameter 4.8 mm (3001788, TSI) connected the sampling funnel to the optical particle sizer. This had an internal volume of 145 ml giving a transit lag between the funnel and the particle sizer (with a flow of 1 l.min^{-1}) of 8.7 s which was taken into account in the time registration of measurements.

In an initial set of pilot studies in the ultraclean theatre environment, it was possible to reliably detect a volitional cough from a subject lying supine (JB) at a sampling distance of 0.5 m from the mouth to the funnel. Sampling at 0.5 m approximates the distance from the face of the airway management practitioner to the patient's mouth during the intubation sequence. For recordings during intubation and extubation, the sampling funnel was, therefore, positioned at a distance of 0.5 m facing the patient's mouth and close to the anaesthetist (Fig. 1). For several extubations, we repositioned the funnel to lie above and behind the patient's head, again at 0.5 m and facing the patient's

Figure 1 Simulation of aerosol measurement approach within operating theatre environment. The sampling funnel was positioned 0.5 m above the source of aerosol in the airway management zone allowing a sampling stream of air (1 l.min^{-1}) to be routed to the optical particle sizer.

airway. The funnel was handheld to ensure it could be quickly removed from the airway management zone in case of clinical need (this was not needed in the course of the study). All healthcare workers, and members of the investigating team, wore airborne precaution PPE during aerosol-generating procedure measurements.

Tracheal intubation and extubation consist of a series of discrete events and procedures which we designated as sequences. For tracheal intubation measurements, anaesthetic induction followed a conventional sequence with pre-oxygenation, intravenous induction by administration of anaesthetic and neuromuscular blocking drugs, manual ventilation of the lungs via a facemask, direct laryngoscopy and intubation of the trachea followed by inflation of the tracheal tube cuff which was the reference end point of the intubation sequence. Standard anaesthetic monitoring was used including waveform capnography. This whole intubation sequence typically lasted 3–4 min with continuous aerosol monitoring throughout. The 5-min period before inflation of the tracheal tube cuff was analysed.

For recordings during tracheal extubation, the level of anaesthesia was lightened, spontaneous breathing allowed

to recommence, the oropharynx was suctioned before the tracheal tube cuff was deflated, and the trachea was then extubated according to the anaesthetist's normal practice. After extubation and confirmation of airway patency, the patient received oxygen via an anaesthetic facemask and then a Hudson™ mask. The reference point for the start of extubation was tracheal tube cuff deflation (releasing the seal on the airway). Continuous monitoring with the optical particle sizer was conducted throughout and a period of 3 min before and up to 2 min after cuff deflation was analysed.

Airway management events including cuff inflation, deflation and coughs were recorded contemporaneously by the researcher using a time stamp application (Emerald Timestamp, Emerald Sequoia LLC, <https://emeraldsequoia.com/ts/index.html>). Data were exported from the TSI optical particle sizer, processed in the TSI Aerosol Instrument Manager software, and analysed in Origin Pro (Originlab, Northampton, MA, USA) and Prism v8 (Graphpad, San Diego, CA, USA). Comparisons were made between aerosol-generating events with unpaired t-tests with the significance level set at $p < 0.05$.

Results

Environmental aerosol monitoring was conducted over a 3-week period during operating lists for orthopaedic trauma and neurosurgical emergencies. Recordings were made of 19 intubations and 14 extubations. The conduct of anaesthesia was left at the discretion of the anaesthetist, who ranged in experience from junior trainee to senior consultant. Control environmental monitoring recordings showed the ultraclean, laminar flow ventilation and air filtration system produced a very low background of aerosol particles averaging 0.4 l^{-1} when the theatre was empty, and 3.4 l^{-1} when the theatre was in use but no aerosol-generating procedures were in progress. Thirty-eight volitional coughs were sampled at 0.5-m distance. These coughs showed a characteristic profile with a rapid and transient spike of expectorated particles (Fig. 2a). Peak aerosol concentration occurred 2 s after the cough was registered and averaged $1310 (905) \text{ particles.l}^{-1}$. The spike in aerosol particle count decayed back to baseline with a time constant of approximately 2.7 s. Each cough contained an average of 134 (77) detected airborne particles (over the 12 s window). The large majority of the particles were $< 1 \mu\text{m}$ diameter (Fig. 2d). Although we conducted our monitoring under the ultraclean ventilation canopy, the temporary suspension of the laminar flow system (0.2 m.s^{-1}) did not alter the number of particles detected

per cough: 164 (80) with ventilation on vs. 153 (82) with ventilation off ($p = 0.77$, $n = 9$ per group).

All tracheal intubation sequences included manual facemask ventilation and three also required repeated attempts at laryngoscopy/intubation. The mean (SD) number of particles detected in a 5-min period during anaesthetic induction and intubation was 7 (6) ($n = 14$), compared with a background in the empty theatre of approximately two particles per 5-min period (Fig. 2b). The average concentration of particles recorded during the intubation period ($1.4 (1.4) \text{ l}^{-1}$, $n = 14$) was 500-fold lower than the mean (SD) concentration recorded during volitional coughs ($732 (418) \text{ particles.l}^{-1}$, $n = 38$, $p < 0.0001$). Similarly, the maximum concentration recorded during intubation averaged across events ($77 (49) \text{ particles.l}^{-1}$, $n = 14$) was 22-fold lower than that seen with volitional coughs ($1688 (872)$, $n = 38$, $p < 0.0001$). An equivalent series of aerosol measurements during tracheal intubation with laminar flow ventilation suspended produced a similar particle count to that seen in the presence of flow (6 (2) particles with flow off, $n = 5$, $p = 0.65$ vs. flow on).

Extubation produced a mean (SD) concentration of aerosolised particles of $21 (18) \text{ l}^{-1}$ ($n = 10$, Fig. 2c) which was 35-fold lower than that seen during a volitional cough ($p < 0.0001$) but 15-fold greater than that seen during intubation ($p = 0.0004$). The maximum concentration recorded during extubation averaged across events ($432 (209) \text{ particles.l}^{-1}$, $n = 10$) was lower than that seen with volitional coughs ($1688 (872)$, $n = 38$, $p < 0.0001$). The average total number of particles detected during the period of extubation was 100 (85). This is similar to that detected during a single volitional cough, although sampling during extubation summed particles produced over 5 min and each cough over 12 s. During four of the ten extubations, the patient coughed at least once (typically after tube removal) (Fig. 2c). These extubation coughs produced aerosolised particles of a similar size distribution to the reference coughs (Fig. 2d) but were always smaller in magnitude than the average volitional cough and, on average, produced only a quarter of the number of particles: 33 (10) (from a total of five coughs during four extubations, Fig. 2e). Because the usual position for the anaesthetist during extubation is to stand above and behind the patient, who is typically semi-recumbent, a further set of aerosol recordings were made with the particle collector located in that position (0.5 m away and still facing towards the patient). Aerosol monitoring from that position during extubation (three with cough events) greatly decreased the concentration of detected airborne particles to close to background levels seen in an active theatre ($3.7 (5.9) \text{ l}^{-1}$).

Figure 2 Aerosol measurements during intubation and extubation in operating theatre environment. (a) Temporal profile of aerosol generation from volitional coughs. Individual recordings ($n = 38$) represented on heat map showing the total number particle concentration over time. Average time course plotted (mean with 95%CI) showing a peak after 2 s and a rapid decay back to baseline. (b) Profile of the total number concentration of aerosol detected during the critical phase of intubation (arrow at 300 s marks completion of intubation with cuff up). When plotted on the same scale as the cough (b) then this looks essentially flat and when shown on a ten-fold expanded scale below it can be seen that it is not significantly different to baseline as the confidence intervals always span zero (mean $\pm$ 95%CI). (c) Extubation recordings from each patient ($n = 10$) plotted as the average and individually as rows on heat map of number concentration of particles (lower, on same scale as b). This showed sporadic aerosol events (red, ringed) after cuff deflation set on a low baseline level of particles. The average concentration of aerosol shown above was low overall (mean $\pm$ 95%CI). (d) The extubation cough events ($n = 5$) had a similar aerosol particle size distribution to volitional coughs with a predominance of diameters < 1 μm (mean $\pm$ SD). (e) The extubation coughs were of a smaller magnitude than the volitional coughs (particle number concentration profile shown overlaid, mean $\pm$ 95%CI).

Discussion

We conducted aerosol sampling in an ultraclean operating theatre environment during routine clinical practice enabling quantitative measurement of aerosols produced by tracheal intubation and extubation. Using the quantity and concentration of aerosolised particles generated by volitional coughs as a reference, we have shown that both intubation and extubation sequences produce less aerosol than voluntary coughing. For the sequence of tracheal intubation, in particular, the concentration of aerosol generated is several orders of magnitude less than a single cough and is only very modestly above background levels of circulating particles in an ultraclean theatre. These findings demonstrate that the process of tracheal intubation is associated with a very low risk of aerosol generation.

Standard anaesthetic induction and intubation sequences are designed to obtund airway reflexes and the use of a neuromuscular blocking drug ensures that the anaesthetised patient can neither breathe nor cough. Of note, we detected no increases in aerosolised particles above the patient's face during anaesthesia, facemask ventilation, airway suction and, on occasion, several repeated attempts at intubation. This reflects typical clinical practice by anaesthetists with a range of experience, providing further reassurance regarding the low level of aerosol generation.

A more nuanced picture is seen during the tracheal extubation sequence where aerosol concentration was greater than that seen with intubation but substantially less than a single cough. The total number of expectorated airborne particles (over a 5-min period) was similar to a single volitional cough. Indeed, a cough event was noted clinically in 50% of extubations and this was frequently detected as an aerosol spike. These extubation coughs produced a similar particle size distribution but there were fewer airborne particles than with volitional coughs (approximately 25%). Extubation cough aerosol was also transient and only detectable for approximately 5 s. Therefore, it would appear that aerosol generation during extubation with a cough is quantitatively different from extubation without a cough. Although a cough at extubation may be interpreted as a positive sign signalling the return of protective airway reflexes, it is likely to increase the risk of aerosolised particle generation. Therefore, mitigation strategies should be considered to reduce the risk of coughing and exposure to aerosols. As sampling showed much reduced particle numbers behind the patient's head compared with above their airway, clinician exposure could be reduced by the simple expedient of standing behind the

patient's head (as is conventional) and, thus, out of the direct stream of any potential cough plume. Coughing on extubation could also be minimised by modifying the anaesthetic technique in higher risk patients [21].

The combination of monitoring within an ultraclean ventilation theatre and the use of a highly sensitive optical particle sampler has afforded sufficient resolution to quantitate aerosol generation in real time during anaesthetic delivery. To put this in context, it is worth noting that we are unaware of any previous recording of aerosol generated even by coughing in a routine healthcare environment as this normally requires highly specialised and controlled laboratory conditions [17–20]. The ultraclean laminar flow ventilation system theatre had a very low level of airborne particles (0.4 l^{-1}); in comparison the baseline aerosolised particle concentration in a nearby non-laminar theatre was more than 3 orders of magnitude higher ($15 \times 10^3 \text{ l}^{-1}$), which would have precluded detection of aerosols generated either by tracheal intubation or extubation (and perhaps even a cough). To assess the impact of the laminar flow on our observations, we undertook measurements with the ultraclean theatre ventilation on and off both for coughing and for tracheal intubation and these did not differ. This demonstrates that the low aerosol particle counts were not secondary to immediate aerosol clearance by high laminar ventilation flows. Although we did not assess the impact of ventilation flow on the aerosol generated during extubation (because of the pragmatic issue of turning off the ventilation while the case is in theatre and the perceived need to disperse any accumulated aerosol) we have no reason to believe, based on the cough and intubation measurements, that the presence of laminar flow has materially influenced these extubation measurements.

There are a number of limitations to the study and these include a relatively small number of observations, the use of pragmatic design without control over the specific anaesthetic administered or the grade of practitioner and sampling aerosol from a limited arc encompassed by the funnel. The reference coughs were from a single subject (one of the investigators), but data from another study (Brown et al., unpublished data) indicate that they were not outliers when compared with other healthy subjects. Additionally, we have made no measurements from subjects known to have COVID-19 or other intercurrent respiratory comorbidity, which would be an important area for investigation, although challenging to conduct. The measurements were taken during anaesthesia for patients receiving urgent orthopaedic and neurosurgical interventions

and may not be generalisable to intubations in a critical care/emergency setting that may be conducted in extremis.

Importantly, it should be acknowledged that we are unable to make any conclusion about the risk of actual SARS-CoV-2 transmission as aerosol generation is still only a presumed risk-factor and particle number concentration is a plausible but unproven surrogate measure of that infection risk. We have presented our data as mean particle concentration during the event, maximum concentration recorded during the epoch and total numbers of detected airborne particles and note that there is no available evidence to indicate which measure will prove to be the best surrogate measure of infection risk [3]. Other dimensions that are likely to be important are the size distribution of the aerosolised particles (which influences their airborne transport and ability to be carried into the respiratory tract), the total volume of expectorate (which can be derived if assumptions about sphericity and composition are made) and the concentration of live virions within the particles (not measured here). Each measure has limitations, but we consider that the average concentration over time gives the best estimate of the relative exposure smoothed over the at-risk period during which particles may be inhaled or deposited on mucous membranes. We note that the peak concentration is likely to overestimate the risk; for example, a single particle detected in a 1-s time bin during an intubation sequence (5-min period of recording) would correspond to a maximum of 60 particles. l^{-1} (with 1 $\text{l}\cdot\text{min}^{-1}$ air flow through the particle detector). However, this is probably better represented as the average concentration of 0.2 particles. l^{-1} when assessing the relative risk over time, reflecting the fact that no particles are detected for 299 of the 300 s recording period. Notwithstanding these considerations, we believe that our aerosol measurements constitute a valuable quantitative dataset and we note that the methodology could be applied to other anaesthetic airway management techniques and designated aerosol-generating procedures to extend the relative risk ranking.

Our results for the risk of aerosol generation associated with tracheal intubation are at odds with previous retrospective evidence that was used to designate intubation in an aerosol-generating procedure [12, 14]. These studies found an association between acquiring SARS and being in the room during intubation but without any measure of aerosol generation. It is difficult to directly compare these two sources of evidence: in our study, all patients received a controlled anaesthetic induction that included a neuromuscular blocking drug. Conversely, during the SARS epidemic patients were unwell, may have been coughing during the intubation sequence and it is

likely that viral secretion was at peak levels at the point of initiating intensive care management (which is not the case for COVID-19 Cevik et al., preprint: doi.org/10.1101/2020.07.25.20162107). It is equally plausible that other mechanisms of transmission, such as direct exposure to respiratory secretions or fomites or association between those who undertook tracheal intubation and performance of other high-risk activities, could have contributed to the spread of SARS.

By the definition noted earlier, aerosol-generating procedures are considered to have a greater likelihood of producing aerosols compared with coughing [16]. Our study indicates that the process of elective tracheal intubation produces a barely recordable increase in aerosol and, consequently, should not be designated as an aerosol-generating procedure. When a patient coughs during tracheal extubation, a measurable particle plume is produced but the aerosol is still smaller than a single volitional cough. These relative risks of aerosol generation need to be balanced against the knowledge that the use of airborne precaution PPE has substantial impact on clinical practice. Additionally, methods introduced to mitigate the risks posed by bio-aerosols have reduced operating theatre turnover, decreased hospital productivity and increased waiting times for elective and cancer surgery. A further important consideration relates to the cost and limited supply of PPE which has to be targeted to appropriate healthcare settings on the basis of risk. These results, therefore, should help inform future airborne prevention PPE guidelines by providing evidence on the relative risk of aerosol generation associated with tracheal intubation and extubation.

How can airborne transmission of COVID-19 indoors be minimised?

ARTICLE INFO

Handling Editor: Adrian Covaci

ABSTRACT

During the rapid rise in COVID-19 illnesses and deaths globally, and notwithstanding recommended precautions, questions are voiced about routes of transmission for this pandemic disease. Inhaling small airborne droplets is probable as a third route of infection, in addition to more widely recognized transmission via larger respiratory droplets and direct contact with infected people or contaminated surfaces. While uncertainties remain regarding the relative contributions of the different transmission pathways, we argue that existing evidence is sufficiently strong to warrant engineering controls targeting airborne transmission as part of an overall strategy to limit infection risk indoors. Appropriate building engineering controls include sufficient and effective ventilation, possibly enhanced by particle filtration and air disinfection, avoiding air recirculation and avoiding overcrowding. Often, such measures can be easily implemented and without much cost, but if only they are recognised as significant in contributing to infection control goals. We believe that the use of engineering controls in public buildings, including hospitals, shops, offices, schools, kindergartens, libraries, restaurants, cruise ships, elevators, conference rooms or public transport, in parallel with effective application of other controls (including isolation and quarantine, social distancing and hand hygiene), would be an additional important measure globally to reduce the likelihood of transmission and thereby protect healthcare workers, patients and the general public.

1. Recognising the potential for the airborne transmission of SARS-CoV-2

The significance of viral transmission via small airborne micro-droplets (also commonly referred to as ‘aerosols’) has been intensely discussed in the context of the SARS-CoV-2/COVID-19 (severe acute respiratory syndrome coronavirus-2/coronavirus disease 2019) pandemic (Lewis, 2020; Morawska and Cao, 2020). This is one of three commonly accepted modes of viral transmission, the other two being via larger respiratory droplets (which fall close to where they are expired), and direct contact with contaminated surfaces (fomites). Especially with the ongoing global shortage of personal protective equipment (mainly surgical masks and N95/FFP2/FFP3 respirators) (WHO, 2020c), additional methods to reduce the risk of SARS-CoV-2 transmission indoors need to be considered. The need is acute in particular in hospitals and other healthcare facilities managing COVID-19 patients.

While evidence for airborne transmission of COVID-19 is currently incomplete, several hospital-based studies have performed air-sampling for SARS-CoV-2, including one published paper (Ong et al., 2020), one early-release paper (Guo et al., 2020) and 5 papers still in pre-print at the time of writing (Chia et al., 2020; Ding et al., 2020; Jiang et al., 2019; Liu et al., 2020; Santarpia et al., 2020). Four of these studies found several positive samples for SARS-CoV-2 genome (RNA) in air using polymerase chain reaction (PCR) testing (Chia et al., 2020; Jiang et al., 2019; Liu et al., 2020; Santarpia et al., 2020), two found very small numbers of positive samples (Ding et al., 2020), and only one (Ong et al., 2020) found no positive air samples. This evidence at least demonstrates a *potential* risk for airborne transmission of SARS-CoV-2.

In addition, amongst these studies, three also reported some quantitative viral RNA data. The Singaporean study found positive air samples in 2 of the 3 patient infection isolation rooms, with samples in

the 1–4 μm and $> 4 \mu\text{m}$ size ranges containing a range of viral loads (1.8–3.4 viral RNA copies per L of air) (Chia et al., 2020). The study from Nebraska, USA found that 63% of the air samples were positive with a mean viral load of 2.9 copies/L, including in patient rooms and the hallway air (Santarpia et al., 2020). In one case, they sampled close to the patient (mean: 4.1 copies/L) and at $> 1.8 \text{ m}$ (mean: 2.5 copies/L), suggesting some dilution with distance. The highest viral loads were found in personal samplers worn by the sampling team when in the presence of a patient receiving oxygen via nasal cannula (mean: 19 and 48 copies/L), indicating that this treatment may promote the spread of airborne virus. A study in Wuhan, China (Liu et al., 2020) provides quantitative data for their small number of positive air samples, with 0.02 RNA copies/L in a toilet area and 0.02–0.04 copies/L in a room used to remove PPE. More than half the viral RNA in these samples was associated with aerosols $< 2.5 \mu\text{m}$. This study also measured deposition through passive aerosol sampling, reporting deposition rates of 31 and 113 RNA copies/ m^2 per h at samplers located approximately 2 m and 3 m from the patients, respectively (Liu et al., 2020).

Whilst this evidence may be deemed to be incomplete at present, more will arise as the COVID-19 pandemic continues. In contrast, the end-stage pathway to infection of the droplet and contact transmission routes has always been assumed to be via self-inoculation into mucous membranes (of the eyes, nose and mouth). Surprisingly, no direct confirmatory evidence of this phenomenon has been reported, e.g. where there have been: (i) follow-up of fomite or droplet-contaminated fingers of a host, self-inoculated to the mucous membranes to cause infection, through the related disease incubation period, to the development of disease, and (ii) followed by diagnostic sampling, detection, sequencing and phylogenetic analysis of that pathogen genome to then match the sample pathogen sequence back to that in the original fomite or droplet. It is scientifically incongruous that the level of evidence

Fig. 1. Traditional infection control pyramid adapted from the US Centers for Disease Control (CDC, 2015).

required to demonstrate airborne transmission is so much higher than for these other transmission modes (Morawska et al., 2020).

The infectious agents of several other diseases (tuberculosis, measles, chickenpox) are recognised to be transmissible via the airborne route, either by the short-range (face-to-face, conversational exposure) or by longer-range aerosols (Department of Health, 2015; Tellier et al., 2019). Measles and varicella zoster (the virus causing chickenpox) can also be efficiently transmitted through direct contact during their acute phase of infection (e.g. by kissing). During a close contact situation, all transmission routes can be potentially responsible for infection.

For other respiratory viruses, including SARS-CoV, MERS-CoV (Middle-East Respiratory Syndrome coronavirus), respiratory syncytial virus (RSV – a common cause of bronchiolitis in infants) and influenza, both short-range and longer-range airborne transmission are possible, but the predominance of longer range transmission route in various exposure scenarios is difficult to quantify (Booth et al., 2013; Kim et al., 2016; Kulkarni et al., 2016; Li et al., 2007; Tellier et al., 2019), and may at times be opportunistic (Roy and Milton, 2004).

A recent mechanistic modelling study showed that short-range airborne transmission dominates exposure during close contact (Chen et al., 2020). Other studies investigating the transport of human-expired microdroplets and airflow patterns between people also provide substantive support for this transmission route (Ai et al., 2019; Li et al., 2007; Liu et al., 2017). Therefore, in light of this body of evidence for these other respiratory viruses; we believe that SARS-CoV-2 should not be treated any differently – with at least the potential for airborne transmission indoors.

Yet despite this, international health organisations, like the WHO (World Health Organization) (WHO, 2020b), continue to place insufficient emphasis on protection from small, virus laden, airborne droplets. Other organisations that deal with building environmental control systems, such as REHVA (the Federation of European Heating, Ventilation and Air Conditioning Associations) and ASHRAE (the American Society of Heating, Ventilating, and Air-Conditioning Engineers), have acknowledged the potential airborne hazard indoors and recommended ventilation control measures accordingly (ASHRAE, 2020a; REHVA, 2020).

Infection control specialists also often inquire about the relative contribution of airborne transmission compared to the other transmission modes ('contact' and 'droplet'). Multiple studies provide strong evidence for indoor airborne transmission of viruses, particularly in crowded, poorly ventilated environments (Coleman et al., 2018; Distasio et al., 1990; Knibbs et al., 2012; Li et al., 2005; Moser et al., 1979; Nishiura et al., 2020). However, it is generally difficult to quantitatively compare and conclude which transmission route is the most significant in a given situation. Infection may occur via all routes to different degrees depending on the specific exposure circumstances. Effective infection control necessitates protection against all potentially important exposure pathways.

Here, in the face of such uncertainty, we argue that the benefits of an effective ventilation system, possibly enhanced by particle filtration and air disinfection, for contributing to an overall reduction in the indoor airborne infection risk, are obvious (Eames et al., 2009).

2. Engineering controls to reduce the potential airborne transmission of SARS-CoV-2

To maximise protection of the population against the airborne spread of SARS-CoV-2 and any other airborne virus-containing small microdroplets, several recommendations are necessary as presented below. These focus on indoor environments, because this is where most transmission occurs (Nishiura et al., 2020). Further, the measures mostly apply to public buildings. In residential houses and apartments, normal practices (e.g. segregating infected individuals, opening windows and doors, and using portable air-cleaning devices when practical) to ensure healthy indoor air, should stay in place at any moment.

Ventilation airborne protection measures which already exist can be easily enhanced at a relatively low cost to reduce the number of infections and consequently to save lives. The options discussed below should always be implemented in combination with other existing measures (like hand-washing and use of PPE) to reduce infection via other important routes of transmission, as none of them can be completely excluded in any exposure event. The remainder of this article will only cover recommendations for 'engineering level' controls, as described in the traditional infection control hierarchy (Fig. 1) to reduce the environmental risks for airborne transmission.

2.1. Ventilation should be recognised as a means to reduce airborne transmission

Ventilation is the process of providing outdoor air to a space or building by natural or mechanical means (ISO, 2017). It controls how quickly room air is removed and replaced over a period of time. In some cases, it is necessary to remove pollution from outdoor air before bringing it into a building, by using adequate filtration systems. Ventilation plays a critical role in removing exhaled virus-laden air, thus lowering the overall concentration and therefore any subsequent dose inhaled by the occupants.

Appropriate distribution of ventilation (e.g. placement of supply and exhaust vents) ensures that adequate dilution is achieved where and when needed, avoiding the build-up of viral contamination (Melikov, 2011, 2016; Thatiparti et al., 2016, 2017). The central guiding principle is to replace contaminated air with clean air, but sometimes local barriers to this process may occur, e.g. where partitions are used or curtains drawn for privacy or medical procedures. If these barriers are in use, secondary or auxiliary measures may be needed to achieve requisite ventilation effectiveness.

Good ventilation practices are already in place in many hospital settings, as part of everyday and emergency measures to protect against droplet and contact transmission (Phiri, 2014). Good ventilation also protects the occupants against airborne transmission. The capacity to increase ventilation rates when needed (such as during the COVID-19 pandemic) may differ, and may be somewhat limited by their original design specifications and implementation.

Note that many hospitals are naturally ventilated in ward areas, including in some rooms used for critical care. However, if the airflow passage is obstructed (e.g. by closing windows and doors), airborne pathogen concentration can sharply rise leading to an increased risk of

airborne transmission and infection (Gilkeson et al., 2013). Natural ventilation concepts apply to healthcare facilities in both developed and resource-limited countries in favourable climatic conditions. The design, operation and maintenance of naturally ventilated facilities is not straightforward, and comprehensive guidance is available (WHO, 2009). For instance WHO in March, (WHO, 2020a) specifies that in a COVID-19 infective ward at least 160 L/s/patient have to be provided if natural ventilation is used.

We have recently seen the creation of very large emergency hospital wards, within exhibition centres for example, which house hundreds or even thousands of patients (MSN, 2020). Although these facilities will have mechanical ventilation that is adequate for normal exhibition or conference use, it is not clear if sufficient ventilation will be available for patient management and infection control purposes when they are adapted for such purposes, as during the COVID-19 pandemic.

The situation can be worse in public buildings and other shared spaces, such as shops, offices, schools, kindergartens, libraries, restaurants, cruise ships, elevators, conference rooms or public transport, where ventilation systems can range from purpose-designed mechanical systems to simply relying on open doors and windows. In most of these environments, ventilation rates are significantly lower than in hospitals for various reasons, including limiting airflows for energy and cost savings.

Hence, in such environments, with lower ventilation rates intended primarily to control indoor air quality (which may also include some hospital emergency, acute admissions, general ward and clinic areas) (Booth et al., 2013; Jo et al., 2019; Kulkarni et al., 2016; Rule et al., 2018; Sornboot et al., 2019), the likelihood of infected persons sharing air with susceptible occupants is high, posing an infection risk contributing to the spread of the infectious disease.

Various studies have been performed on the survival of airborne pathogens (Brown et al., 2015; Kim et al., 2016; Kormuth et al., 2018; Kulkarni et al., 2016; Marr et al., 2019; Pyankov et al., 2018; Tang 2009). The SARS-CoV-2 virus has been shown to be stable in airborne particles with a half-life of more than one hour (van Doremalen et al., 2020), so it can potentially be inhaled by susceptible individuals causing infection and further spreading of the disease.

As 'stay-at-home' lockdown measures are gradually relaxed, much of the population may return to spending increasing amounts of time in inadequately ventilated workplaces, offices, schools and other public buildings, where they may be exposed to a risk of acquiring viral infections by inhalation.

2.2. Ventilation rates should be increased by system modifications.

In a mechanically ventilated building, ventilation air is typically provided by a heating, ventilating and air conditioning (HVAC) system. Sometimes, ventilation air is provided by dedicated fans or outdoor air units.

HVAC system control strategies can usually be modified to increase ventilation to a certain extent in the occupied zones, with relatively little additional cost, to reduce the risks of airborne transmission between occupants. However, this is not via a simple 'flip of a switch', as HVAC systems are complex and usually designed for individual buildings within standard specific operating parameters. Many requirements need to be considered apart from the ventilation rate, including control of temperature, relative humidity, air flow distribution and direction.

Such systems can be specifically customised as needed by HVAC engineers, e.g. to reduce the risks of airborne transmission. Indeed, the ventilation guidance of ASHRAE (The American Society of Heating, Refrigerating, and Air-conditioning Engineers), REHVA, SHASE (The Society of Heating, Air-Conditioning and Sanitary Engineers of Japan) have all just been updated to address the spread of COVID-19 (ASHRAE, 2020b; REHVA, 2020; SHASE, 2020). Another example is the modification of a hospital ward ventilation system to create a negative pressure isolation ward (Miller et al., 2017).

If ventilation is provided using windows openings (aeration) or other means (fixed openings, e.g., natural ventilation), an estimation of the possible outdoor flow rate can be made using CEN Standard, EN 16798-7:2017 (CEN, 2017), or other available references as (AIVC, 1996; CIBSE, 2005). The outdoor air flow rate that is achieved is strongly dependent on the specific local conditions (opening sizes, relative positions, climatic and weather conditions, etc.) and should be estimated case by case; it can easily range from 2 up to 50 ACH or more.

For naturally ventilated public buildings, particularly in cold climates, other challenges will arise, but these can also be addressed in order to reduce the risk of airborne infection transmission. It may be necessary to provide additional heating in some buildings to maintain thermal comfort, particularly where the occupants are vulnerable.

2.3. Avoid air recirculation

The recirculation of air is a measure for saving energy, but care must be taken, as it can transport airborne contaminants (including infectious viruses) from one space and distribute them to other spaces connected to the same system, potentially increasing the risk of airborne infection in areas that otherwise would not have been contaminated. This concern has been noted previously in regard to the possible recirculation of biological agents during terrorist attacks that have investigated the effectiveness of eliminating recirculation (e.g. providing 100% outside air to spaces and exhausting all of it) as a countermeasure following an indoor release of the agent (Persily et al., 2007). A study modelling the risk of airborne influenza transmission in passenger cars provided also a case against air recirculation in such situations (Knibbs et al., 2012).

Particulate filters and disinfection equipment in recirculated air streams can reduce this risk, but they need to be purposely designed to control risk of airborne infection and need regular service to maintain their effectiveness. Many systems are designed for filters that are intended to remove larger particles that may affect the functioning of equipment and that are not effective at removing small, sub micrometre or micrometre size particles associated with adverse health effects. Filter ratings by test methods, such as ASHRAE Standard 52.2 (ASHRAE, 2017) that give an indication of performance as a function of particle size should be utilized in choosing appropriate filters.

Following the above considerations, during an epidemic, including the current COVID-19 pandemic, air should not be recirculated as far as practically possible, to avoid the dissemination of virus-laden particles throughout the indoor environment. For central air handling units at a building level or serving multiple zones, recirculation should be avoided, and the system operated on 100% outdoor air (OA) if possible. Disabling recirculation can be achieved by closing the recirculation dampers and opening outdoor air dampers. In systems where it is not possible, one should try to maximize the OA-level and apply filtering or ultraviolet germicidal irradiation to remove or deactivate potential viral contamination from the recirculated air. In many health care settings, air recirculation is, in most cases not allowed at all, though though recirculation is commonly used in non-hospital settings for improving energy efficiency. At a room (decentral) level, secondary air circulation systems may be installed. One needs to assure that any of such systems also provides ventilation with outdoor air (e.g., induction units). If this is the case, such a system should not be switched off. Other systems, which do not have this feature (e.g., split air-conditioning units) should if possible be turned off, to avoid potential transfer of virus through air flows between people. When such a system is needed for cooling then additional ventilation with outdoor air should be secured by regular/periodic ventilation through, e.g., window opening.

2.4. Air cleaning and disinfection devices may be beneficial

In environments where it is difficult to improve ventilation, the addition of local air cleaning or disinfection devices, such as germicidal

ultraviolet (GUV, or UVGI - ultraviolet germicidal irradiation) may offer benefits. Under laboratory conditions GUV has been shown to be effective against a suite of microorganisms including coronaviruses (Walker and Ko, 2007), vaccinia (McDevitt et al., 2007) and *Mycobacteria* (Xu et al., 2003), and even influenza (McDevitt et al., 2012; McLean 1961). Several studies show that inactivation decreases with increased humidity for both bacterial (Xu et al., 2005) and viral aerosols (McDevitt et al., 2012). Darnell et al. (2004) showed that SARS-CoV-1 could be inactivated by UV-C, while Bedell et al. (2016) showed a UV-C decontamination device could inactivate MERS-CoV at 1.22 m, with almost a 6 log reduction in 5 min. There is no data yet for SARS-CoV-2, but the data for other coronaviruses suggest it is highly likely that it is susceptible to UV-C.

One application that grew dramatically during the multi-drug resistant tuberculosis outbreaks of the 1980s (Young and Wormser, 1994), is the 'upper-room' system in which lamps are placed in the upper part of the room, either on the walls or mounted on the ceiling, directing the UV light into the upper zone with louvers and limiting UV exposure in the occupied space (Xu et al., 2005, 2003). Upper-room GUV is a good technology to consider in crowded, poorly ventilated environments where aerosol transmission could occur and where the ability to increase ventilation is limited. Long ago, McLean (1961) presented data showing interruption of influenza transmission in a hospital setting. It has been estimated that upper-room GUV may reduce infection risk by an amount equivalent to doubling the ventilation rate (Noakes et al., 2015). Escombe et al. (2009) showed 77% reduction in human to guinea pig transmission in a hospital setting, while chamber based studies show the effectiveness of GUV against a number of bacterial aerosols (Xu et al., 2005, 2003; Yang et al., 2012). These concur with modelling studies (Gilkeson and Noakes, 2013; Noakes et al., 2004; Sung and Kato, 2010; Yang et al., 2012) showing that the effectiveness depends on the placement of the lamps relative to the ventilation flow and that addition of a ceiling fan enhances GUV effectiveness (Xu et al., 2013; Zhu et al., 2014).

Factors that must be considered when evaluating the ability of upper-room GUV to kill or inactivate airborne microorganisms include the sensitivity of the microorganisms to GUV and the dose received by a microorganism or population of microorganisms. GUV dose is the ultraviolet (UV) irradiance multiplied by the time of exposure and is usually expressed as $\mu\text{W}\cdot\text{s}/\text{cm}^2$. Well-designed upper-room GUV may be effective in killing or inactivating most airborne droplet nuclei containing mycobacteria if designed to provide an average UV fluence rate in the upper room in the range of $30 \mu\text{W}/\text{cm}^2$ to $50 \mu\text{W}/\text{cm}^2$, provided the other elements stipulated in these guidelines are met. In addition, the fixtures should be installed to provide as uniform a UVGI distribution in the upper room as possible (CDC/NIOSH 2009). A zonal infection risk model (Noakes et al., 2015) suggests that an upper-room GUV with a plane average irradiance of $0.2 \text{ W}/\text{m}^2$ at the UV fixtures could be comparable to increasing the ventilation rate from 3 to 6 ACH.

Portable consumer air cleaning devices may be beneficial in smaller rooms, although it should be recognised that such devices must be appropriately sized for the space (Miller-Leiden et al., 1996). There is wide variation in performance of air cleaners depending on air cleaner design and size of room in which it is used (Shaughnessy and Sextro, 2006). A useful metric for determining performance is the clean air delivery rate, which is equivalent to the volumetric flow rate of

particle-free air produced by the air cleaner (Foard, 1999). Kujundzic et al. (2006) reported air cleaners were similarly effective against removing both airborne bacterial and fungal spores from the air at clean air delivery rates of between 26 and $980 \text{ m}^3/\text{h}$ corresponding to effective cleaning of between 5 and 189 m^3 room volumes respectively.

GUV 'in-duct' application within air-conditioning systems and ventilation ducts may also be a practical approach for disinfecting contaminated extracts or in cases where it is not possible to stop recirculation of ventilation flows (Kujundzic et al., 2007). However, these systems are of little benefit against person-to-person transmission when installed in the supply air of once-through systems that do not recirculate air within the space or building. The US Centers for Disease Control has approved both upper-room and in-duct systems for use in controlling tuberculosis transmission as an adjunct to HEPA filtration (CDC/NIOSH, 2009).

2.5. Minimise the number of people within the same indoor environment in an epidemic

This measure is self-explanatory in the context of the need to lower the concentration of airborne virus-carrying particles, and reduce the number of people who can be exposed at any time. There is no one specific value for a number of people who could share the same space during pandemics, and this measure should be considered in conjunction with the engineering measures discussed above, and particularly in relation to the ventilation parameters of the space. Although the physical distance required to avoid transmission through direct contact dictates the requirements for the floor area per person, the rate of ventilation provided and the efficiency of ventilation are the parameters that control the concentration of virus-laden microdroplets in the air exhaled by the occupants, and will guide decisions on safe occupancy numbers. In a school or a supermarket, for example, if the number of infected students or shoppers is low, and the ventilation rate is high, the risk of airborne transmission can be low. Similarly, during an epidemic, reducing the number of people using public or private transport *at the same time*, e.g. in subway train systems or busses, is part of effective social distancing (Knibbs et al., 2012; Stopera and Stopera, 2020).

3. Conclusions

Until effective pharmacological treatments or vaccines are available to reduce the effective reproductive number to less than 1.0 and stop the ongoing COVID-19 pandemic, enhanced ventilation may be a key element in limiting the spread of the SARS-CoV-2 virus. These are the key ventilation-associated recommendations (see Fig. 2):

- (1) To remind and highlight to building managers and hospital administrators and infection control teams that engineering controls are effective to control and reduce the risks of airborne infection – and SARS-CoV-2 has the potential and is likely to be causing some infections by this route.
- (2) To increase the existing ventilation rates (outdoor air change rate) and enhance ventilation effectiveness - using existing systems.
- (3) To eliminate any air-recirculation within the ventilation system so as to just supply fresh (outdoor) air.

Fig. 2. Engineering level controls to reduce the environmental risks for airborne transmission.

- (4) To supplement existing ventilation with portable air cleaners (with mechanical filtration systems to capture the airborne microdroplets), where there are areas of known air stagnation (which are not well-ventilated with the existing system), or isolate high patient exhaled airborne viral loads (e.g. on COVID-19 cohort patient bays or wards). Adequate replacement of the filters in the air cleaners and their maintenance is crucial.
- (5) To avoid over-crowding, e.g. pupils sitting at every other desk in school classrooms, or customers at every other table in restaurants, or every other seat in public transport, cinemas, etc.

If implemented correctly, these recommended building-related measures will lower the overall environmental concentrations of airborne pathogens and thus will reduce the spread of infection by the airborne route. Together with other guidance on minimising the risk of contact and droplet transmission (through hand-washing, cleaning of hand-touch sites, and the appropriate use of PPE), these ventilation-related interventions will reduce the airborne infection rates not just for SARS-CoV-2 in the current COVID-19 pandemic, but also for other airborne infectious agents.

While much of the focus has been on case finding, isolation and quarantine, social distancing and hand hygiene, we emphasise that a parallel reduction in airborne transmission using such engineering controls in hospitals and other public buildings will further protect healthcare workers, patients and the general public.

Declaration of Competing Interest

The authors declare that they have no known competing financial interests or personal relationships that could have appeared to influence the work reported in this paper.

The control by ventilation of airborne bacterial transfer between hospital patients, and its assessment by means of a particle tracer

II. Ventilation in subdivided isolation units

By O. M. LIDWELL

*Cross-Infection Reference Laboratory, Central Public Health Laboratory,
Colindale Avenue, London, NW 9 5HT*

(Received 11 October 1971)

SUMMARY

Values are deduced for the efficiency of isolation against airborne particulates, e.g. micro-organisms, of a variety of ventilation systems. The calculated values show reasonable correspondence with the limited experimental data available. Much better control and indication of the air flow is necessary if high degrees of isolation are required.

INTRODUCTION

In an isolation unit ventilation may serve any or all of three purposes, to maintain a comfortable environment, to remove smells, to reduce the possibilities of airborne transport of micro-organisms from one patient to another. The criteria for the first two purposes are well known and not difficult to meet. The third, however, is less clear. Epidemiological evidence as to the relevance of airborne infection is generally lacking so that a precise specification cannot be given. It seems likely, however, that if any clinical benefit is to be obtained it will only be gained by reducing the extent of airborne transport by several orders of magnitude. There are very few data on the physical effectiveness of different ventilation systems, but some deductions can be made from a theoretical analysis and these then compared with the scanty material available.

As a simplified model we may consider a number of rooms opening off a communications area (Fig. 1).

EXCHANGE OF AIR BETWEEN ROOMS

In calculating the transport of particles from the air exchange between the parts of a system, it is convenient to assume that turbulent air mixing within each room is sufficient to produce a substantially uniform concentration of particles within it. This is a satisfactory approximation so long as the spaces involved are not too large or unusually shaped.

In assessing the performance of any system it is more realistic to compare it with the situation in which all the patients are housed in one room having the same

Fig. 1. Schematic diagram of the system analysed. The arrows show the directions of the air movements between the n patient rooms and the communications area together with the air supply and consequent exhaust. The symbols u and v , with suffixes as appropriate, indicate the volumetric rates of air movement, for example in m^3/hr . Symbols c_1 , c_2 denote the equilibrium particle concentrations arising from a source, Q particles per unit time (e.g. per hr.), in one patient room where the equilibrium concentration is c_s . A_1 and A_2 are the floor areas (more properly the aggregate areas of the horizontal surfaces on which particle sedimentation takes place) of the rooms.

total ventilation and floor area than just to compare the particle concentration in a room housing a source with that in the other patient rooms. The ratio of these concentrations, α in equation (5) below, which is all that is available for measurement by observations made within the system itself, gives an unduly favourable estimate of the efficiency of the isolation since the particle concentration in the source room is increased when the source is contained in a small room.

If, then, there is a source generating Q units of particle contamination/hr. in one of the rooms of the system shown in Fig. 1 the following equations will define the equilibrium state, neglecting the effect of particle settling

$$c_s (v_1 + v - u) + c_s u = v c_2 + Q, \quad (1)$$

$$c_1 (v_1 + v - u) + c_1 u = v c_2, \quad (2)$$

$$c_2 (v_2 + n (u - v)) + c_2 n v = u c_s + c_1 (n - 1) u, \quad (3)$$

where the symbols have the meaning shown in Fig. 1.

In addition if the system were replaced by a single space with a floor area and ventilation supply equal to the sum of those of the individual rooms and the communications area then the equilibrium state would be defined by

$$c_m (v_2 + n v_1) = Q. \quad (4)$$

This value of the particle concentration, c_m , is the value to which c_s , c_1 and c_2 all tend as u and v both become very large but $v \sim u$ remains small.

From equations (1)–(4) it is easy to deduce that

$$c_s/c_1 = \alpha = 1 + (v_1 v_2 + v_2 v + nuv_1)/uv, \quad (5)$$

$$c_m/c_1 = \beta = (v + v_1) (v_1 v_2 + v_2 v + nuv_1)/uv (v_2 + nv_1). \quad (6)$$

If both u and v are small relative to v_1 and v_2 then

$$\alpha = c_s/c_1 \simeq v_1 v_2/uv, \quad (5A)$$

$$\beta = c_m/c_1 \simeq v_1 v_1 v_2/uv (v_2 + nv_1), \quad (6A)$$

and

$$\alpha/\beta = c_s/c_m = n + v_2/v_1. \quad (7)$$

In addition

$$c_s/c_2 = \alpha' = 1 + (v_1 v_2 + v_2 v + \overline{n-1} uv_1)/u (v_1 + v), \quad (8)$$

$$c_2/c_1 = \alpha'' = 1 + v_1/v, \quad (9)$$

or if both u and v are small as before

$$\alpha' = c_s/c_2 \simeq v_2/u, \quad (8A)$$

$$\alpha'' = c_2/c_1 \simeq v_1/v. \quad (9A)$$

In all the above equations u and v , the volumes of air passing between the individual rooms and the communications area, include air movements due to imbalance in the air supplied to or extracted from the rooms, air exchange across the doorways or other openings as a result of thermal differences and air exchanged across doorways when the doors are opened and shut and when people pass through them.

The effects of particle size

In addition to the effects of ventilation, the particles carrying the micro-organisms will be settling under the influence of gravity. The effect of this on the dispersal and air-concentration of the particles is equivalent, under conditions of complete turbulent air mixing within the individual rooms, to adding to the clean air input into any room a quantity As , where A is the floor area of the room concerned and s is the effective settling velocity of the particles. For bacteria-carrying particles the value of s is usually close to 0.3 m./min. (Noble, Lidwell & Kingston, 1963).

Transport through airlocks

In order to apply the results of the preceding section to systems which include airlocks, with doors to both the patient room and the communications area, it is necessary to obtain some estimate of the effective transfer of air through them when a person enters or leaves the room, i.e. of the rate of direct transfer of air from the room to the corridor, or in the reverse direction, that would transfer the same amount of airborne contamination as that effected by passage through the airlock. These estimates can then be introduced into equations 5–9 as the appropri-

Fig. 2. Airlocks. Symbols c_1 , c_s and c_2 , as in Fig. 1, denote the equilibrium particle concentrations in the n patient rooms and in the communications area. V_L is the volume of an airlock, A its floor area and h its internal ceiling height. (a) Unventilated airlock. (b) Input ventilation at v_L of which v_R passes into the patient room and v_c into the communications area. (c) Extract ventilation at u_L of which u_R is drawn from the patient room and u_c from the communication area.

ate values of u and v . Three situations are illustrated in Fig. 2: (a) an unventilated lock; (b) a lock with clean air input; (c) a lock with extract.

The direction of air flow around the door edges with a balanced ventilation system and an unventilated lock are indeterminate. If there is no flow in either direction when the doors are shut then $u = v = mw^2/V_L$, when there are both m entries into the room and m exits from the room through the airlock in unit time, w is the volume of air exchanged across a door opening each time a door is opened and shut and V_L is the cubic volume of the lock. Loss by sedimentation within the lock is small, a dwell time of about 6 min. would be necessary to halve the concentration of particles within the lock even if it were no more than 2.5 m. high, given the assumed settling velocity of 0.3 m./min. A consequence of this slow die-away, however, is that particles already introduced into the lock may be transferred by a subsequent passage through. For an assumed rate of five passages/

hr. in each direction, one in either direction every 6 min., this will approximately treble the particle transfer,

$$u = v = mw^2/V_L (1 + \frac{1}{2} + \frac{1}{4} + \dots + \frac{1}{2} + \frac{1}{4} + \dots) = 3mw^2/V_L.*$$

In practice there will almost certainly be a flow in one direction or the other, due to residual imbalance in the ventilating system so that either u or v will be many times larger than this figure.

For locks with clean air input greater than any extract, the air in the lock will be clean in the absence of any passage through. Even with an input of 200 m.³/hr. into a lock of volume 10 m.³, 80 % of any contamination introduced on entering the lock will remain after a dwell time of 0.01 hr.; but this is of no significance, since any contamination introduced by opening doors will be distributed to the two sides of the airlock in proportion to the air flows. The effect of this is identical in whichever direction a person passes through the lock, so that $u = 2mwv_C/v_L$ and $v = 2mwv_R/v_L$. If there is no extract and $v_C = v_R = \frac{1}{2}v_L$ then $u = v = mw$. Loss by settling during the time taken to flush the contamination out of the lock will however reduce the effective particle transfer. The proportion so lost by settling is given by $60sA/(60sA + v_L)$. If the air input is 100 m.³/hr., the settling area within the lock is 4 m.² and s is taken as 0.3 m./min. then the proportion so lost = $72/(72 + 100) = 0.42$. If $v_C = v_R = \frac{1}{2}v_L$ then as far as the transport of particles through the airlock is concerned effectively $u = v = (1 - 0.42)mw = 0.58mw$. The net air input to the lock must be regarded as additional ventilation air to the system, divided according to the proportionate air flows in the two directions (i.e. v_R is to be included in v_1 and nv_C in v_2). Any contamination produced by activities within the airlock, e.g. putting on or taking off protective clothing etc., will be carried both into the room and into the communications area in proportion to the air flows, subject to losses from sedimentation similar to those described above.

The air within an airlock with extract in excess of any input is always contaminated from both sides in proportion to the relative input flows from both sides. Dwell time in the lock is therefore again irrelevant, since it is not entry into the lock that introduces the airborne particles. On entering or leaving the lock, particles are transferred across the door concerned, hence $u = 2mwu_R/u_L$ and $v = 2mwu_C/u_L$. If there is no input and $u_R = u_C = \frac{1}{2}u_L$ then $u = v = mw$. The continuous loss by sedimentation within the airlock will reduce this to a similar extent to that given above for the positive input situation substituting u_L for v_L . Contamination produced by activities within the lock itself will be transferred in the direction of subsequent passage. With little effect from any dwell time of less than 2–3 min., the fraction will approximate to w/V_L , usually substantially less than the amount transferred from a positively ventilated lock.

Further reduction in the transfer through an airlock can be obtained by a high

* This assumes that w/V_L is sufficiently small for the reduction in concentration of particles left in the airlock each time a volume w is lost on opening a door to be negligible. If w/V_L is as large as 1/10 when the other conditions are as assumed above then the values of u and v will be reduced to approximately $2.2mw^2/V_L$.

rate of near balanced ventilation to the lock, or recirculation through a filter within it. The advantage gained will depend upon the recirculation rate, the time during which recirculation is applied, if not continuous, and the type of airlock involved.

For a lock with positive supply v_L in addition to recirculation at a volumetric rate R , applied on entry to the lock, transfer on passage in the forward direction is reduced to approximately $mw(w/V_L + v_R/(R + v_L))$ for rapid passage through and to $mwv_R/(R + v_L)$ if the dwell time is sufficiently long. Return through the lock will also transfer $mwv_R/(R + v_L)$ in the same direction irrespective of dwell time, i.e. $v = mw(w/V_L + 2v_R/(R + v_L))$ for rapid passage, dropping to $2mwv_R/(R + v_L)$ with sufficient dwell time. Transfer in the reverse direction, u , will be determined by replacing v_R by v_C in the above formula. As an example, if recirculation at 2000 m.³/hr. is applied to a lock of volume 10 m.³ with $v_C = v_R = 50$ then the transfer on rapid passage is $mw(0.1w + 100/2100) = mw(0.1w + 0.048)$. With this rate of ventilation the effects of sedimentation are negligible and the residual concentration in the lock is reduced to about 12 % after a dwell of 0.01 hr. Transfer on passage is then reduced to $mw(0.012w + 0.048)$ which is insignificantly different from that resulting from indefinitely long dwell time, i.e. $0.048mw$, since w is likely to be of the order of 1 m.³ (see below). The effects of recirculation applied continuously are identical with those obtained with operation only on entering the lock.

If there is extract from the lock, continuous recirculation will reduce transfer to $u = 2mwu_R/(R + u_L)$ and $v = 2mwu_C/(R + u_L)$ irrespective of dwell time. If the recirculation is switched on only on entry into the lock, the recirculation will have no effect on transfer by rapid passage, and the transfer rate can be no more than halved even with prolonged dwell time.

By the use of directed downward flow ventilation in the airlock nearly 100 % clearance could be obtained in a single air pass. At a velocity of 0.5 m./sec. this would take little more than 5 sec. If, however, the floor area of the airlock were 5 m.² the air supply rate would then need to be some 9000 m.³/hr. or 150 m.³/min.

Calculated transfer values

The relationships discussed above may be applied to an infinite variety of possible systems. For illustrative purposes the results obtained for a series of variations on a single layout, using plausible values for the various parameters, have been set out in Table 1. The assumptions of complete and uniform mixing within each space and of uniform regular entries and exits to the several rooms are manifestly approximations so that the precise numerical values must be treated with reserve.

In addition to selecting values for the physical dimensions of the system and for the rates of ventilation, it has also been necessary to assume values for m , the number of passages in each direction between a room and the communications area and for w , the volume of air exchanged between the two sides of a door when it is opened and closed in quick succession.

One study of a two-bed isolation room (Lidwell & Towers, 1970) has shown an

Table 1. *Calculated reductions in exposure to airborne particle transfer*

Condition	u	v	α	β
A. Balanced supply (no airlocks)	1000	1000	11 (6)	2 (1.7)
	500	500	28 (11)	4 (2)

Directed ('laminar') flow	$\rightarrow 0$	$\rightarrow 0$	$\rightarrow \infty$	$\rightarrow \infty$

The table shows values of the ratio, α , of particle concentration in the source room to that in other patient rooms, and the ratio, β , of the concentration if all the rooms were combined into one space with uniform mixing throughout to the concentration in non-source patient room for the particular system, i.e. the larger the figure the better the isolation. u and v , the air flows from each room into the communications area and in the reverse direction are given in m.³/hr.

The following values have been used in the evaluation of α and β , particle settling velocity 0.3 m./min. Ten patient rooms each with floor area 15 m.² and air input at 300 m.³/hr. (this corresponds to a ventilation rate of 6/hr. for a room height of 3 m.). Settling in these rooms is then equivalent to an additional clean air supply of $0.3 \times 60 \times 15 = 270$ m.³/hr., hence $v_1 = 300 + 270$ and has been taken as 600 m.³/hr. The communications area covers 80 m.² with an air input of 1200 m.³/hr. (this corresponds to a ventilation rate of 5/hr. for a ceiling height of 3 m.). Settling in this area is equivalent to an additional clean air supply of $0.3 \times 60 \times 80 = 1440$ m.³/hr., hence $v_2 = 1200 + 1440$ and has been taken as 2500 m.³/hr. Entries and exits to and from each room have each been taken as 5/hr. ($m = 5$) and 1 m.³ of air has been assumed to be exchanged across the door opening each time a door is opened and shut. The volume of an airlock has been taken as 10 m.³ with a floor area of 4 m.² and with 100 m.³/hr. input or extract when appropriate. When the airlock is ventilated the air has been considered as delivered to or taken from both sides of the lock in equal amounts. Recirculation has been taken as 2000 m.³/hr. and assumed to come into operation only on entering the locks. The figures in parentheses in group A relate to conditions of negligible ventilation supply to the system. The values for the unventilated airlock have been enclosed in square brackets since this condition is practically unrealizable unless sealed doors are used.

average of 360 openings of the room door, entries or exits, per 24 hr. or 15/hr. ($m = 7.5$). Observations on single rooms in a burns unit (Hambræus & Sanderson, 1972) gave a figure of about half this for a burned patient and rather more for an amputee. It would therefore seem reasonable to take a value of 10 exits or entries/hr., i.e. $m = 5$, for the number of passages/hr. in each direction.

There do not appear to be any published data available on the exchange of air through a doorway on opening and closing the door. Since the volume swept out by a hinged door of conventional size is of the order of 1 m^3 this figure has been taken as an approximation for the purposes of calculation.

Unpublished experiments carried out recently by the Building Services Research Unit of Glasgow University (W. Whyte & B. Shaw, personal communication) indicate values of 0.5 m^3 for the air transfer on opening a swing door of conventional dimensions. The figure is substantially less for a sliding door, but the large gaps around such doors may lead to significant air exchange across the closed door unless there is sufficient directed air supplied to swamp reverse convectional air flow.

In general hospitals in Britain the doors of patient rooms without airlocks are commonly found to be left open for considerable periods of time (Baird, 1969; N. Foord & O. M. Lidwell, to be published). There have been several published studies of air exchange through open doors or similar apertures as a consequence of small temperature difference (Wolf, Harris & Hall, 1961; Brown, Wilson & Solvason, 1963; Kethley, 1966; Ma, 1965). Unfortunately the numerical values given by the different authors are not in agreement. They range from 40 to $1100 \text{ m}^3/\text{hr.}$ for a temperature difference of 1°C. across a $2 \text{ m.} \times 1 \text{ m.}$ doorway, with as much as $350 \text{ m}^3/\text{hr.}$ for only 0.1°C. temperature difference in one instance. Since the air flow, theoretically, is proportional to the square root of the temperature difference quite high air flows may result from very small differences and values of between 100 and $500 \text{ m}^3/\text{hr.}$ seem not unlikely in practice.

DISCUSSION

With balanced or natural ventilation systems (group A, Table 1) values of α might be expected to lie between 10 and about 250. The actual advantage of subdivision compared with the exposure expected if all the patients were in a single room, given by the value of β , is, as explained earlier, much less, a reduction of between 2- and 20-fold in exposure to airborne particles. Comparison with the limited experimental results available, given in Table 2, shows a reasonable correspondence with the calculated figures. The degree of isolation obtained was, as would be expected, markedly less and the probable extent of air exchange between the parts of the ward much greater in the first situation referred to in Table 2. In this hospital the ward was partitioned but the patient areas opened directly off the communications corridor, being separated from it by no more than a low wall less than 1 m. high.

The introduction of a substantial directional flow to swamp the convectional exchange (group B, Table 1) raises the value of α to around 10^3 and β to about 100

Table 2. *The exposure to airborne particle transfer observed in some hospital situations*

The table shows the observed values of α , the ratio of the particles concentration in the source room to that in other patient rooms. The values of v_1 , the ventilation supply to a patient room and v_2 , that to the communication area, both given in m.³/hr., are usually only rough estimates based on limited information. Values of u or v , also in m.³/hr., have been deduced from the above using equation 5. For the balanced and natural ventilation system u and v are assumed equal. For references 6 and 7 u has been taken as 200 and 400 m.³/hr. respectively and the values given in the 7th column are those calculated for v . Where the tracer is particulate v_1 and v_2 have been doubled to allow for sedimentation (this is true if $s = 0.3$ m./min., $h = 3$ m. and ventilation is at 6 changes/hr.) before applying the formula. No estimates of v_1 or v_2 can usefully be made for the first four situations listed. The values of u and v given in parentheses are deduced from those given in Table 1 for the no ventilation condition.

The two values of u , v and α for reference 8 refer to 10 and 60 entries/exits per hr. respectively ($m = 5$ and $m = 30$).

* The discrepancy between the value of α in this row and that for the same system with a similar-sized tracer particle in the row below, suggests that the micro-organisms reached the non-source rooms by other routes than air transfer.

(this assumes the figure of 10 entries or exits to or from the room in each hour transferring 1 m.³ of air with each door opening). The observed ratios (group B, Table 2) are not quite as high as this and correspond to transfer against the direction of air flow of 20–50 m.³/hr., 2–5 times the assumed figure. This would suggest that the directional flows were inadequate to prevent reverse flow. The insertion of an airlock between the room and the corridor, group C, further increases the ratio α to between 10^4 and 10^5 , on the same assumptions of the frequency of door opening and the extent of air transfer associated with this. The calculated

performance for a ventilated airlock is independent of any delay or dwell on passing through the lock. Extract from the lock has the advantage of reducing dispersal of any airborne contamination generated within it. The one set of figures available in Table 2 show quite close agreement with the theoretical calculations and are presented in greater detail in the next paper (Hambraeus & Sanderson, 1972).

By using high volume recirculation in an airlock it should be possible to increase the value of α to very high values indeed but these could be realized in practice only if transfer of particles by other means than free air, for example on clothes or in the respiratory system, was kept to similarly low levels.

The clinical significance of these calculations and observations is quite uncertain since in no situation have we precise knowledge of the risk of infection by the airborne route as a function of exposure. It is, however, desirable that whenever studies are made of the clinical value of an isolation system measurements of the airborne particle transfer within it should be made under working conditions and that, if a high level of air isolation is considered desirable, the design should be such as to produce this. In order that any system may function effectively the actual air volumes and balances must be stable and correspond to those called for by the design. This is not generally the case, and most systems that I have examined have been both variable and divergent from their design intentions, for example the isolation unit referred to in reference 8 (Table 2) was designed for an input of 200 m.³/hr. to each of the patient rooms with an extract of 100 m.³/hr. from the airlock, supplied as to 50 m.³/hr. from the room and 50 m.³/hr. from the corridor. The value of α given in the table was obtained as between rooms where these flows were, at least approximately, maintained. However, out of 27 observations of the air flow around the doors into the air locks made on six separate days the *direction* of flow was reversed around one or other door on no fewer than 11 occasions. Hambraeus & Sanderson (1972) report similar observations. It must always be difficult to maintain the balance between flows as small as the above and if it is to be achieved some stabilizing factor, for example a relatively high-pressure drop across a filter or control orifice, must be included in the system. In addition, visual or other indicators of the flow directions are called for to ensure maintenance of the design conditions.

arrive tired and wish to sign on with minimum fuss. To avoid queues at the registration booths, all queries should be referred to the secretariat. Any delegate who is unable to produce a congress registration card should be escorted personally to the secretariat, where the problem should be resolved. The common cause of a problem is usually a lost card (in which case a duplicate may be issued), or perhaps registration fees have been paid late, in which case no card would have been issued. It is not unusual for delegates from Eastern Europe to prefer to pay on arrival.

Queries may also arise over tickets for the various social events and here you reap the benefit of being able to produce, from the

same plastic envelope as the record card, the delegate's original ticket application form.

A cashier is essential in the registration area to handle registrations, including day registrations and ticket payments. Life is much simpler if only *one* person handles cash and if they have proper facilities.

Throughout the conference, and especially during peak registration times, members of the local organising committee should be constantly on hand to deal with contingencies and also to introduce themselves to any delegate who looks lost. The impression this gives, and justifiably so, of looking after your delegates, greatly helps the success of the entire project.

Hospital Topics

Isolating patients in hospital to control infection*

Part III—Design and construction of isolation accommodation

K D BAGSHAWE, R BLOWERS, O M LIDWELL

British Medical Journal, 1978, 2, 744-748

Good isolation practice is easier in a well-designed building. Easy, direct, and short-distance access to patients, supplies, and facilities lightens the nursing load, thereby giving more time for the proper observance of isolation procedures. There is, however, a potential conflict between the advantages of compact planning and the increased possibilities that this affords for transfer of micro-organisms between patients, by contact and airborne routes. Segregation of patients from each other and separation of clean from potentially contaminated materials is of first importance in creating an effective isolation complex. Reconciling these factors in a practical way is the problem of isolation-unit designs.

Remoteness

It is common experience that infection with particular strains of micro-organisms may be widespread in one ward of a hospital but spread only slowly, if at all, to other ward units. Several factors might be implicated. There will be different nursing and probably domestic staff for each ward, although auxiliary and,

*This paper was prepared with the help of the Hospital Infection Committee of the Medical Research Council but it represents the views only of the authors.

O M LIDWELL, DPHIL, deputy director

to some extent, medical staff may be in common. The wards are usually physically separated from each other by stair-wells and corridors or may be in separate buildings; this will reduce considerably the possibilities of airborne transfer. There will also be a time interval for any contact transfer between the separate units, and during this time micro-organisms might die or be lost from clothing.

These factors that reduce the transfer of microbes between ordinary wards are still more relevant for an isolation unit that is physically separate from the rest of the hospital. For example, hand-washing and clothing changes are more likely to be performed; regulations for restricted access are more likely to be observed. The use of "tacky" mats at the entrance is probably of little bacteriological importance but will improve the general cleanliness within the unit, which may encourage high standards in other respects.

The open ward

If a patient is to be isolated in an open ward the isolation area should be defined as generously as possible and demarcated by washable screens. Selection of the area should take account of ward traffic, location of wash-bowls and toilets, etc. Tables or trolleys for supplies from the central sterile supplies department (CSSD) should be available and a generous supply of bags provided for disposing of contaminated articles. Good lighting is necessary. Clear notices with instructions to exclude cleaners, etc., are important.

VENTILATION OF OPEN WARDS

Good ventilation is a traditional requirement. It does not seem likely, however, that mechanical ventilation of large wards can have any substantial value in controlling hospital cross-infection; the possible reduction of airborne contamination by this means is slight. It is possible to design the ventilation of a

subdivided ward so as to reduce substantially airborne-particle transfer between rooms, by a system in which all the sections are supplied with excess air while the corridor acts as a common air drain, or alternatively all the sections have excess extract and air is supplied from the corridor supply.^{1 2}

The airflows needed and the degree of effectiveness will depend on whether or not doors are kept closed and on temperature differences and wind pressures acting on the building. It is not usually practicable to keep doors closed except in a specifically designated isolation unit. If doors are often open the excess air volumes required to maintain unidirectional flows over the whole door aperture are about 0.3-0.4 m³/second (500-700 ft³/min)³ with temperature differences as low as 0.5°C (1°F). In a fully air-conditioned building, however, where the temperatures are uniform, as little as 0.1-0.2 m³/second (200-300 ft³/min) may be enough.² Although airborne-particle transfer may be a hundredfold less than in an unventilated unit, it is very doubtful whether any clinical benefit results. With normal nursing the opportunities for transfer of micro-organisms by direct or indirect contact and from resuspended airborne material derived from contaminated clothing are great.⁴

AIRCURTAIN BEDS

Attempts have been made to provide a clean environment for a patient still remaining in a general ward. Air drawn from the ward is passed through high-efficiency filters and discharged over the patient, either vertically downwards from an overhead canopy or horizontally from a panel behind the bedhead. Without impermeable side curtains the effectiveness of the air jets in containing the clean air and preventing ingress of contaminated air is limited.⁵ This reduction is probably not worth while. If side curtains were provided the result would be equivalent to a single room with a high level of ventilation, which could be designed to be either positive or negative with respect to the general ward area. If effective barrier-nursing procedures were then used good isolation should be possible.

Single rooms: ventilation and airlocks

Airborne transfer of infective material between the rooms of a ward or isolation unit may occur in various ways (see part I). For controlling these methods of transfer, several methods of ventilating rooms can be considered.

SIMPLE DIRECTIONAL VENTILATION AND SINGLE DOOR TO CORRIDOR

Fig 1 shows two types of simple directional ventilation in a room with a single door into a corridor. In (a) the air is extracted from the room and made up from the corridor. No special conditioning plant is required, and the room is suitable for isolating infective patients. In (b) air is brought into the room and discharged into the corridor. Air-conditioning equipment is

FIG 1—Simple ventilation arrangements for isolation room: (a) extract from room; air enters from the corridor through doorway or gaps around door; (b) input to room; air passes into corridor through doorway or gaps around door.

needed unless a recirculating system taking air from the corridor through a filter is used.⁶ This system is suitable for isolating susceptible patients.

These systems need only simple engineering and there are no problems of balancing airflows, so that malfunction and reversed air flows are unlikely to occur. In practice single doors are often left open, which encourages unnecessary entry to the room and increases air exchange with the passage. At least 0.1-0.2 m³/second (200-300 ft³/min) is needed to prevent air exchange across an open doorway; if there is a temperature difference of no more than 1°C (2°F) between the room and the corridor this figure will be more than doubled.³

If all the rooms in a unit are ventilated in the same way (a) and (b) give similar degrees of protection from airborne contamination between rooms. The effective improvement over an open situation is about a hundredfold⁷; (a) keeps the corridor free from contamination from patient sources in the isolation rooms but exposes the patients to airborne material from the corridor; (b) uses the corridor as a kind of air sewer but protects patients in the rooms from the corridor.

It is usually unnecessary to provide grilles or other apertures for the airflow; gaps round doors and other structural cracks generally leave enough room for air to escape.

If the doors to the patients' rooms are kept closed the efficiency of the system can be greatly increased. By using close-fitting doors, eliminating other leaks into the corridor, and providing alternative input or discharge ports that do not communicate with the corridor, the airflow from or to the corridor—which ever corresponds to the design direction—can be reduced to less than 0.03 m³/second (50 ft³/min). The resulting improvement in air isolation between rooms may be tenfold or more. Reverse flow will occur only when the doors are opened.⁷

DIRECTIONAL VENTILATION WITH LOBBY AND HATCHES

Adding a lobby or airlock improves the air isolation, possibly by a factor of 10 compared with the simple arrangements of fig 1.⁷ Either direction of airflow may be used with the same advantage of engineering simplicity and reliability. The lobby and hatches do, however, facilitate better control of contact transfer (see fig 2). Doors will more often be kept closed, with a

FIG 2—Addition of unventilated entrance lobby and pass-through hatches to room layout; broken arrows indicate movement of materials. Room ventilation may be as indicated in fig 1 (a) or (b).

reduction of entries and exits. Because only one door to the lobby is open at a time it is necessary only to maintain the desired direction of airflow around the doors and through other gaps. This may be done with quite small air volumes even if there are appreciable temperature differences between the room and the corridor; 0.05-0.1 m³/second (100-200 ft³/min) is probably adequate.

A two-bed dismountable isolation unit has been designed by the Atomic Energy Research Establishment (AERE) for the Department of Health and Social Security.⁸ This incorporates several interesting design features. It seems unlikely that isolation rooms will, in fact, often be dismantled and moved and erected elsewhere in a hospital; the equipment needs to be considered primarily as a convenient and possibly cheap way of providing additional isolation facilities.

TWO-WAY ISOLATION WITH A VENTILATED AIRLOCK

With a ventilated airlock it is possible to isolate a room in both directions simultaneously and to obtain a high degree of protection against airborne room-to-room transfer (fig 3). For example, the degree of protection may be about 10 000 times that found in an open situation, and considerable isolation may be maintained between room and corridor.^{7 9 10} There is no difference in this respect between input to or extract from the airlock but the extract arrangement reduces transfer into the room of any contamination generated in the airlock itself and is therefore preferable.

FIG 3—Isolation room with extract-ventilated airlock, toilet, and pass-through hatches. Arrows indicate directions of airflow.

When there is a room supply of air of 0.1–0.15 m³/second (200–300 ft³/min) about half may be extracted from the room (including extract from the toilet). If 0.1–0.15 m³/second (200–300 ft³/min) is extracted from the airlock about half this will be drawn from the room and an equal volume from the corridor. To maintain the isolation across pass-through hatches part of the airflow—perhaps one-third of the total—should be directed through these.

This system demands a more elaborate ventilation system than other arrangements; in particular the input and extract air volumes must be maintained in the appropriate relation; the maximum tolerance in the designed volumes will be about $\pm 25\%$. Actual installations are usually unsatisfactory in this respect.^{10 11}

UNIDIRECTIONAL (LAMINAR) AIRFLOW

The need for dust-free environments for industry has led to the development of high-efficiency air filters which are used to provide particle- and microbe-free air as a directed non-turbulent flow which sweeps out the working space. This arrangement has been applied to the care of highly susceptible patients.^{12 13} Because it is relatively easy to reduce airborne contamination to a level at which contact and autogenous infection become predominant even with the best precautions against these, some of the technical requirements for ventilating patient

rooms may be considerably less rigorous than for industrial work. The linear air velocity needed to reduce turbulence sufficiently for unidirectional horizontal flow to be established appears to be no more than 0.15–0.25 m/second (30–50 ft/min),¹⁴ and even 0.1 m/second (20 ft/min) may suffice in a downflow room.¹⁵ A filtration efficiency of 90% to the US standard DOP test or BSI sodium-flame test (using particles of 0.1–0.2 μ m in diameter) is probably adequate to reach limiting air sterility in the room. Noise control is, however, a major concern and ratings of no more than NC 35–40¹⁶ are required. (This scale takes account of noise concentrated at particular parts of the frequency range.) It has been claimed that this form of ventilation actually reduces autogenous infection,¹⁷ which suggests that this is sometimes airborne.

It is possible to use this form of ventilation to isolate several patients in one room without partitions (fig 4).¹⁵ This may be

FIG 4—Open-ended multibed unit ventilated by a unidirectional airflow. Air enters through the filter bank behind bedheads and is extracted through slot in roof. Only about 10% of airflow passes into downstream end of the room beyond roof slot. Screens or curtains may be positioned between beds.

advantageous for patients who need much nursing and supervision and for those with claustrophobia in single rooms. Those who come into direct contact with the patients must obviously practise non-contact techniques—for example, with regard to clothing, hand preparation, etc—but others who enter the room for activities not needing patient contact need observe only minimal precautions if they remain downstream or to the side of the patients.

With this form of ventilation about 90% of the air is recirculated with the addition of enough fresh air to control smells, carbon dioxide, and other gases. Full air-conditioning is required to control heat gain from the fans. The cost is considerable but convenience and comfort are high and the level of isolation that can be attained is limited only by the measures used to reduce contact transfer. The ease of access itself makes considerable demands on aseptic discipline.

Plastic isolators and ultraviolet light

“Wrapping” the patient in a sterile bag to isolate him from the outside environment is another possibility. The “bag” is held on a frame to give the patient space; is ventilated with a filtered air supply, which may be unidirectional; and is provided with ports for introducing and removing materials, and with

glove ports or invaginations for nursing procedures.¹⁸ Some designs also incorporate enough space around the bed for the patient to sit, stand, or even walk a few paces. Toilet accommodation can also be provided. Such systems seem to approach the ultimate in isolation, but carry inherent difficulties in management.¹⁹

Ultraviolet light has been used as part of isolation systems, especially as a barrier at room doors. There are some difficulties associated with its effect on skin and eyes; the need to screen the lamps from direct vision, unless protective clothing is worn, reduces their effect considerably. Calculations do not suggest that sufficient intensity can conveniently be used to provide an effective barrier to airborne micro-organisms carried on air currents through an open doorway. But irradiation of airlocks may somewhat reduce airborne bacterial transfer through them.²⁰ Whole-room effects, obtained by irradiation of the air above 2 metres (7 ft), do not exceed those obtained by dilution ventilation and are probably not large enough to be useful. The bactericidal effect of ultraviolet irradiation is less at high relative humidities.²¹

Doors and communications

Doors in isolation units introduce some difficulties. Swing doors need space in which to operate, which may be particularly difficult to find in airlocks, and cause considerable air disturbance. Sliding doors may overcome both these disadvantages, but they are mechanically less satisfactory and need more effort to operate. The grooves in the floor or the hollow spaces into which some doors slide may collect dirt and be difficult to clean.

The need to operate a door handle is inconvenient when something is being carried and provides a possible route for bacteriological transfer via the handle. Mechanically operated doors are becoming more widespread and more reliable. Operation may be by foot pressure or photoelectric; hand press-buttons defeat one object of mechanical operation. The AERE isolation unit⁸ incorporates simple mechanically operated sliding doors.

Restricted access from outside the unit needs to be accompanied by means of communication from the entrance to some point within, preferably by two-way telephone, if there is no receptionist or secretary at the entrance. In a unit of any size a means of locating and communicating with nurses from some central point avoids much wasted time. This may be combined with the patient-call system or integrated with a centralised hospital communications system, such as the Cass system.²²

Many isolation rooms, especially when provided with entrance airlocks and toilet facilities, are effectively cut off from direct communication with the access corridor. This is often disliked by the patients and introduces unnecessary difficulties in nursing. For some patients the sense of abandonment leads to appreciable psychological problems.⁷ This aspect of design has usually been ignored by medical staff and architects alike. The design layout in fig 3 allows good direct vision for patient and nurses and if a speaking panel or window of unperforated plastic (as in the AERE design⁸) is used, direct speech is also possible. The provision of separate pass-through hatches for clean and dirty supplies in the area below the inner window allows separate circulation of these two classes of materials and eliminates the need for many entries into the isolation room itself.

Some units have been designed so that visitors can see and speak to the patient without entering the unit. Providing a special corridor for this purpose is expensive. Visitors are usually less of a bacteriological hazard than the hospital staff, and if they take the same precautions with regard to clothing, etc, as the nursing staff they may generally be allowed to enter the patient's room. When this is undesirable, as for the extremely susceptible or highly infectious patient, the use of plastic speaking panels may provide adequate communication

similar to that afforded by a visitors' corridor. It will be more acceptable if the layout can be arranged to provide some privacy.

Materials and finishes

Smooth, clean, impervious surfaces without lodgement for dust are obviously desirable. In the extreme their effect can be acoustically and visually repelling. In most places perforated acoustic ceiling materials are bacteriologically unobjectionable. Washable vinyl-faced or vinyl-sheet wall coverings are satisfactory. Noise and the risks of falls are reduced by soft-backed vinyl flooring.

Easy cleaning is important because the appearance of cleanliness is valuable, and minimal maintenance is especially important when some cleaning has to be done by the nursing staff. For strict isolation the fewer patient-staff contacts the better.

Engineering

The requirements for wash basins are discussed below. Avoidance of any risk of bacteriological contamination of the water supplies, as in holding tanks,²³ is clearly more important than usual for highly susceptible patients.

Water closets should be siphonic to reduce aerosol dispersal during flushing^{24 25}; for extreme forms of protective isolation exhaust ventilation of the pan may be useful.²⁶

The cost of ventilation plant is high, but a high proportion of installations rarely or never function in accordance with the design specification. It is therefore important that an adequate testing programme should be completed before the work is accepted and that this forms part of the contract.¹⁰ Account should be taken in the testing programme of the possible effects of varied weather, especially winds. Good regular maintenance is equally important. This is more likely to achieve its object if there are visual indications, preferably in the isolation unit itself, that critical airflows are within the design limits and that the directions of airflow are correct.

Control of relative humidity (humidification) is likely to be needed for some patients, such as those with exposed burns and those who have undergone chest operations. It will be needed more often if temperatures are kept above 22°C (72°F), which may be advantageous in that it reduces the amount of bedding needed.

Filtration of outside air will rarely need to be better than that recommended for the surgical operating room²⁷—that is, to 5 µm—unless there are problems of dust staining. Recirculation or the need for unusually high degrees of bacteriological cleanliness may call for filtration to 90% against 0.1–0.2 µm particles as indicated by the DOP or sodium-flame tests. Contamination of ducts is slight under normal conditions and re-dispersal rare.²⁸ There has been vigorous advocacy of terminal filters. These undoubtedly eliminate any small risk there might be from the ducts and may be taken down and cleaned or replaced after an especially infectious patient, but in most circumstances the extra cost does not seem to be justified. In any case the diffusers should be easily cleanable because air turbulence often leads to substantial dust deposits on them from the air of the room.

Isolation rooms should be designed so that, so far as possible, engineering maintenance can be done by staff working outside the rooms.

VALUE OF SUBDIVISION AND VENTILATION

Building design and, in particular, ventilation and air-movement control are primarily relevant when the infecting agent is transmitted by airborne material. In general, the potential for transmission by contact is much greater than by

the airborne route but varies according to the nature of infection and the nursing regimen.

There is almost no information to indicate how large a reduction in airborne exposure should be aimed at in any given circumstance. There is, however, reason to think that reductions of less than a factor of 10 are not valuable. Whenever the population exposed to risk varies substantially in susceptibility the number infected will vary less than any variation in exposure.²⁹ Observations on nasal acquisition of *Staphylococcus aureus* suggest that this effect may be large. The risk of nasal acquisition of this organism appeared to vary less than the change in the inhaled dose and no more than one-half to one-fifth power of the inhaled dose.³⁰

MATERIA NON MEDICA

"Turn down the sound, you're disturbing the elephants"

We woke at dawn in a train trundling slowly through the African bush to the sight of wildebeest, gazelle, and giraffes browsing unconcernedly at the side of the track. This was not the end of an exotic holiday or the last lap of a long safari. We were, in fact, returning from the annual meeting of the Kenya Association of Radiologists.

Once a year we hold an out-of-town meeting, both to let the non-Nairobi members take part and to enable us to have a scientific and social get-together in pleasant surroundings. This year's meeting was held in a coast hotel near Mombasa, where the off-season temperature was kept to a cool 29°C by the brisk south-east monsoon. Our small group managed to produce a scientific session of a reasonable standard with interest added by a variety of unusual cases from leukaemic kidneys to calcified splenic cysts. It would, however, be surprising to a British radiologist to be shown films of Paget's disease, asbestosis, and diverticulitis as examples of rare conditions.

Business over, we relaxed with a swim in the Indian Ocean followed by a dinner-dance held under the stars and gently blowing palm trees.

Last year's meeting was in the no less exciting setting of Tsavo National Park. From the lodge bar, between papers, we were able to view a variety of game at the water-hole against the magnificent backdrop of the snow-capped Kilimanjaro, while inquisitive ground squirrels searched for crumbs around our feet and tropical birds added their brightly coloured plumages to the scene.

Such exotic settings for meetings are, however, not without their disadvantages, or, as we were told by the lodge manager at our evening film, "Turn down the sound, you're disturbing the elephants!" JOHN F CALDER (radiologist, Nairobi).

Seeds of time

Hearing that the garden of a well-known medical institution in London had lost all its foxgloves, I said I would be happy to supply some more seed. Returning home, I thought how much more appropriate it would be if I got the seed from William Withering's former country seat, a short walk away. Edgbaston Hall is hidden behind the Old Church where he is buried, an imposing, Georgian, red-brick mansion overlooking extensive parklands. Now the site of a peaceful golf-course and a 50-acre lake inhabited by geese, duck, and grebes, the estate seems far removed from those lawless days in 1791 when the Birmingham mob, infuriated by dissenters celebrating the French Revolution, burnt down Joseph Priestley's home and threatened to do the same to his friend Withering's. The surrounding

woodland has recently been taken over by the University as a small nature reserve, and we had joined an extra-mural class to study its ecology, so it was not difficult to collect the seed, and it was duly dispatched.

Earlier this summer we stood in Gloucestershire fields on a beautiful evening admiring the remains of a Roman village being excavated near Kingscote. On a heap of rubble to one side a group of magnificent poppies tinged blood red by the dying sun reminded us of flowers we had seen in the Mediterranean. "Oh yes," said the custodian proudly, "those are Roman poppies." Driving back we laughed at the woman's naiveté; after all, seeds were carried across fields by the wind or scattered by birds. And then I suddenly remembered my Withering foxgloves: I too was guilty of romanticising, but could cold reason prove either of us wrong?—ALEX PATON (physician, Birmingham).

The vision splendid

If, as I do, you travel a good deal by air you get used to sunsets. The plane, flying into them, prolongs the picture almost interminably and often only with a persistent gold or red rim. Flying away from the sun leads to a rapid depressing suffocation of day, guaranteed to make me reach for my novel and my martini. But to fly across a sunset can be an emotional experience without equal. I've done it often enough—helicoptering into doubtfully secure fire bases, homing from the Australian outback, and merely commuting from city to city in various continents.

Nevertheless, only occasionally does one in Banjo Peterson's words see "the vision splendid." It was my good fortune to catch such a moment flying from Aberdeen recently. Somebody celestial had daubed a streak of smoky red horizontally across the upper azure sky. Below this, from an altitude of 29 000 ft, what another poet called "the upshot beam" was tinging the underbelly of cloud with a pink that in some subtle way interacted rather than clashed with the upper heaven. As ever, the beam was due to fade both as the sun marched westward and the aircraft descended, but not before a last lingering flash of salmon-coloured cotton wool wiped the western horizon clear of detail.

Out of curiosity I looked to my fellow passengers. Only one on the west side of the aircraft was sharing my experience. Most obvious were a quartet of well-organised television executives, whose casual clothes, good suntans, and repeated bar orders exuded the confidence of their self-created, if artificial, environment. They played cards and the beauties of their immediate surroundings were as if they had never been. As the lofty shade advanced, their loud voices established a pseudo-reality and I returned to scribbling a grant application—HUGH DUDLEY (professor of surgery, London).

Guidance on ventilation revised and updated

Speaking in the 'System Governance' stream on the first day of last October's IHEEM Healthcare Estates 2021 conference, consulting engineer, Malcolm Thomas, the main author of the 2021 version of HTM 03-01, *Specialist Ventilation for Healthcare Premises*, published last June, explained the background to, and aims behind, the HTM's revision, and highlighted some of the major changes that those responsible for ventilation plant in hospitals and other healthcare facilities need to be aware of. *HEJ* editor, Jonathan Baillie, reports.

Malcolm Thomas was the lead author for both editions (published in 2007 and last year) of HTM 03-01, and also of the ventilation-related HTM 2025 that preceded them. Also the lead author of the engineering section of several HBNs, he has worked in the healthcare sector for over 40 years – both within and outside the NHS. He is President of the Specialised Ventilation for Healthcare Society, and a visiting lecturer at the University of Leeds. Welcoming attendees to his presentation, he explained that as the lead author of HTM 03-01 (2021), he would explain some of the main thinking behind it, and set out the reasons for a number of key changes in the 'rewritten version'. He began: "As some background to where the HTMs and other guidance on ventilation originated, back in 1972 Dr Owen Lidwell led a Joint Working Party on ventilation and operating suites, and this was the foundation of all the guidance that has emerged since. Many people have asked me," he continued, "why we bother with material that is 'so old'? The reason is that when this work was done, it was very evident what worked well in practice, and what didn't, in a way that's no longer nearly so clear. When you have significant infection rates in operating theatres, it's quite easy to see whether – if you change the colour of the paintwork – it makes any difference. Conversely, with very small infection rates – which fortunately we have now – it's very difficult to know whether changing the surgeons' gowns, the air change rate, or the colour of the walls, or putting carpet in, makes any significant difference. We're talking about low percentage changes. We're in a situation now where people think changes will improve things, but they don't actually know, and it's hard to prove what is a good or a bad thing. Back when Owen

Malcolm Thomas, the main author of the HTM 03-01 (2021), *Specialist Ventilation for Healthcare Premises*, published last June.

Lidwell did this work, it was relatively easy, there were step-changes, and he was able to conduct a number of trials."

Comparative trials

Malcolm Thomas explained that in one, Owen Lidwell and his team took a particular acute hospital, and identified two operating theatres as theatres 'A' and 'B', with had two surgical teams – also named 'A' and 'B', staffing them. He elaborated: "They picked out patients at random, drawing lots to decide which theatre they were operated in. They could thus see which team and which patients fared better under certain circumstances, and thus demonstrate changes in the

outcomes in infection rate terms." From this work, and drawing on theatres with low infection rates and good patient outcomes, Owen Lidwell and his team were able to determine the optimal airflow and temperature, and consider elements such as the impact of different gowning procedures. This in turn enabled them to draw some conclusions.

"The conclusions they drew have stood the test of time," said Malcolm Thomas. Following Owen Lidwell's work, the Department of Health and Social Security – as it was then – set up a working group, and codified the ventilation of operating departments in a document called DV4, specifying what was required for the theatre, and what worked and what didn't, 'taking Lidwell's work forward'.

Request to update guidance

"When I came on board," Malcolm Thomas explained, "I was asked to update DV4, but soon after I'd finished doing this, I was told it was now going to be an HTM, and HTM 2025 was duly published in 1994. Some years later I was asked if I could I take that forward again, and HTM 03-01, *Specialised ventilation healthcare*, was published in 2007. It was delayed by SARS, and avian flu, just as the Coronavirus outbreak delayed the publication of the current version of HTM 03-01. So, all of these iterations are based on some good solid work many years ago. I've been working in this area for some time, and it's very evident that these earlier learnings have stood the test of time. Where we have encountered problems, it's generally been clear that the guidance wasn't followed."

Historical reasons for not following guidance

Among the historical reasons for failure to follow established guidance, the speaker explained, had been changing procedures in both operating suites, and other 'spaces' in healthcare facilities, while on occasions people 'had not perhaps been as careful as they should have been' –

We're in a situation now where people think changes will improve things, but they don't actually know, and it's hard to prove what is a good or a bad thing

A48946859

leading to 'something going wrong with the ventilation'. Malcolm Thomas said: "Put the people right, and – if I can put it like that – we'll get the ventilation right. There's a good pedigree, a good history, and we can have some confidence in past learnings and guidance. It isn't just people's opinion; it's what works." 'Backing this up, he added, was 'a fair amount of ongoing research by Department of Health, the NHS, and private companies', with the findings taken on board when HTMs were revised and updated. He said: "So, in these guidance documents we try to avoid just featuring people's opinion of what works and what doesn't, and instead coming down to some facts. History appears to show that this is a correct way of doing it."

Do we need the HTM guidance?

'Back in 2017/18', he explained, when it was decided to look at revising HTM 03-01, one of the questions asked had been: 'Do we need it?' He explained: "We have, in fact, been trying to reduce the amount of guidance issued, because at one point there were something like 400 different pieces of guidance, and it's almost impossible to keep that sort of volume of guidance up to date." Over the years there had thus been some 'pruning', together with a 'focus on what is different about ventilation in healthcare'. The speaker said: "What matters to us is, for example, whether CIBSE guidance on ventilation is adequate. If so, that's great, but if not, do we need to do more than CIBSE is suggesting, or perhaps less in some cases? Things that CIBSE would allow may not be what we want to do. They may not be appropriate in a hospital or other healthcare setting. So," he said, "having decided we did indeed need HTM 03-01, we questioned whether it needed updating, and, having determined that it did, began looking at how." This resulted in a 'scoping exercise' which ran for over a year with wide-ranging consultation, to look at what was in the documents, whether the HTM could just be given 'a dust down' and a little updating, or whether indeed some fundamental changes were needed. He said: "That led to the move to produce a new document, in two parts, with part A on design and installation for those putting in something new, and Part B about how you manage an existing healthcare ventilation system."

A 'complete re-write' required

He continued: "It was decided that Part A needed to be completely rewritten, it having become clear from the scoping exercise that in existing form it assumed that designers knew what the healthcare industry needed." "Interestingly," he added, "back when I authored the HTM for the first time, I was told: 'Well, you

The latest iteration of HTM 03-01 – on which Malcolm Thomas primarily focused – followed several previous guidance documents on healthcare ventilation.

can't put that sort of thing in, Malcolm. People who do these things already know what they're doing.' On the contrary though, it became very evident – and particularly with the PFI process – that a lot of people designing hospitals and hospital systems in fact had no idea what their customer wanted."

Historical context

Here Malcolm Thomas showed slides of Owen Lidwell's report, followed by DV4, then HTM 2025, and then HTM 03-01, both in 2007 form and in the latest iteration. Referring to HTM 03-01 (2021), he said: "It was decided that we should produce the latest HTM 03-01 in two parts – it was clear that Part A needed to have more of an explanation, not just of what we wanted, but why – so that people understood the importance of things. We thus changed the title, the Concept, the Design, Specification, Installation, and Acceptance Testing – the whole process. We tended in the PFI days to say: 'Give us a new hospital, and give me the key when it's finished', and clearly that wasn't a good idea. While we have some very good hospitals, constructed and built and working well, some were much less successful than they should have been. Part A of the 2021 HTM 03-01 thus refers both to all new installations, and to refurbishments and changes in use of existing installations. I would stress that it's not retrospective; you don't have to rip everything out and re-start. However, if you're in the middle of the project, and you find that the new HTM would suit you better, then providing everybody else agrees, and

you've addressed any cost implications, there's no reason why you can't move over to the new standard." This, Malcolm Thomas said, applied even where a project team was working to guidance set out in the 'old' HTM."

Part B of the new HTM

He continued: "Part B is about the management, operation, maintenance, and routine testing, of existing healthcare systems. It's much as it was, but there are some additional changes. The thing to remember with Part B is that it applies to all installations; it doesn't matter how old." He continued: "I'm often told a hospital installation dates from the time of HTM 2025, and that's why it doesn't conform. However, the minimum standards have been there ever since that HTM was published; in fact they were introduced because of the Stafford outbreak and Legionnaires' disease in 1986, and were in the Big White Book, for which I wrote a section on standards for ventilation plant." These had – he said – been carried forward in every HTM since.

Moving to the 'major themes' in HTM 03-01 Part A, he said: "One thing we have had to focus on particularly is supporting the Government's zero carbon policy – so there's quite a push in terms of energy use, and how we go about things to support this objective."

Also considered in compiling the new guidance, Malcolm Thomas explained, had been the EcoDesign Directive and regulations, which he pointed out were 'legal requirements'; he was surprised many equipment manufacturers still viewed them as 'options'.

He expanded: "So, you will find, scattered throughout, little blue boxes with little aide-memoires, which highlight why the preceding paragraph is important, particularly in a healthcare setting. They are very sound ideas, so please don't depart from them."

A clarification of design parameters

The new HTM also incorporated 'a clarification of design parameters'. "There's been problems in the past with what standards we actually want," he explained. "We've now got much more of a clarification of design parameters." In terms of 'the new elements', the HTM's authors had put in the user requirements, listed under 'surgical', 'medical', 'mental health', 'palliative care', 'and so on'. He said: "We have thus sought to answer the questions: 'What does the user want, and why have we provided ventilation?', 'What's it for?', 'Is it for infection control, comfort, or to remove odours?' What's it about?' Again, it is about trying to clarify for the designers exactly what is important, and what you can do some adjustment on." He continued: "We've also introduced the concept of the Ventilation Safety Group, mirroring what we already have with the Water Safety Group, i.e. a group of Trust stakeholders made up of people from Estates, Finance, and Infection Control, and other key

Taking advantage of new technology

He continued: "On carbon reduction, we changed quite a few things to try to get maximum benefit from new technology and reduced energy use – fans being a good example." He elaborated: "Those of us who grew up with belt-drive fans know we were stuck with a particular fan speed, regardless of whether it was optimal, and with specific outputs; there wasn't much you could easily do about either.

"Nowadays, we have a whole range of more efficient fans, and more coming along; control technology has moved on – we can be more accurate in how much air comes down the system, and we don't need to build in such a big margin to allow for system deterioration over time. We've striven to take advantage of all this in the new HTM." Malcolm Thomas explained that the authors had also striven to provide background information to assist the understanding of client needs.

personnel, all of whom have an input, and make some decisions on the ventilation systems and their operation."

Derogations

In circumstances where somebody wanted to derogate in future, they would now need to take the matter to the Ventilation Safety Group, which must agree and sign up to the derogation. He added: "The Group must also record what the derogation was, why it was agreed, and who agreed it. It thus takes away this 'Mr Jones said it was OK'-type approach. Notice too," he said, "that somebody from Finance is involved, because some of these things have ongoing financial commitments. For example, some of the ways of installing ventilation plant mean they need more regular cleaning over time, with a financial implication ongoing for the system's lifetime, so it's essential that the Finance people are involved and recognise that if you go down that path, there needs to be provision to undertake the maintenance correctly over a period of perhaps 20 years."

Guidance on refurbishments

Malcolm Thomas explained that while the new ventilation HTM covers refurbishments and change, the old one didn't. He and his counterparts had encountered 'a lot of problems' with people refurbishing theatres, where they had 'completely gutted' an existing such facility, installed new ceilings, plastered the walls, put in new doors, a new floor, new operating tables, lamps, 'and everything', but kept a 30-year old ventilation plant. He said: "This is like buying a new car, but taking the engine out of the old one because that will save you a bit of money." He continued: "The ventilation plants are not as expensive as an operating table; you wouldn't dream of using a 30-year-old operating table, so

why consider using 30-year-old ventilation plant? We should surely be taking advantage of new technology. We want new plant with good controls, not old plant 'mashed up to save a couple of bob'. That's an important aspect which is clearly spelt out.

Natural ventilation where possible

"We have also suggested various ventilation strategies; we would like natural ventilation where practical. Such ventilation can, however, 'be tricky in the case of hospitals', Malcolm Thomas acknowledged. As he put it: "You're relying on the wind blowing, and blowing in the right direction, not too much and not too little, so it's not easy, particularly in a hospital." However," he added, "mixed mode ventilation, taking advantage of natural ventilation while it's there, and then supporting it with a fan that will come on when it's needed, and perhaps some supplementary heating etc, can be one potential solution."

Natural ventilation wasn't 'just about opening a window'. The speaker elaborated: "It's about having ventilation openings, which may be supported with some ductwork attached, with a means of adjusting the ventilation rate when the natural ventilation is available, and taking advantage of it when it is." Where full ventilation, 'which costs money', was selected, the question arose about whether it needed to run 24 hours a day, seven days a week, 52 weeks a year. He said: "The answer, in most cases, is 'no'. If there's nobody there, you can turn it off – a really good energy-efficient way of doing it. This is not new; it was in EnCO₂de for many years."

Unnecessary plant operation

Noting that people still left theatre ventilation running '24/7' to keep the rooms sterile, which was 'absolutely not

required', Malcolm Thomas explained that he and the co-authors of HTM 03-01 (2021) had expanded the 'Operating theatres' section 'quite significantly'. He said: "We've, for example, changed the parameters for air change rates to reflect what we can do to take advantage of the latest technology. We don't need to have as much slack in the systems as previously. So, the advice is much more appropriate for today, although still in line with what Owen Lidwell found worked, and history has subsequently proven right." Some of the 'old information' for where older theatres were still in use had been retained, but the new HTM 03-01 also incorporated 'a whole new set of information'.

Installation guidance

Malcolm Thomas told attendees: "In a new 'Installation standards' section, we've spelt out some of the things that cause us numerous problems – including guidance on very simple things, which cost no money to do, but if not done right cost an awful lot of time and effort. So, for instance, with a basic thing like balancing damper handles, why install them at the top of the damper? When the ceiling is up, you then can't reach them. Air doesn't know where the handle is, but putting the handle on the bottom of a damper costs no more installation-wise, but means that when you come to balance, or subsequently re-balance, the system, you can reach the handle without killing yourself."

Turning to another key topic in the new HTM – 'Acceptance testing and validation', Malcolm Thomas explained that 'validation is a process of accepting the whole job, the whole project', so in the theatre, wasn't 'just about how much air goes in, but rather about where the air comes from: what the air-conditioning and air-handling unit is like, what the ductwork is like, and what the fabric of the theatre is like'. The speaker stressed that it was 'very different from commissioning', and entailed looking more holistically at 'Does it work, and can we at the end of the validation say it is safe to operate?'

Appendices expanded

The authors had also expanded the appendices 'to cover some of these things'. Here he showed a diagram of 'an example of one of new standard schemes, and the amount of air in the theatre'. He said: "The air change rate has changed, and above this, if you look in the appendices, there's a whole range of information that's much more definitive compared with what we have before. So, there are four schemes – single-corridor and two-corridor schemes for standard theatres and ultraclean, and another four

A ventilation diagram for a standard operating theatre taken from HTM 03-01 (2021).

Part A

- The Concept, Design, Specification, Installation and Acceptance testing of Healthcare ventilation systems
- Applies to all new installations and refurbishments and changes of use of existing installations
- It is not retrospective

Part B

- The Management, Operation, Maintenance and Routine testing of existing Healthcare ventilation systems
- Applies to ALL installations regardless of when they were installed
- Minimum standards for all installations

Malcolm Thomas urged all those with a professional interest in, or responsibility for, healthcare, to read and familiarise themselves both Parts A and B of the new HTM 03-01 – ‘including the appendices and the accompanying explanations’.

historical schemes for those of you with older, smaller, theatres.”

The authors of the new HTM had also created quite a lot of application-specific guidance – for instance dividing up applications into ‘Treatment and Procedure Facilities’, ‘Airborne Protective Facilities’, ‘Airborne Isolation Facilities’, ‘Maternity Facilities’, ‘Pharmacy Facilities’, ‘Sterile Services Facilities’, and ‘Extract systems and local exhaust ventilation’. Malcolm Thomas said: “We have presented that information in terms of tables.” Here, by way of example, he showed a slide of an ‘Airborne Isolation Facilities’ table, covering Isolation rooms, Categories 2 and 3. He explained: “If you want to know what the categories are, look at the bibliography in the index at the back of the HTM, and it’s all explained.” Down the side of the table were the areas or zones being discussed, with the next column highlighting the reasons and purpose of the ventilation, and the next ‘some typical design factors to help make it easier for people to understand what’s required’.

Part B

Turning to Part B and its ‘major themes’, Malcolm Thomas said that, in writing it, the authors had sought to ‘clarify things’, ‘plug up the holes’, and ‘explain more clearly what we require’. So,” he continued, “there is a legal requirement to keep records and information on ventilation systems, but many hospitals don’t, so they have broken the law.” In fact, he explained, Part B now includes a requirement for an inventory with a uniform system of identification. He said: “Go round some hospitals and they have 10 air-handling units all called ‘Air-handling unit number 1’ in 10 different plantrooms, so we obviously need to be a lot clearer. Part B thus suggests that each ventilation plant has a unique number,

corresponding to all the information about it, what it is, the spaces it serves, all the parameters and information about the equipment, the system performance over the years, and when we should ‘scrap it’. Then,” he continued, “we archive that information with its number plate, and put a new number plate on the new plant. We thus have an auditable trail. Generally, when you go around hospitals, a lot of information about systems is in people’s heads, so when they leave it goes with them.” This, Malcolm Thomas argued, was not only ‘not conducive to running an efficient system’, but was also dangerous.

Phased replacement

Part B of the 2021 HTM also discusses ‘mid-life refurbishment’, and phased plant replacement. The speaker explained: “We suggest that after 10 years, the air-handling unit should be taken out of use, cleaned, examined, and any corrosion treated, fitted with new controls, updated to get the best from the technology available, and then put back into use. After 20 years, plant should be replaced. If you don’t start thinking about this when you put the plant in the equipment doesn’t get replaced, and you then find 30-40-year-old plant still in use in the NHS. We want to take the best, get the most efficient systems, and take advantage of the latest technology; not cling to the older things.”

The Ventilation Safety Group

Malcolm Thomas explained that the Ventilation Safety Group had a key role here in getting a phased replacement programme going. He said: “With a brand new hospital, there may be 50 ventilation plants installed, all of the same age; you’ll have a mountain to climb to replace them all at the 20-year period, so you need to try to split that up somehow, and start

looking at the critical ones maybe slightly earlier.”

At any time they needed specialist guidance or help, NHS healthcare engineering teams could, of course, call on an Authorised Engineer (Ventilation) – ‘people with independent knowledge, totally independent of the Trust/Health Board’, and thus ‘there to tell you the truth’. He said: “You may not like what your AE (V) says about your ventilation, but they are there to tell you it like it is, so please listen to them. Similarly,” he added, “they should be involved in the process of providing plant to advise on what goes in. The reason I say this is – and I’ve been a hospital engineer – is that your knowledge here will be limited, and it’s very easy to be bamboozled by an outside design team into accepting something they think is alright. It may be that what’s being proposed is a great solution, but, conversely, it could be that it won’t benefit you long term. Authorised Engineers are there to help with those decisions.”

Observing standards

Nearing the end of his presentation, Malcolm Thomas said: “There are minimum standards for all plants – as I said at the beginning – and they should certainly be observed. They are there because there are legal requirements about access, cleanliness, and the efficiency of the plant, listed in both Parts A and B; most of the major pieces of legislation that affect and handling ventilation systems, in a hospital or anywhere else. In a hospital, we also have the Medicine Act, and the Health Act, which impose a duty of care on us for our patients and what we do in healthcare settings.” These, the speaker said, ‘sat alongside’ other legislation such as the Health & Safety At Work etc, the COSHH Regulations, *et al*.

Lastly, Malcolm Thomas explained, Part B of HTM 03-01 (2021) included a section on ‘Verification’. He said: “This requires you to ensure, every year, that the critical systems in your hospitals are still safe to use. They may be getting slightly older, but the things that matter within your ventilation system must still be working correctly, and then there is the annual routine inspection and maintenance. All the standards on these areas have been there for a considerable time, but need to be adhered to.”

He added: “So, to conclude, the HTM has been entirely revised, with many changes, and I would encourage all those with a professional interest in, or responsibility for, healthcare ventilation, to read and familiarise themselves with both Parts A and B, including the appendices and the accompanying explanations.” With this, he closed his presentation, and invited questions. 

The control by ventilation of airborne bacterial transfer between hospital patients, and its assessment by means of a particle tracer

III. Studies with an airborne-particle tracer in an isolation ward for burned patients

BY A. HAMBRAEUS AND H. F. SANDERSON*

*Institute of Medical Microbiology, Department of Clinical Bacteriology,
 University of Uppsala, Uppsala, Sweden*

(Received 25 October 1971)

SUMMARY

Airborne-particle transfer has been studied in a burns unit using potassium iodide particles. The observed rates of transfer were in good agreement with the values predicted by a theoretical model.

An estimate of the average transfer between rooms under conditions of normal activity and with correctly functioning ventilation showed that the isolation system was highly efficient, the proportion transferred being probably less than 1 in 10^5 . However, the ventilation often did not function as designed and under these conditions the efficiency was reduced by a maximum of a factor of ten. These rates of transfer do not seem great enough to account for the high rate of cross-infection found in this unit.

INTRODUCTION

Much effort has been expended in recent years in devising ventilation systems to reduce the airborne spread of bacteria in hospital wards, but methods for evaluating the efficiency of these are not altogether satisfactory and have only occasionally been attempted. In a preceding paper (Foord & Lidwell, 1972) a method has been described for studying airborne particle transfer between parts of a ward by use of potassium iodide particles. We now present the results of a series of experiments using this method in an isolation ward for burned patients at Akademiska sjukhuset, Uppsala. In spite of a complete ventilation system, including airlocks, earlier studies have revealed a considerable amount of cross-infection between patients in the ward (A. Hambræus, to be published). The purpose of the investigation was to determine the effectiveness of the ventilation system and hence the role of airborne bacteria as a possible cause of cross-infection. Comparison could also be made with the theoretical analysis of isolation system elaborated in the second paper of this series (Lidwell, 1972).

* Present address: St Mary's Hospital Medical School, Paddington, London, W. 2, England.

Fig. 1. Plan of the ward. Input ventilation is shown for each space as $\text{m}^3/\text{hr.}$, extract volumes are given in parentheses, an additional $100 \text{ m}^3/\text{hr.}$ was extracted from each of the patient room W.C.'s, except no. 6. The sampling sites, when room 1 was the source room, are indicated by $\bullet$; S = service room.

MATERIALS AND METHODS

Ward design and ventilation

Fig. 1 shows the plan of the isolation ward. It is entered via an airlock with double doors and a passage runs down the middle of the ward. There are five patients' rooms of similar dimensions and a sixth larger room containing an air bed. All of these have individual airlocks and they are situated along one side of the passage. On the opposite side of the passage are service rooms and the bathroom. The bathroom has three doorways; one of these opens directly to the passage for bed transport, and the other two open via airlocks; one into the passage (I) and the other into the ward airlock (II). The designed ventilation input and extract are shown in each part of the ward (the extract is in brackets). The net result is a near-balanced ventilation with little or no other air flow between the ward and the exterior.

Fig. 2 shows the air flow as designed for a typical patient room. The air input to the room is 200 m.³/hr. (which approximately equals 4 air changes/hr.). Of this input, 150 m.³/hr. is extracted directly from the room, the remaining 50 m.³/hr. passes into the airlock. A further 50 m.³/hr. is drawn from the passage into the airlock making up the total extract from the W.C. of 100 m.³/hr.

The ventilation of the bathroom is shown in Fig. 3. The designed input is 1350 m.³/hr. and the extract is 1150 m.³/hr. Airlock I has an input of 350 m.³/hr. and an extract of 440 m.³/hr., this results in a net deficit in airlock I of 90 m.³/hr. which is supplied as 45 m.³/hr. from both the bathroom and the passage. The extract from airlock II is 260 m.³/hr., this is provided as 130 m.³/hr. from both the bathroom and the ward airlock. This leaves a net surplus of air supply in the bathroom of (200-175) m.³/hr. = 25 m.³/hr. which escapes into the passage beneath the direct door.

Titanium tetrachloride smoke was used to determine the direction of air flow beneath the doors.

Isolation of burned patients

Fig. 2. Diagram showing the design ventilation of patient rooms 1-5.

Fig. 3. Diagram showing the design ventilation of the bathroom.

Fig. 4. Ventilation patterns observed for the patient rooms. (a), directions of air flow designed; (b), (c), (d) and (e), other observed air-flow patterns. The table shows the number of times the respective pattern was observed in the specified room.

Over a preliminary period of 32 days it was found that the designed ventilation was not maintained at all times and the frequency of variation is shown in Fig. 4. It can be seen that the commonest fault was a reversal of air flow beneath the door between the airlock and the passage, thus allowing escape of air from the room to the passage. We therefore included this type of ventilation in our experiments and all references to incorrect ventilation refer to this. The direction of air flow was checked before every experiment.

Particle generation

A spinning disk particle generator was used throughout the experiments. The rotation rate of the disk was 60,000 rev./min. and a main air-flow rate of 60 ft.³/min. (1.7 m.³/min.). The satellite air flow removes smaller satellite particles from the main air flow and this was found to operate satisfactorily at 6 ft.³/min. (0.17 m.³/min.).

Potassium iodide dissolved in methyl alcohol and supplied to the spinning disk at a rate of 1 ml./min. gave rise to a particle production rate of $c 10^7$ particles/min.

Sampling methods

Air sampling was carried out by trapping the particles on 2.5 cm. diameter membrane filters (Millipore Filter Corp.) of 3 μ m. pore size. Two types of sampler were used.

(a) Where the KI particle concentrations were high, known volumes of air were sucked through the millipore filters. Open-ended plastic filter holders were used (Foord & Lidwell, 1972). Owing to the high air-flow resistance of the filters the maximum air flow obtainable with the pumps which were available was 10 l./min. This was suitable for use with KI particle concentrations of more than 5/l.

(b) In situations where there were low particle concentrations the centripetal samplers described by Foord & Lidwell (1972) were used. These were designed to have a collection efficiency of 100 % at flow rates above 60–70 l./min. for 13 μ m. equivalent diameter particles (i.e. particles which have the same sedimentation rate as a 13 μ m. particle of specific gravity 1). A suction pressure of 20 cm. water gave a flow rate of 100 l./min. and under these conditions only 3 % of the air flow passed through the filter.

Staining. After particle collection the filters were immediately stained with 1 % palladium chloride in 0.1 % HCl.

Counting. Particle counting was performed with the aid of a low-power plate microscope and a grid. Up to 200 particles were counted.

Determination of particle size

Two ways of determining particle size are available:

- (a) By direct microscopy of particles deposited on a silicone grease coated slide.
- (b) By calculation of the sedimentation rate and hence the equivalent particle diameter by Stokes Law ($s \approx 0.002d^2$), where the sedimentation rate, s , is in units of m./min., and the diameter, d , is in units of μ m.

Methods of calculating the sedimentation rate of airborne particles are described

in 'Studies in Air Hygiene' (Bourdillon, Lidwell & Lovelock, 1948). Two independent methods of determining the sedimentation rate were used. First, from the die-away rate (K), which is the logarithmic rate at which particles disappear, $K \simeq \text{slope} \times 138/\text{hr}$. In an unventilated room K is due solely to sedimentation and thus $K = sA/V$, from which the equivalent diameter can be found (A is the area onto which sedimentation is occurring and V is the volume of air from which sedimentation occurs).

Alternatively, the sedimentation rate can be calculated from the number of particles sedimenting onto a known area when the number of particles in a unit volume of air is known. This can be represented as: no. of particles sedimenting = $s \times$ the concentration of particles in the air.

EXPERIMENTAL DESIGN

Preliminary studies to find an appropriate particle size

A small sealed room was used in which particles were generated. Different size particles are produced by varying the concentration of the potassium iodide solution fed to the spinning disk and the concentrations used were 2.0, 3.5 and 5.0 %. Particles were generated for 20 min. and 1 l. air samples were taken at 5 min. intervals during this time and for the 20 min. after particle generation had ceased. In addition filters were exposed on the bench for the last 5 min. of particle generation. The concentrations of KI gave particles with the following sedimentation rates: 2.0 % = 0.15 m./min.; 3.5 % = 0.23 m./min.; 5.0 % = 0.31 m./min.

A 5 % potassium iodide solution was used for the transfer experiments and this gave particles with a sedimentation rate close to the median found for airborne particles carrying *Staphylococcus aureus* in hospital wards (Noble, Lidwell & Kingston, 1963).

Studies on the transfer of particles from the room to the passage

Since the earlier study had shown the variability of air flow in the ward, it was decided to perform experiments using both the correctly ventilated air locks and also the commonest type of ventilation defect (i.e. that in which the air flow beneath the door between the passage and the airlock was reversed).

The generator was situated in the room chosen and adjusted to give a concentration of 500–1000 particles/l. in the room. There was no activity for the first 30 min. and then, for the following 30 min., one walk from the room to the passage was performed every second min. The dwell time in the airlock was 30 sec. Throughout the experiment samples were taken at the following sites; (a) in the room, samples taken at 5 min. intervals; (b) in the airlocks, samples were taken at 5 min. intervals during the period of no activity; (c) across the passage 2 m. from the room door, 7.5 m. up the passage, 7.5 m. down the passage, and at 15 m. either up or down the passage according to the room in use. These sites are shown in Fig. 1 for the experiments when the generator was in room 1. One 10 min. sample was taken between 20 and 30 min. and then during activity samples were taken at 5 min. intervals.

Particle transfer from passage to room

The generator was situated in the passage about 3 m. from the door of the room to be investigated. The periods of activity and non-activity were the same as before, as was the type of activity. Samples were taken at 1 m. from the door (at 5 min. intervals throughout the experiment), in the airlock (at 5 min. intervals during the period of no activity), and in the centre of the room where one 10 min. sample was taken between 20 and 30 min. and then 5 min. samples were taken continuously during the period of activity. Correct and incorrectly ventilated airlocks were used.

Transfer of particles from the bathroom to the passage

The generator was situated in the bathroom and there was no activity for the first 30 min. of generation, for the next 30 min. there was activity through the airlock I at the rate of one walk to the passage and back every 2 min. There was then a period of non-activity for 15 min. and for the last 20 min. there was activity through the direct door to the passage at the same rate as before. During this time samples were taken in the same six sites as they were in the room to passage experiments and the sampling times were also the same. The only exceptions to this were that no samples were taken in the airlock during the second period of non-activity and only for the last 10 min. of this period in the passage. During the last period of activity samples were taken once every 5 min. in the passage and in the bathroom.

Transfer of particles from passage to the bathroom

Particles were generated at about 3 m. from the bathroom doors which opened into the passage. Samples were taken between these two doors (about 1 m. from each). Samples were also taken in the airlock I and in the bathroom. The activity was the same as that in the bathroom to passage experiments and the sampling was the same as that in the passage to room experiments, except that no samples were taken in the airlock during the second period of non-activity. In the last two experiments correctly and incorrectly ventilated airlocks were used.

In addition to the above samples, blank samples were taken at each site before the start of each experiment.

Calculation of results

In all the experiments the particle concentration at any site started at zero and rose to a steady value in a short time. The steady values were determined by inspection of the data. For the source site, equilibrium was usually achieved within 10 min. of the start of generation, and at the receiving site a steady state was usually achieved after 10–15 min. of walking (depending on the site of sampling). The average particle concentration during the steady-state period was used in all calculations.

The behaviour of ventilation systems of the type under investigation has been studied theoretically by Lidwell (1972), making a number of simplifying assump-

tions. The analysis which follows is based on this study and has been carried out in collaboration with him.

The ratio α of the number of particles at the source to that at the receiving site gives a measure of the effectiveness of the system in protecting the patient from airborne infection, i.e.

$$\alpha = \frac{\text{Concentration of particles in the source room}}{\text{Concentration of particles in the receiving room}}$$

(large values of α indicate a high degree of protection).

Since the passage intervenes between the patient rooms, transfer of particles may be conveniently analysed by breaking the process down into two stages: (1) transfer from the source room to the passage; (2) transfer from the passage to the receiving room.

α' and α'' are used as symbols for these ratios, i.e.

$$(1) \quad \alpha' = \frac{\text{Concentration of particles in the source room}}{\text{Concentration of particles in the passage}},$$

$$(2) \quad \alpha'' = \frac{\text{Concentration of particles in the passage}}{\text{Concentration of particles in the receiving room}}.$$

Similar ratios can be calculated for bathroom to passage transfer and vice versa. Thus

$$\alpha' (\text{bathroom}) = \frac{\text{Concentration of particles in the bathroom}}{\text{Concentration of particles in the passage}},$$

$$\text{and} \quad \alpha'' (\text{bathroom}) = \frac{\text{Concentration of particles in the passage}}{\text{Concentration of particles in the bathroom}}.$$

The theoretical calculations predict that

$$\alpha \simeq v_1 v_2 / uv, \quad \alpha' \simeq v_2 / u, \quad \alpha'' \simeq v_1 / v,$$

where v_1 is the total rate of ventilation (both real and apparent due to sedimentation) in each patient room and v_2 is the total rate of ventilation in the passage (including the effects of sedimentation). v is the rate of air movement from the passage to the room, and u is the rate of air movement from the room to the passage. In addition to any continuous air flows due to incorrect ventilation conditions u and v will include air transferred by movement through the doors. This is related to the frequency of movement through the doors (m) and the amount of air swept through the door in the direction of movement on each occasion (w).

The ventilation input to the patient rooms is 200 m.³/hr. The apparent ventilation due to particles sedimenting at 0.3 m./min. onto the floor area of 16 m.² = 16 × 0.3 × 60 = 300 m.³/hr.

Similarly in the passage, the ventilation input is 1100 m.³/hr. and the apparent ventilation when the floor area is 90 m.² is 1600 m.³/hr. The input to the bathroom is 1350 m.³/hr. The apparent ventilation due to a floor area of 30 m.² is 550 m.³/hr.

Hence $v_1 = 200 + 300 = 500 \text{ m}^3/\text{hr}.$

and $v_2 = 1100 + 1600 = 2700 \text{ m}^3/\text{hr}.$

and $v_1 (\text{bathroom}) = 1350 + 550 = 1900 \text{ m}^3/\text{hr}.$

For a purely extract-ventilated airlock with air drawn equally from both sides it can be shown that $u = v = mw$ (Lidwell, 1972). However, the actual transfer of particles will be less than this because of the loss of particles by sedimentation within the airlock. The room airlock has a floor area of 4 m^2 and an extract ventilation of $100 \text{ m}^3/\text{hr}.$ The proportion of particles with a settling velocity of $0.3 \text{ m}/\text{min}.$ lost by sedimentation is then $0.42.$ If the air was drawn equally from both sides then the effective value of u and v for the transport of particles becomes $(1 - 0.42)mw = 0.58mw.$

The bathroom airlock had an air supply of $350 \text{ m}^3/\text{hr}.$ The extract of air from the bathroom airlock was $440 \text{ m}^3/\text{hr}.$ Assuming that the difference was drawn equally from both sides $45 \text{ m}^3/\text{hr}.$ will have come from the passage and $45 \text{ m}^3/\text{hr}.$ from the bathroom itself. As a consequence $u = v = 45/440 \times 2mw = 0.2mw.$ The floor area was 5 m^2 so the proportion lost by sedimentation was, making the same assumptions as earlier, $(60 \times 0.3 \times 5)/(60 \times 0.3 \times 5 + 440) = 0.17.$ The effective values of u and v for the transport of particles through the bathroom airlock are then given by $u = v = (1 - 0.17) \times 0.2mw = 0.19mw.$

The experimental value of m was $30/\text{hr}.$ and for the purposes of calculation we have assumed that $w = 1 \text{ m}^3.$

For the room airlock therefore the predicted value of u and v during the experiments was $30 \times 0.58 = 17 \text{ m}^3/\text{hr}.$ and for the bathroom airlock $30 \times 0.17 = 5 \text{ m}^3/\text{hr}.$ For the direct bathroom door the corresponding value would be $60 \text{ m}^3/\text{hr}.$ (there is no sedimentation loss to allow for in this instance).

Substituting these values in the equations for α' and α'' gives the following results:

- (1) room to passage $= \alpha' = \frac{v_2}{u} = \frac{2700}{17} = 160;$
- (2) passage to room $= \alpha'' = \frac{v_1}{v} = \frac{500}{17} = 29;$
- (3) room to room $= \alpha = \alpha' \times \alpha'' = \frac{2700 \times 500}{17 \times 17} = 4.7 \times 10^3;$
- (4) bathroom to passage $= \alpha' (\text{bathroom}) = \frac{2700}{5} = 540;$
- (5) passage to bathroom $= \alpha'' (\text{bathroom}) = \frac{1900}{5} = 380;$
- (6) bathroom to room $= \alpha = \frac{2700}{5} \times \frac{500}{17} = 1.6 \times 10^4;$
- (7) room to bathroom $= \alpha = \frac{1900}{5} \times \frac{2700}{17} = 6.1 \times 10^4.$

Fig. 5. Distribution of particles along the passage. Source in room 1 with correct ventilation and activity at 30 entries and exits/hr. Right-hand scale is the ratio of the particle concentration in the passage to that in the source room, i.e. $1/\alpha'$. The points show the approximately steady values attained in the individual experiments. The short horizontal bars are the log mean values as given in Table 1.

These values are calculated for the experimental movement through the doors of 30/hr. in each direction. The values of α' and α'' for correctly ventilated airlocks are inversely proportional to m and α is inversely proportional to m^2 .

For other values of m

$$\alpha'_m = \alpha'_{30} (30/m), \quad \alpha''_m = \alpha''_{30} (30/m), \quad \alpha_m = \alpha_{30} (30/m)^2.$$

If, however, the ventilation is unbalanced so that there is air flow between passage and room independent of movement of persons through the doors the transport of particles by this air flow is unaffected by a change in the value of movement through the door and

$$\frac{1}{\alpha'_m} = \frac{1}{\alpha'_0} + \left(\frac{1}{\alpha'_{30}} - \frac{1}{\alpha'_0} \right) \frac{m}{30},$$

and similarly for α'' .

Where α'_m denotes α' when the movement through the door is m /hr., α'_0 is the value of α' when there is no activity and α'_{30} corresponds to the experimental value of α' , when there are 30 entries and exits/hr. through the door, the number employed in the experiments.

RESULTS

Fig. 5 shows the way in which the ratio of particles in the room and passage vary with increasing distance of the sampling site from the room; it also shows variability of the estimates obtained in the several experiments. The values used were obtained from room to passage transfer experiments with a correct ventilation.

The mean values of α' and α'' for the various sampling positions for all the experiments performed are presented in Table 1. The values are log means of at least five experiments. The table also shows the log mean values of α' over all the positions. The corresponding values of α are calculated from these values and also shown in Table 1. As can be seen from the table there is no detect-

able transfer of particles from room to passage or passage to room when the ventilation functions correctly, i.e. α' is $> 10^5$, α'' is $> 10^5$. When a steady state has been achieved under activity α' is 245 and α'' is 39. For an incorrectly ventilated room with no activity α' is 251, i.e. about the same value as α' during activity for a correctly ventilated room, and during activity this falls to 83. However, α'' for an incorrectly ventilated room is 66, which is considerably higher than that for a correctly ventilated room. When the source room and receiving room are both correctly ventilated α is 9.6×10^3 ; the corresponding α for incorrectly ventilated rooms is 5.5×10^3 . An incorrectly ventilated source room and a correctly ventilated receiving room gives an α of $83 \times 39 = 3.2 \times 10^3$, and a correctly ventilated source room and an incorrectly ventilated receiving room gives an α of $245 \times 66 = 1.6 \times 10^4$. The bathroom α' when the airlock is ventilating correctly is rather low, 155; this is due to the fact that particles are always passing from the bathroom into the passage underneath the direct door; because of this α' bathroom due to activity does not vary greatly between correct or incorrect ventilation or activity through the airlock or the direct door. α'' bathroom, however, is lower if the ventilation is correct than if it is incorrect, 215 as opposed to 400. There is also a difference between α'' bathroom if the activity is performed through the airlock or through the direct door. The value of α for transfer from the bathroom to a patient room during activity (entering and leaving the bathroom via airlock I) is 3.8×10^3 , when ventilation to rooms is correct. For transfer from a patient room to the bathroom under similar conditions the value of α is 5.3×10^4 .

DISCUSSION

As stated above there were two objectives in this work, to obtain an estimate of the degree of protection from airborne cross-infection provided by the ventilation system used in this ward and to compare the experimentally determined values for particle transfer with the values predicted by a theoretical analysis.

Owing to incomplete mixing of air in the passage there was a rapid fall in particle concentration with increasing distance from the door of the source room (Fig. 5). Because of this it is necessary to derive average values of α' . To estimate the average cross-infection risks of all the rooms, the logarithmic mean of α' at the different points was used since the risk of nasal acquisition (and hence the risk of infection) is probably more nearly related to the logarithm of the concentration of bacteria in the air (Lidwell, 1963; Lidwell *et al.* 1971) than to the arithmetic value. To compare the results with theory it is best to take an arithmetic average of the particle concentrations at the sampling points, i.e. the average of $1/\alpha'$ because the points are equidistant along the passage and the theoretical value of α' is based upon the assumption of complete mixing of the air. These values are given in Table 2. This average value was also used to calculate values of u ($u = v_2/\alpha'$). In deriving the experimental value of α' for the bathroom the particle transfer due to air passing beneath the direct door (i.e. $1/\alpha'$ with no activity) was subtracted from the particle transfer when there was activity. It is not possible to estimate the transfer when the ventilation is incorrect as the amount of extra transfer between the room and the passage (or vice versa) is not

Table 2. *Comparison of observed and predicted values (for designed ventilation)*

		α'	u	α''	v
Room (airlock)	Observed value	143	19	39	13
	Predicted value	160	17	30	17
Bathroom (airlock)	Observed value	170	16	215	9
	Predicted value	640	5	450	5
Bathroom (direct door)	Observed value	59	41	63	21
	Predicted value	45	60	23	60

The α' values have been derived as the arithmetic average of the particle concentrations at the different sampling positions, i.e. by summation and averaging of $1/\alpha'$, see text.

Predicted values of u and v assume a value of 1 m.^3 for w , the volume of air transferred through a door on opening it, passing through and shutting it again.

known. For the room experiments, correlation of predicted and experimental values of α' and α'' is good.

For the bathroom the correlation is not so good but the ventilation of this room was certainly not in accordance with the specification and the leakage under the door into the passage meant that the values of α' had to be derived as a difference between two experimentally determined values. The general closeness of the estimates to the experimental results suggests that the theoretical model is broadly correct, but that errors are present in the estimation. Thus, the value of w is only an approximation and may be subject to considerable variation depending upon thermal difference across the door, size of the door and room, angle to which door is opened etc. Values of v_1 and v_2 were taken from the engineer's plan and in view of the variable ventilation state of the ward may have borne little relationship to the true values of v_1 and v_2 . We were unfortunately unable to check the accuracy of the figures.

Experimental errors were due to two main contributions: (1) relatively small air samples were taken; (2) random air movements caused great variation in the particle concentration at different sites. A number of factors caused these air movements, amongst them were thermal currents, disturbances due to opening of doors, movements of staff and uncontrolled day to day variations in ventilation.

Estimation of the cross-infection risk

The estimated value of α for transfer of particles from one room to another with correct ventilation is $> 10^9$ when there is no activity (i.e. transfer of particles was undetectable) and 9.6×10^3 when the rate of activity is 30 walks/hr. However, normal activity in the ward is much less than this and observations in this unit indicate a value of 3–5 door openings/hr., about half that found in a two-bed isolation room (Lidwell & Towers, 1969) and we have deduced that a reasonable estimate of the normal value is 5 walks/hr., i.e. $m = 5$. This leads to an α of 3.4×10^5 between correctly ventilated rooms with normal activity. It would seem that this should provide good protection against cross-infection due to airborne contamination since a value of 1 colony forming unit (c.f.u.)/l. in a source room would give rise to a concentration of only 3×10^{-6} c.f.u./l. in the receiving room. This estimate of the concentration of bacteria-carrying particles in the room is

equivalent to only 0.15 c.f.u. in the whole volume of the room (5×10^4 l) or 1 c.f.u. inhaled every three weeks at an inspiration rate of 10 l./min. If $1/3$ m.² of body surface were exposed to contamination by settling and the airborne particles were of the size commonly found (settling velocity 0.3 m./min.) then the dose received in this way would be no more than 1 c.f.u. in 50 hr.

If the airlocks do not function correctly then the value of α will be different. The results of experiments upon the type of incorrectly ventilated airlocks investigated showed that in the absence of all activity α' for a room with an incorrectly ventilated airlock was as much as α' for a room with a correctly ventilated airlock when the level of activity was 30 walks/hr. However, α'' for such an incorrectly ventilated airlock during activity was higher than the corresponding value for a correctly functioning airlock. Thus the worst situation for which we can derive an estimate will be when the source room has an incorrectly ventilated airlock, and the receiving room has a correctly ventilated airlock. With a normal activity of 5 walks/hr the value of α would then be 4.4×10^4 . Thus if one airlock is functioning incorrectly the risk in all the other rooms is about ten times greater than under correct conditions, e.g. for a concentration in the source room of 1 c.f.u./l. a patient in a receiving room would inhale 1 c.f.u. every 2 days and about 5 c.f.u. might settle on $1/3$ m.² of exposed body surface each 24 hr.

There are two other possible ways in which contaminated air might reach the patient. Large amounts of bacteria may be dispersed during bathing in the bathroom and be transferred throughout the ward. Alternatively the patient might become infected in the bathroom with bacteria transferred from another patient room. In the first case there is continuous contamination of the corridor from the bathroom due to air passing beneath the direct door even when there is no activity through the correctly ventilated airlock. But it is greater when there is activity and when the airlock is ventilated incorrectly. The airlock, however, was usually ventilated correctly, and under normal conditions there was little activity through the airlock and none through the direct door. For the purposes of calculation we have assumed the activity through the bathroom airlock to be 5 walks/hr. although this is probably too high a value. This leads to a value of α for transfer from the bathroom to a patient room of 3.9×10^4 . In the second case the value of α for transfer from a patient room to the bathroom, again assuming 5 walks/hr. through the bathroom airlock, would be 1.9×10^6 if the patient room ventilation functions correctly and 2.4×10^5 if the airlock is incorrectly ventilated.

In neither of the above 3 cases is the risk of cross-infection much higher than the risk run by patients when in patient rooms, if one room with an incorrectly ventilated airlock is occupied by a disperser.

Conclusion

It would seem from the above results that, under normal conditions, the isolation system was highly effective at preventing the airborne transfer of particles and even when the ventilation was not operating correctly the particle transfer was very small. Since there has been a considerable cross-infection rate over the past years it would seem likely that other routes of infection have been responsible for this.

Development of Particle Tracer Techniques to Measure the Effectiveness of High Containment Laboratories

Allan M. Bennett, Simon R. Parks, and John E. Benbough

Centre for Emergency Response and Preparedness, Health Protection Agency, Porton Down, Salisbury, UK

Abstract

Biosafety Level 3 (BL-3) laboratories are designed to prevent the escape of pathogenic microorganisms by operating at negative pressure so that if microorganisms become airborne, they remain within the laboratory. However, the authors are not aware of any published evidence or international guidance on the level of pressure differential required for BL-3 laboratories. This uncertainty was reflected in a survey of BL-3 laboratories in the United Kingdom where a range of pressure differentials between 30 and 100 Pascals (Pa) were found. In this paper, an attempt is made to address this issue. The authors have developed techniques to quantify the effectiveness of containment laboratories in preventing the egress of airborne microorganisms. A potassium iodide (KI) aerosol tracer method was adapted to measure the degree of containment in an experimental facility and in five working BL-3 laboratories. The level of laboratory containment was expressed as the laboratory protection factor (LPF). Using this technique, it was found that providing an anteroom increased the LPF by approximately one order of magnitude. No direct relationship was found between the magnitude of negative pressure and LPF. There was, however, a direct relationship between inflow velocity and LPF: A volumetric inflow of 10 m³/min into a laboratory through an anteroom gave a LPF of greater than 10⁵. The KI aerosol tracer method offers a simple and appropriate means of validating the performance of BL-3 laboratories in terms of the LPF.

Introduction

Manipulations utilizing category 3 pathogenic microorganisms that may lead to the generation of infectious aerosols must be carried out within primary containment such as microbiological safety cabinets and sealed centrifuge rotors. Secondary containment is also required; this involves protecting the surrounding rooms and environment in the event of the breakdown of the primary containment or after an accidental release. The construction, design, and operation of these facilities are described in a range of national and international guidelines (Advisory Committee on Dangerous Pathogens, 1995; US Department of Health and Human Services, 1999; World Health Organization, 1993). BL-3 laboratories need to be physically separated from the surrounding environment and specific rules govern entry to this facility. These can involve passage through two sets of doors that create an anteroom to accommodate personnel changing from their normal clothing into protective clothing.

BL-3 containment laboratories are designed to prevent the egress of pathogenic microorganisms by keeping the room at a negative pressure with respect to the outside environment and ensuring a high air-change rate. Negative pressure is maintained in containment rooms partially by increasing the air flow extracted from the room and partially by minimizing the leakage of air through gaps between the door and door frame and any vents in the doorleaf. In

addition, the ventilation is designed so as to replace the air at such a rapid rate that any aerosol generated within the room is quickly diluted and removed. The combination of these two factors should allow laboratory personnel to evacuate the laboratory safely after a breach of primary containment and return to the laboratory to deal with the accident after a given time, confident that any generated aerosol has been removed.

Due to the lack of experimental evidence, no information is provided in international and national microbiological containment guidelines on the magnitude of negative pressure required for effective containment of category 3 agents. Also, no documented evidence is available to show the effects of changing the magnitude of negative pressure on containment. Regulations are also vague on whether providing an anteroom between the laboratory and the outside environment is required to enhance the overall containment. This contrasts with the highly detailed national and international standards for the design of primary containment equipment such as centrifuges and microbiological safety cabinets (British Standards Institute (BSI), 1992; International Electrical Commission (IEC), 1993; National Sanitation Foundation (NSF), 1983). This also contrasts with the regulations pertaining to the design of cleanrooms for the manufacture of medical products and electronic components.

As part of this study, an informal survey of BL-3 laboratories in 10 institutions (including universities, research institutes, and pharmaceutical companies) throughout the United Kingdom (UK) showed that a wide range of pressure differentials—between 30 and 100—Pa were routinely used. Marked differences in laboratory design in the public and private sectors were noted. Anterooms were linked to all these laboratories and were used as changing and temporary storage facilities. In university and hospital laboratories, the BL-3 facilities generally comprised an anteroom and laboratory having no independent ventilation system but relying on a ducted Class I microbiological safety cabinet in the main laboratory to create a negative pressure, normally of approximately 30 Pa. In some instances, the practice was to ensure the cabinet was operating for an additional 10 minutes after the day's work was com-

pleted. In contrast, most pharmaceutical and research laboratories in commercial organizations had independent ventilation systems that were continuously monitored by sensors and alarm systems. Microbiological safety cabinets in these facilities were continuously operated 24 hours a day to maintain the desired air balance. In one facility, entry to the laboratory was achieved through a sequence of three anterooms. The total negative pressure gradient in this case was 100 Pa between the laboratory and the corridor.

The use of excessive negative pressures to ventilate containment facilities can create problems. These may include:

1. Increased energy costs due to heating losses
2. Structural damage to wall and ceiling surfaces and sealants
3. Significant quantities of airborne particulate matter that can be drawn in from the surrounding environment

The aim of the present study was to develop test methods to measure the degree of containment of BL-3 laboratories. These techniques may be used to investigate the effects of various design factors on the containment provided by these laboratories. The information gained should prove useful to the laboratory designer.

The study was comprised of two stages:

1. Initial studies were carried out in an experimental laboratory complex where the air flow and differential air pressures could be altered whenever required. This facility was sealable and so could be decontaminated readily after use.
2. Further studies were carried out in operating containment laboratories of various sizes and designs and having a wide range of airflows and pressure differentials.

The effectiveness of open-fronted microbiological safety cabinets is routinely tested in the UK, using monodispersed aerosols of potassium iodide (KI) (BSI, 1992). The KI methodology was originally developed to study movement of particulate contaminants between rooms in burns units in hospitals (Foord & Lidwell, 1972). The effectiveness of open-fronted microbiological safety cabinet performance is measured in terms of the operator protection factor (OPF), which is the ratio of KI particles gener-

ated within the cabinet to those detected outside the cabinet. An OPF of greater than 10^5 is regarded as being adequate (ACDP, 1995). Using the same principle, the OPF can also be determined using aerosolized bacterial spores. These procedures were adapted to assess the performance of the high-containment laboratories in this study.

The effectiveness of the containment of laboratories was assessed in terms of the laboratory protection factor (LPF), which is defined as the ratio of the number of particles generated in the laboratory to the number of particles collected in the area outside the laboratory. This protection factor was measured using airborne particle tracers containing either aerosol-stable microorganisms such as spores of *Bacillus subtilis* var niger (Cox, 1987) or KI.

Since the use of microbial tracers was impractical in working laboratories, only the KI tracer technique was used in this setting. The advantages of this technique over the microbial methods are rapid results and no contamination of the laboratory under test, avoiding any need for subsequent decontamination.

Materials and Methods

Experimental Laboratory

This laboratory was designed to allow volumetric inflows and pressure differentials to be easily adjusted independently of each other. The room complex (Figure 1) consists of three units that simulate

the laboratory, the anteroom, and a corridor. The dimension of the “laboratory” was 3.0 m x 3.1 m x 2.3 m high, the “anteroom” was 3.7 m x 1.7 m x 2.3 m high, and the “corridor” room was 3.0 m x 2.4 m x 2.5 m high. (Note that in the remaining portions of this paper, the environmental laboratory rooms are referred to within quotes to differentiate them from the working laboratory rooms.) The pressure differentials were monitored by calibrated Magnahelic (Michigan City, USA) manometers, and the volumetric inflows were calculated from the air flows measured by a rotating-vane anemometer as detailed below (under calculation of airflow). This “anteroom” and “laboratory” were operated at the following respective combinations of negative pressures—0,0; 15,30; 20,40; and 40,70 Pa—for microbiological tests. In experiments to assess the effect of inflow velocity on room containment using KI, the pressure differentials were held at -30 Pa, -60 Pa, while the volumetric inflow was varied between 6.1 and 14.7 m³min⁻¹. This was achieved by adjusting ventilation grilles incorporated in the laboratory doors.

Test Laboratories

Tests were carried out in five BL-3 laboratories with anterooms (Laboratories A-E) and one BL-2 laboratory without an anteroom (Laboratory F). The characteristics and experimental variables of the

Table 1

laboratories are given in Table 1. The pressure differentials were measured on Magnahelic (Michigan City, USA) manometers. All the laboratory extract and supply air flows were measured using a rotating-vane anemometer (Model AV2, Airflow Developments, High Wycombe, England), and the laboratory inflows and air changes were calculated from these data and the room volumes as detailed below. Each laboratory was tested using the potassium iodide (KI) technique also detailed below.

Potassium Iodide Method-Principle

The potassium iodide (KI) method was developed by Foord and Lidwell (1972) to study the movement of particles in hospitals and was later adapted by Clarke and Goff (1981) to test microbiological safety cabinets *in situ*. In 1992, the method was adopted as the British Standard and is currently used in the UK (BSI, 1992). An integrated piece of equipment using these principles is commercially available for testing microbiological safety cabinets (Containment Technologies, Wimborne, UK). This equipment was adapted for use in this study. The principal to operate the equipment is as follows: A solution of 1.5% (w/v) potassium iodide in 95% (v/v) aqueous ethanol is fed dropwise at a regulated rate to a spinning disc at a fixed speed. Droplets of a defined size are flung off the spinning disc. The number and size of the droplets depend upon the injection flow rate and the speed and diameter of

the disc, respectively. The water and the ethanol instantly evaporate from the droplets formed, providing solid monodispersed particles of average size (7 microns). The aerosol generator is designed to produce 6.2×10^6 KI particles in a 10-minute period.

Air-containing particles that escape from the containment space are sampled by four centripetal membrane filter samplers drawing 100 liters min^{-1} through a 3.0-micron, 25 mm-diameter cellulose nitrate membrane filter (Whatman, Maidstone, England (cat. No: 7188 002)). After each test, the filters are immersed in a solution of 0.1% palladium chloride in 0.1 M hydrochloric acid which reacts with any KI to form brown spots that can be easily identified and counted using a hand lens.

Measurement of Laboratory Protection Factor Using the KI Method

The spinning disc aerosol generator was placed at a height of 0.8 m inside the laboratory and 1 m from the door of the environmental room or containment laboratory. Two of the centripetal sampling heads were placed in the anteroom, 0.3 m from the door and 1 m from the wall at heights of 0.3 m and 0.8 m. The other two sampling heads were placed in the corridor area at the same heights (1 m from the door and 0.8 m from the wall). Experiments were carried out for either 5-minute or 10-minute periods. This technique was also used in the working laboratories.

Measurement of Laboratory Protection Factor Using the Microbial Aerosols

Microbial aerosols were generated within the experimental laboratory using a Collison nebulizer (May, 1973) operating at a pressure of 180 kPa containing a suspension of *Bacillus subtilis* var niger spores in distilled water at a concentration of 3.16×10^7 spores ml^{-1} . The nebulizer was placed 1 m from the laboratory door at a height of 0.8 m from the floor. Two slit samplers constructed in the HPA workshops (BSI, 1992), operating at a flow rate of 25 liters min^{-1} and containing tryptone soya broth agar (TSBA) plates that were placed in the anteroom and in the "corridor." Experiments were carried out for a period of 10 minutes. The nebulizer was weighed and the spore suspension was assayed before and after the experiment to calculate the number of spores aerosolised.

Microbial Tracer

Spores of *Bacillus subtilis* var niger (ATCC 9372) were used as the challenge microorganism. The spore suspension was prepared as described by Sharp et al. (1989) and washed three times in distilled water and heated to 60°C for 1 hour before using to kill any vegetative forms that were likely to be inactivated by aerosolisation (Sharp et al., 1989). The suspension was assayed by serial dilution and plating out onto TSBA plates (Oxoid, Basingstoke, England). The plates were incubated at 37°C for 18 hours and the distinctive orange colonies were then counted to determine the spore concentration.

Laboratory Test Conditions

The performance of the experimental room complex and the various test laboratories were assessed in three distinct operating modes.

1. With the laboratory doors closed as is the normal situation for a working laboratory
2. When an operator enters the anteroom during the tests and exits after 1 minute
3. When an operator enters the laboratory and exits after 1 minute. This is intended to model a situa-

tion where a laboratory worker enters the laboratory, discovers an accident situation, and leaves after removing his or her contaminated clothing.

In each laboratory, the pressure differentials and the volumetric airflow through the doors were measured and noted.

Calculation of Air Flow

The air flow in each room was measured using the rotating vane anemometer. The volumetric flow ($\text{m}^3 \text{min}^{-1}$) passing through inlet and extract grilles was determined by multiplying the average of a minimum of four face velocity readings by the area of the grille. The volumetric inflow through the door was then calculated from the difference between the total volumetric outflow and inflow through any supply grilles. As all the rooms tested were sealed, it can be assumed that the bulk of the make up air volume was drawn through the door.

Calculation of the Protection Factor

The laboratory protection factor is a measure of the effectiveness of the laboratory to prevent release of aerosols into the rest of the premises. It is calculated according to the following formula:

$$\text{LPF} = P_a/P_s \quad (1)$$

Where,

LPF = laboratory protection factor

P_a = Number of particles aerosolised

P_s = Number of particles sampled outside the laboratory

The KI aerosol generator is designed to consistently generate 6.2×10^5 aerosol particles per minute. The number of spores aerosolised in the experimental room studies was calculated by weighing the Collison nebulizer and its contents before ($M_{o,g}$) and after use ($M_{e,g}$) (i.e., weight loss, assuming a density of 1g ml^{-1} ; this allows the volumetric output ($V = M_o - M_e$) to be calculated). Since the concentration of spores in the suspension (C_s) is known, then the aerosol output of the spores (P_s spores) can be calculated:

$$P_s = V \times C_s \quad (2)$$

For the purpose of this study, it was assumed that all airborne particles that escaped from containment were collected by the air samplers. Hence, the number of spores or particles outside the test area represents the number released into the environment. Realistically, this is unlikely despite the fact that the samplers were placed at the same height as the aerosol generator where the highest aerosol concentrations would be found. However, it would be unrealistic to assume perfect mixing in the anteroom and, therefore, normalize the particle release for the room volume. Furthermore, this would be impossible for the corridor measurements. Therefore, the calculated LPF may be slightly higher than the actual LPF.

Results

Microbiological Tests

With the doors of the experimental room complex closed, no airborne spores were detected outside even when there was no pressure differential between the rooms. When an operator entered and exited the experimental room complex, there was a release of aerosol from the “laboratory” into both the “anteroom” and the “corridor” at all pressure differentials (Figure 2). However, no relationship between increasing differential and biological LPF (bLPF) in the “anteroom” or “corridor” could be identified. In all cases, the bLPF in the “corridor” exceeded 1×10^6 . For “anteroom” entry there was a

lower bLPF at static pressure than when a pressure differential was applied (Table 2).

KI Tests in Working Laboratories

The KI tests were carried out in the working laboratories (described in Table 1) for static and for laboratory-entry tests. The results are shown in tabulated form in Table 3 and plotted as LPF vs. maximum pressure differential in Figure 3. There was minimal or no release of material from laboratories when the doors were left closed, even from the BL-2 laboratory without an anteroom. The LPF measured in the corridor during the laboratory entry test varied from 7.6×10^3 to 9.6×10^4 for the BL-3 laboratories (1.5×10^3 for the BL-2 laboratory). Figure 3 shows that the LPF was not dependent on the magnitude of pressure differential.

Table 4 lists the LPFs for anteroom entry tests for the BL-3 laboratories. Again, there was no direct

relationship between magnitude of pressure differential and LPF.

Effect of Volumetric Inflow

The KI test method was also used to measure the effect of altering the laboratory inflow rate in the experimental room complex. The pressure differential was kept constant at -30 Pa in the “anteroom” and -60 Pa in the “laboratory” while the inflow was altered. The results of these tests for “laboratory” entry are shown in Figure 4. The results of the operating laboratory studies are also shown in this figure. The results of the anteroom entry tests are shown in Figure 5 combined in the same way. Each of these graphs shows a direct relationship between volumetric inflow and LPF. The results obtained in the working laboratories and the experimental room are similar.

Discussion

This study demonstrates that the KI method can be usefully applied to quantify the secondary containment provided by negative-pressure laboratories. This technique has been shown to be much more sensitive than the microbiological method described in the experimental room complex. The increased sensitivity is caused by at least two factors. First, the high sampling rate of the centripetal samplers allows more of the released aerosol to be collected. Second, the higher effective particle size of the KI particles (7 microns) makes them more penetrative against directional air flows than microbial spores (ca1 micron) due to their greater inertia. The KI method is also more sensitive and representative of microbial aerosol particles than various gas tracer methods that

have been used to measure air transfer from rooms (Keene & Sansone, 1984). Thus, the KI test method may be considered a useful technique for commissioning and regular validation of containment laboratories.

The significant feature of this study is the finding that the LPF, a measure of containment, is dependent on the laboratory inflow and not the magnitude of the pressure differential. Since negative-pressure laboratories are normally designed on the basis of magnitude of pressure differential, this finding has major implications for containment-laboratory designers. This result can be explained by analyzing the effects produced when the doors of negative-pressure laboratories are opened. At negative pressure, or even at equal pressure, particles will not leak from the room through door gaps when the

Figure 5

The effect of volumetric inflow on laboratory protection factors during anteroom entry tests in the BL-3 laboratories (circles) and environmental room complex (triangles) measured in the anteroom (closed symbols) and corridor (open symbols).

pressure differential is static (i.e., when the door is closed). Release of particles is possible only when a door is opened or when the room pressure becomes positive as a result of ventilation malfunction. The latter may be identified by sensors linked to alarmed manometers. However, if an accident occurred resulting in the release of an aerosol, the staff involved are likely to leave the laboratory immediately. When the occupants leave through the laboratory door, the pressure differential will be reduced and will eventually become zero. In fact, in some cases the room pressure may momentarily become positive. During the evacuation period, some airborne material may be carried in eddy currents created by the departing occupants. Without differential pressure this airborne material can be prevented from escaping from the laboratory only by providing sufficient air flow

into the room through the open door.

The effect of opening the laboratory doors when the occupants leave can be demonstrated by calculating the velocity through the open doors of the individual laboratories from the laboratory inflow data in Table 1. The inflow velocity through the laboratory door (area 1.9 m²) of laboratory E, the laboratory with the lowest volumetric inflow, was only 0.02 m s⁻¹. In laboratory C, with the highest volumetric inflow, the inflow velocity was 0.14 m s⁻¹. All these inflow velocities are less than those required for Class 1 microbiological safety cabinets (0.7-1.0 m s⁻¹). However, in safety cabinets these inflows are created over the face of the cabinet before, during, and after the entire working period. In the case of the containment laboratory, the doors will normally be open only for a very small portion of the working period,

albeit sometimes subsequent to accidents. Therefore, these smaller velocities may be just as effective as shown by the experimental results.

When an operator entered the anteroom from the corridor, a release of aerosol from the laboratory into the anteroom and a slight release of aerosol into the corridor occurred (Table 4). The likely mechanism is as follows: When the outside door was opened, there was a transient flow of air out of the laboratory caused by the pressure fluctuation that could be observed from the laboratory manometer. This would cause some of the airborne material to enter the anteroom and subsequently the corridor when the person left.

Containment laboratory ventilation design has traditionally been based on maintaining negative pressures. The pressure differential between a laboratory and its surroundings can be increased in two main ways. The first is to increase the amount of air being drawn into the room. This is the more expensive method and can cause structural problems and contamination problems by drawing dirty ambient air into the laboratory. The second and less expensive method to increase negative pressure requires a lower exhaust flow rate in association with tightly sealing the laboratory door. This method is adequate as long as the laboratory door is closed. However, when the door is opened the pressure differential is rapidly lost and particles released within the laboratory cannot be prevented from escaping, along with air flow going outward through the door. Therefore, the main design criterion to prevent release of material from a laboratory should be the inward air flow. Pressure differential indicators would only have a secondary purpose as a monitor of the correct performance of the laboratory since the magnitude of the pressure differential should be proportional to the laboratory in a fixed system.

These studies also highlight the benefit of including an anteroom in the laboratory suite as shown in Table 3. All the BL-3 laboratories had higher LPF than the BL-2 laboratory F without an anteroom. This was demonstrated even in laboratory E which had a lower inflow than laboratory F. The overall LPF is increased by approximately 10-fold when an anteroom is incorporated into the facility.

In many BL-3 laboratories, negative pressure in

the laboratory is achieved by using Class I microbiological safety cabinets. Assuming that the volumetric throughput into standard Class I cabinets is between 0.7 and 1 m s^{-1} through a front aperture of approximately $0.2 \text{ m} \times 1.2 \text{ m}$ (BSI, 1992; NSF, 1983), the flow through the laboratory door would be 10.1 to $14.4 \text{ m}^3 \text{ min}^{-1}$. This is within the higher range for the laboratories at the Health Protection Agency, Porton Down and therefore should allow the same degree of protection as long as all air is channelled through the laboratory door and there are no other major laboratory air supply ducts.

The UK design guidelines published for operating theatres are very relevant to the needs of laboratory design since they also have a requirement for secure directional air flow rooms (NHS Estates, 1994). In this standard, door sizes, door crack width, air velocity between rooms, and resultant pressure differentials are all defined. This allows the designer to build operating theatres and validate them to an accepted standard. This type of approach can be and should be used for containment laboratories to ensure adequate containment without entailing unnecessary extra costs. The following design guidelines are suggested from the results of this study.

- Anterooms should be provided for all BL-3 laboratories.
- Laboratories should be designed to have a volumetric inflow through a standard door of about $10 \text{ m}^3 \text{ min}^{-1}$ and have a fixed alarmed negative pressure of approximately 30 Pa .

It is important that this type of information is provided by the national and international standards bodies in order to enable architects, safety advisers, and laboratory users to ensure that high category laboratories are constructed with an adequate level of containment.

The LPF can also be used in an assessment of the risks of release of airborne microbial aerosols from laboratories after escaping primary containment. The LPF is a measure of the comparative risk of material release from a containment laboratory. The LPF can be used in conjunction with the "spray factor" concept originally reported by Dimmick (1973) to carry out risk assessments. The spray factor is the proportion of a suspension aerosolised in an accident. This is well illustrated by the following ex-

ample: If a flask is dropped, it is estimated that 1 microorganism in 10^6 may be aerosolised (ACDP, 2001). In this case the spray factor is 10^6 . When a similar flask containing 50 mls of a 10^{10} per ml suspension of a pathogen is dropped, then 5×10^5 microorganisms will be aerosolised ($50 \times 10^{10} \times 10^{-6}$). If the LPF is 1×10^4 , then 50 microorganisms will be released into the corridor. If the LPF is higher (i.e., 1×10^5), the release will only be 5 microorganisms.

The use of quantitative risk assessment for the design and operation of microbiology containment laboratories, as demonstrated in this paper, should lead to a rational basis for biocontainment that does not entail excessive cost for the operators.

Modeling environmental contamination in hospital single- and four-bed rooms

Abstract Aerial dispersion of pathogens is recognized as a potential transmission route for hospital acquired infections; however, little is known about the link between healthcare worker (HCW) contacts' with contaminated surfaces, the transmission of infections and hospital room design. We combine computational fluid dynamics (CFD) simulations of bioaerosol deposition with a validated probabilistic HCW–surface contact model to estimate the relative quantity of pathogens accrued on hands during six types of care procedures in two room types. Results demonstrate that care type is most influential ($P < 0.001$), followed by the number of surface contacts ($P < 0.001$) and the distribution of surface pathogens ($P = 0.05$). Highest hand contamination was predicted during *Personal care* despite the highest levels of hand hygiene. Ventilation rates of 6 ac/h vs. 4 ac/h showed only minor reductions in predicted hand colonization. Pathogens accrued on hands decreased monotonically after patient care in single rooms due to the physical barrier of bioaerosol transmission between rooms and subsequent hand sanitation. Conversely, contamination was predicted to increase during contact with patients in four-bed rooms due to spatial spread of pathogens. Location of the infectious patient with respect to ventilation played a key role in determining pathogen loadings ($P = 0.05$).

Practical Implications

We present the first quantitative model predicting the surface contacts by HCW and the subsequent accretion of pathogenic material as they perform standard patient care. This model indicates that single rooms may significantly reduce the risk of cross-contamination due to indirect infection transmission. Not all care types pose the same risks to patients, and *housekeeping* performed by HCWs may be an important contribution in the transmission of pathogens between patients. Ventilation rates and positioning of infectious patients within four-bed rooms can mitigate the accretion of pathogens, whereby reducing the risk of missed hand hygiene opportunities. The model provides a tool to quantitatively evaluate the influence of hospital room design on infection risk.

Introduction

Risk of healthcare-acquired infections (HCAI) is omnipresent in healthcare facilities worldwide, and understanding transmission routes is key to effective control. While the transmission routes for some diseases are well documented, the precise mode of transmission is uncertain for many infections, particularly for those pathogens that cause HCAI. Although it is probable that the majority of transmission occurs via a contact route (Sax et al., 2009), there is increasing rec-

ognition that the hospital environment plays an important role.

Evidence suggests that at least 20% of HCAs potentially could have arisen from an environmental reservoir (Harbarth et al., 2003) and several recent studies have highlighted the importance of surface contamination and indicated a causal link to subsequent patient infection (Bhalla et al., 2004a). However, there is currently little robust understanding as to how healthcare worker (HCW)–surface contacts and activities in the healthcare environment result in HCW or

patient exposure to such pathogens. Studies of human behavior in the healthcare environment have largely acknowledged the lack of a comprehensive survey which collects the minutiae of hand-to-surface contacts (Duckro et al., 2005; Pittet et al., 1999; Smith et al., 2012). Major studies have however, highlighted that environmental contamination, through the deposition of bioaerosol on surfaces, cannot be underestimated in the contribution to fomite-based infection transmission (Dancer, 2008; King et al., 2013; Otter et al., 2011; Rusin et al., 2002). Surfaces such as bed rails have been linked with harboring microorganisms that cause hospital infections, and many frequently used surfaces in hospitals have been found to sustain viable pathogens including staphylococci, enterococci (Duckro et al., 2005; Hayden et al., 2008; Pittet et al., 2006), and *Clostridium difficile* (Roberts et al., 2008). In addition, indirect infection transmission shows a distinct possibility of being exacerbated by incomplete or non-existent surface cleaning (Bogusz et al., 2013). Pathogens have been also shown to accrue on HCW hands as they touch surfaces (Pittet et al., 1999), and there is evidence they can subsequently be transmitted to patients (Hayden et al., 2008).

Hospital designs are tending toward incorporating single rooms, based on the premise that single room enables 24/7 admissions without disruption to other patients, and the design will improve confidentiality for clinical discussion, examinations, and treatment (Chaudhury, 2005). In reviewing the literature, Chaudhury (2005) further report single rooms to promote a therapeutic environment that is patient and family centered increasing recovery and reducing infections and risks and enhancing the healthcare professional and patient relationship. This evidence is supported by Ulrich and Zimring (2008), when considering the NHS Estates perspectives and further purport that single rooms provide increased levels of protection and prevention from infection.

In addition, research has explored these issues in depth, where there is an increasing body of evidence which points toward a relationship between hospital room design and infection control (King et al., 2013; Pittet et al., 2006; Shih et al., 2007; Tian et al., 2006). Ventilation is well recognized as a control strategy for airborne infection (Zhang et al., 2009) and is recommended for diseases such as tuberculosis, measles, SARS, and more recently influenza (Yang et al., 2011). Aerial dispersion of bioaerosols has been associated with non-respiratory pathogens in hospitals including methicillin-resistant *Staphylococcus aureus* (MRSA) (Sherertz et al., 1996) and *C. difficile* (Roberts et al., 2008), and subsequent contamination of surfaces has been recognized as a potential transmission route for some infections (Bhalla et al., 2004b). However, research into the combined role of airborne dispersion, pathogen contamination of hospital room surfaces,

Modeling environmental contamination in hospital rooms

and interaction with human behavior is still in its infancy (Zartarian et al., 2012). Furthermore, the influence of airflow patterns and ward design on the risk of this combined transmission route is not well understood. Single-bed rooms are widely advocated over four-bed patient environments for their infection control potential, yet there are little data to allow quantification of the touted benefits (Ulrich and Zimring, 2008).

This research focuses on the combined interaction between deposition of airborne microorganisms, room design, and human behavior by considering the question: Are single-bed patient rooms more effective than their four-bed counterparts at reducing the risk of infection from environmental contamination? The study compares hospital single- and four-bed room environments by modeling likely contamination on the hands of healthcare workers resulting from pathogens released from an aerosol source and deposited on surfaces. The model combines computational fluid dynamics (CFD) simulations of room airflow and particle deposition (King et al., 2013) data from HCW hand-surface contact patterns established through a hospital observational study and a dermal pathogen accretion model to simulate contamination of HCW hands. The resulting probabilistic pathogen accretion model (PAM) is used to compare the effect of room layout and ventilation rate on HCW hand contamination during six different types of patient care.

Methodology

Patient rooms

Two room scenarios are considered: a typical hospital single room and a standard four-bed room. Both room layouts are based on the UK Department of Health standard, HBN04-01 (Department of Health Estates and Facilities Division, 2008), and computer aided design models are illustrated in Figure 1.

Rooms are assumed to be fully occupied, with one infectious patient in each scenario. In both rooms, modeling is conducted with the ventilation at 6 air changes per hour (ac/h), as per the UK Department of Health guidance, HTM03-01 (Department of Health, 2007) and at a reduced rate of 4 ac/h. In the case of the four-bed ward (*cases 3–10*), the relative influence of ventilation design was also considered through changing the location of the infectious patient. All cases together with a brief description are shown in Table 1.

Environmental contamination

Computational fluid dynamics (CFD) simulations were carried out to predict the likely spatial deposition pattern resulting from bioaerosols released from a quiescent patient in the single- and four-bed room. The

8	Four-bed		6	Patient 2
9	Four-bed		6	Patient 3
10	Four-bed		6	Patient 4

CFD methodology is detailed below and has previously been shown to compare well to experimental measurements of bioaerosol deposition in chamber studies (King et al., 2013). In this previous study hospital, single-bed and two-bed rooms were replicated inside an aerobiology chamber at the University of Leeds (4.2 × 3.2 × 2.2 m) with steady ventilation at 6 ACH. *Staphylococcus aureus* was aerosolized by a Collision Nebuliser (CN 25; BGI Inc., Waltham, MA, USA) (mean diameter 2.5 μm) and released into the room for 30 min at the head of a supine heated mannequin. Deposition of bacterial colonies was quantified on key surfaces by means of nine agar-filled petri dishes per surface CFD simulations conducted in Fluent v.13 (ANSYS, Canonsburg, PA, USA) and following the methodology outlined below were used to model deposition of 2.5 μm particles released at the same location and with the same geometry as the experimental scenarios. Normalized concentrations on surfaces were seen to compare well between the experiments and CFD model, giving confidence that the CFD modeling approach can predict a realistic spatial deposition pattern in a ventilated room.

In the current study, steady-state airflow simulations were carried out using Fluent v.13 (ANSYS) for the model hospital room geometries shown in Figure 1. Meshing, carried out in ANSYS Workbench v13, was fully hexahedral. Grid density and construction has

been shown to heavily influence flow results (Roache, 1997); therefore, a mesh independence study was based on the formulation set out in King et al. (2013). For this three hexahedral, grids with nominal cell sizes of 50, 25, and 20 mm were compared. Velocity variation was found to differ less than 5% between the 25 and 20 mm meshes at selected points within the bulk flow. A maximum cell volume of $1.5625 \times 10^{-5} \text{ m}^3$ was used within the bulk domain, and $1 \times 10^{-6} \text{ m}^3$ was used 10 cm away from all horizontal surfaces. Final cell count for all simulations was approximately 4 and 8 million volumes for the single- and four-bed rooms, respectively.

Mechanical ventilation was modeled through a simplified four-way ceiling supply diffuser (Zhang et al., 2009) with velocity boundary conditions specified to give the air change rates in Table 1. Air was assumed to be extracted via a wall-mounted grille, with a pressure boundary condition of -10 Pa . Turbulence was modeled with a Reynolds' Stress (RSM) closure model and standard wall functions; this model was shown in the previous study to compare better with experimental bioaerosol deposition data than the more commonly used k-epsilon model (King et al., 2013). Human patients lying supine on the beds were represented through simplified blocks emitting a heat flux of 56 W/m^2 . Air entering the room was at 20°C and all walls were adiabatic. Bioaerosols were modeled using a Lagrangian particle tracking method with discrete random walk. In each case, 10,000 2.5 μm diameter inert particles were released via a volume source located 10 cm above the patient's head and given an inlet velocity of 1 m/s in the positive vertical direction to represent exhalation.

Table 2 Surface categories and modeled surfaces in CFD geometries

Equipment	Patient	Near patient	Far patient	Hygiene areas
Location on bed wall (1 × 0.4 m)	Mannequin	Bed Chair Tray Bedside table	Window Workstation	Sink Towel dispenser

Nine surfaces of interest were defined within the CFD model, as indicated in Table 2, and the modeled particle concentration was determined on the surfaces for each scenario in Table 1. These surfaces were based on those monitored during the observation study outlined below.

CFD simulations were carried out on a University of Leeds' high-performance facility (ARC1 with 672 AMD cores and 128 GB memory), were considered converged when residuals for continuity and all other variables dropped below 1×10^{-4} , and remained below this for at least 100 iterations. All variables are scaled with respect to the sum of the errors in all cells. In addition, continuity is scaled with respect to the largest absolute value within the first five iterations and so can be considered normalized (ANSYS 2010).

HCW–surface contacts

The likelihood of healthcare workers having contact with surfaces during patient care was developed from surface contact data accrued during an observational study carried out at a National Health Service (NHS) single-bed accommodation hospital ward during the first quarter of 2012. Healthcare workers were observed during episodes of care categorized into six areas described in Table 3, following standardized categories set out in Pittet et al. (1999) and Dancer et al. (2010).

In each observed care episode, hand-to-surface contacts with surfaces set out in Table 4 and the sequence

Modeling environmental contamination in hospital rooms

with which they happened were recorded. Typical locations of these surfaces are shown in Figure 2. The occurrence and type of hand hygiene after each care episode was also recorded. Over 400 individual care episodes were observed.

Data from the observations were used to generate representative contact patterns to model the likely sequence of surface contacts by a HCW in a patient room. HCW were found to touch surfaces in a non-random sequential or directed manner, insofar that moving from one surface category to another has a higher probability than a transition to somewhere else. By assigning each surface category a numerical value from 1 to 5, where *Equipment* = 1, *Patient* = 2, *Hygiene areas* = 3, *Near-bed surfaces* = 4, and *Far-bed surfaces* = 5, the movement of the HCW between surfaces can be represented by means of a weighted probability.

The movement of HCW between surfaces is modeled using a Markov chain approach (Allen, 2008). Using the defined weighted probabilities, the movement of a HCW between surfaces can be simulated based on the property that, given the present state, the future and past states are independent. This is termed the Markov Property:

$$P(X_i = x_i | X_j = x_j). \quad (1)$$

Given the five surface categories, the probabilities can be expressed in a transition matrix (P) indicating the maximum likelihood of directed contact between any pair of surfaces. For example, if the HCW is currently touching surface category 1, p_{12} is the probability that they will then touch surface category 2. This probability is derived from the observed data by counting the occurrences of the transition 1→2 for each HCW in the observational study and dividing by the total number of surface transitions throughout their episode of care. Thus, $\hat{P}_{ij} = \frac{x_{ij}}{\sum_m x_{ik}}$, where $m = 1 \dots 5$ states, and indices i, j , and k are dummy indices to indicate summation.

The observed data enabled surface contact transition matrices to be created for single-patient rooms, but to compare single- and four-bed rooms, HCW behavior in the four-bed room must be modeled. This was undertaken by assuming that care approaches were similar in the two room types and adjusting the transition probabilities based on other published information. Smith et al. (2012) conducted an observational study of HCWs in a four-bed room applying the same surface category criteria as used here. However, they note that patient charts become near-bed objects as these are often at the foot of the patient's bed rather the far side of the room; in our single-bed rooms, chart positions were modeled as a far-bed surfaces as the chart was located on the workstation (Figure 2) in the observation study. Therefore, this adjustment is made

to the probability densities derived from the healthcare observations. A Wilcoxon rank-sum nonparametric test comparing Smith et al.'s (2012) data to the current study shows that no statistical difference exists at the 5% level ($P = 0.068$), highlighting that the only difference in HCW behavior between single- and four-bed rooms is the positioning of patient charts. Consequently, this demonstrates the similarity between nurse behavior in single- and four-bed rooms. All four-bed simulations use this adjusted behavior in line with Smith et al. (2012).

Pathogen accretion model

Colonization of HCW's hands through contact with a contaminated surface is considered to be a dynamic process in which multiple factors may vary. The number of microorganism colony forming units, Y (cfu), accrued on HCWs hands from environmental or patient surface contacts during patient care can be shown via sensitivity analysis to depend primarily on six variables (Pessoa-Silva et al., 2004).

$$Y = Y(n, A, V, \lambda, \beta, h). \quad (2)$$

The number of surfaces touched, n . Each type of care shows a variable pattern of surface contact frequencies and sequences. Probabilistic distributions for these were obtained from the observational study as outlined above.

Surface contamination, V (cfu/cm²). The concentration present on each room surface is dependent on the scenario in question. These are obtained from sampling the lognormal distribution based on the CFD simulations for each scenario, as described above. It must be highlighted that this study considers no microbial die-off due to environmental stress as this is a time-dependent phenomenon. Therefore, V is assumed to be

proportional to the amount released initially in each case. The parameter V is regarded as the initial condition for the PAM model simulations, with the surfaces already contaminated at the point the HCW is assumed to enter the room. In addition, if each particle is treated as one cfu, the resulting deposition in cfu/cm² is comparable to actual hospital values (Mulvey et al., 2011).

Hand-surface contact area, A (cm²). This is assumed to exhibit a continuous distribution based on experimental values from Brouwer et al. (1999). They show that this can be modeled as a lognormal distribution with an arithmetic mean of 7 cm² and standard deviation of 1.9 cm² [corresponding to $\ln N \sim (0.84, 1.3)$]. For each surface contact, it is assumed that either hand may be in contact with the surface and no distinction is made for right- or left-handedness.

Surface-to-Hand Transfer efficiency, λ . It is reasonable to assume that not all of the pathogens in contact with the area of skin touching the surface are transferred to the hands. Transfer efficiency, which represents the percentage of surface contaminant transferred to the hand during a contact event, has been shown to be one of the most important parameters when modeling dermal exposure (Xue et al., 2006). Unfortunately, it is one of the most troublesome to accurately measure (Beamer et al., 2009). Transfer efficiency could be a function of multiple ambient parameters such as surface physiology, contact frequency, duration and pressure, concentration of transferrable material on surface, temperature, and humidity. Rusin et al. (2002) conclude from experimental studies that the transfer efficiency from surfaces to hands also varies between microorganism species. In three separate experiments, they reported the transfer of Gram-positive bacteria, Gram-negative bacteria, and bacteriophage to be 38.5%, 65.8%, and 27.6–40%, respectively, from

Fig. 3 Surface-to-hand transfer efficiency (λ). Data derived from Rusin et al. (2002)

non-porous surfaces. However, they indicate the transfer rate reduces to below 10% when porous fomites are evaluated. As there are insufficient data available in the literature to model the influence of specific parameters, the model employs the distribution developed by Rusin et al. (2002), as shown in Figure 3, to represent the variability in transfer efficiency.

Hand-to-surface transfer efficiency, B . A significant quantity of material residing on hands may also be transmitted to the surface during contact (Otter et al., 2013). Montville and Schaffner (2003) demonstrate that a difference exists between the direction of transfer, with statistically significantly lower transmission shown during transfer from hands to fomites than vice versa. They also highlight the influence of inoculum size on the efficiency of transfer, showing that when high levels are used, transfer rates are more accurately characterized (Montville and Schaffner, 2011). Surface-to-hand transfer efficiencies (β) are sampled from Monteville et al.'s empirical data. Therefore, during hand-to-surface contact, a proportion of pathogens already acquired by the HCW may be deposited from the hand onto the surface (Rusin et al., 2002). Random sampling is conducted from data in Montville and Schaffner (2003).

Antisepsis efficacy, h (%). This refers to the efficiency of reducing microbial contamination of HCWs' hands after performing one of three types of hand hygiene: hand washing with either bland or medicated/antibacterial soap, removal of non-surgical gloves, or dry rubbing with a waterless alcohol agent (minimum 61% ethanol by volume). Here, hand hygiene efficacy is based on data from published studies where significant sample sizes are available (Girou et al., 2002; Montville and Schaffner, 2003; Sickbert-Bennett et al., 2005). Microorganism type has been shown to exert a differ-

Modeling environmental contamination in hospital rooms

ence on hand hygiene efficacy, which is likely to be due to their individual adherence properties (Boks et al., 2008). Particular difference is noticed between bacteria and viruses (or bacteriophage), where removal of the latter is often an order of magnitude lower. Nevertheless, bacteria have the primary concern of many infection control teams, where MRSA or *C. difficile* often rank highest on the prevention list. Consequently, the model is non-organism specific, whereby resident or background microflora is ignored. Whether or not hand antisepsis actually occurs following an episode of patient care is based on the probabilities derived from the observation study and depends on care type.

Following a variance based sensitivity analysis using total effect Sobol indices (Nossent et al., 2011), the function shown in Equation 2 can be used to model pathogen accretion (Y) by means of a recurrence relationship given in Equation 3. This represents the hand pathogen loading at any time-step after contact with any one surface.

$$Y_i = \lambda_i V_i A_i + \beta_i Y_{i-1}, \quad (3)$$

where $i = 1 \dots n$ is the surface contact count. For purposes of remaining succinct, let $\sigma = \lambda AV$ then assuming that the transfer of pathogens to the surface from the HCW occurs sequentially and is independent of the surface loading then Y can be described as follows:

$$\begin{aligned} Y_i &= \sigma_i + \beta_i * (\sigma_{i-1} + \beta_i * (\sigma_{i-2} + \dots)) \\ &= \sigma_i + \beta_i \sigma_{i-1} + \beta_i \beta_{i-1} \sigma_{i-2} + \dots \\ &= \sum_{j=0}^i \left(\prod_{k=j+1}^i \beta_k \right) \sigma_j. \end{aligned} \quad (4)$$

HCW touching surfaces during an episode of patient care forms the driving force within this model. The model was programed using Matlab (MathWorks, Natick, MA, USA). For each scenario, a Monte Carlo simulation of 1,000 HCW care episodes was conducted for each care type, modeling the mechanics of pathogen transfer based on the input parameters set out above.

Results and discussion

Bioaerosol deposition

Surface deposition concentrations, cfu/cm² predicted from the CFD simulations following the release of 10,000 cfu, can be seen in Figure 4. These show the breakdown of particle concentration for the five different surface categories and, in the four-bed case, for each infectious patient position in turn (Figure 4b–e). Deposition in the single room (Figure 4a) appears to be mainly focused on the equipment area and the

Fig. 4 Predicted particle deposition (cfu/cm²) on horizontal surfaces within the single- and four-bed accommodation for an initial release of 10,000 cfu. Comparison shown between 4 ac/h and 6 ac/h for each case. (a) case 1 & 2 in the single room, (b) cases 3 & 7 in the four-bed room where the infectious patient is in position 1, (c) cases 4 & 8 in the four-bed room where the infectious patient is in position 2, (d) cases 5 & 9 in the four-bed room where the infectious patient is in position 3 and (e) cases 6 & 10 in the four-bed room where the infectious patient is in position 4. E = Equipment, P = Patient, H = Hygiene areas, N = Near-patient surfaces, F = Far-patient surfaces

patient themselves, and the model predicts little difference in the deposition pattern between 4 and 6 ac/h. In the case of the four-bed room, predicted surface concentrations are highest in the vicinity of the source patient in all cases. Surfaces opposite the source position demonstrate a sharp drop-off; here, particles appeared to be maintained airborne and directed toward the extract. This is particularly the case when *patient 2* is the source (Figure 4c), where a seemingly dichotomous partition within the room can be observed, and few particles are deposited on *patients 3*

and 4. Equally when *patient 3* is the source (Figure 4d), negligible counts can be found in the vicinity of *patient 1* or *patient 2*, and when *patient 4*, closest to the extract, is the source, there are very few counts in the vicinity of any of the other patients. However, the distribution when *patient 1* is the source (Figure 4b) is noticeably different with deposition predicted across the room.

Wong et al. (2010) suggest that as the air change rate increases, the deposition increases further from the source. A one-way nonparametric Wilcoxon signed-rank

test does not uphold this conclusion here, and there is no clear difference between the two air change rates. However, a statistically significant difference is exhibited in the four-bed room ($P = 0.04$) between surface concentrations for different infectious patients at the same air change rates.

Surface contact sequences

Observational study data indicated the probability of contact with different surface categories ($P = 0.04$) along with hand hygiene method ($P = 0.02$) was dependant on care type. Statistical differences were also significant between the total number of surface contacts and the likelihood of hand hygiene being performed for different care types. It should be noted that this is not analogous to hand hygiene compliance as the research team are not able to pass judgment on what hygiene procedures should be followed for a particular care episode. Figure 5 shows the mean and standard deviation of surface contacts observed and used in the model:

Table 5 shows transition matrices $\hat{P}_{ij}$ for all care types derived from all observed HCW surface–contact sequences. Briefly recapping, the transition states are as follows: 1 = *Equipment*, 2 = *Patient*, 3 = *Hygiene areas*, 4 = *Near-bed surfaces*, and 5 = *Far-bed surfaces*.

Using these directed probabilities, Figure 6 shows a typical example sequence of surface contacts by a

HCW during an episode of care in a single room by means of a stochastic simulation.

Hand hygiene

The observational study data showed statistically significant differences in hand antiseptic choice between care types ($P < 0.001$), with some variation within each care type, as shown in Figure 6. Alcohol rub was used abundantly throughout all but *personal care*, where hand washing with soap and water predominated. Glove usage accounted for only 2% of observed episodes of care, half of which were during *housekeeping*. These probabilities are incorporated into the PAM model to account for the likelihood of HCWs undertaking some form of antiseptic after each episode of care (Figure 7).

Model validation

Published data which measures contamination levels of HCWs' hands are scarce. In particular, Pittet et al. (1999) is the only known published study that quantifies both cfu values along with the time spent in the room by the HCW. However, their methodology does not include surface swabbing and hence a specific value for surface contamination, V , is not known. Nevertheless, assuming that other variables such as HCW hand

Fig. 6 Example of surface contacts of HCW #50 performing an episode of *direct care*

surface area, surface types, and nursing behavior are comparable between scenarios, it is reasonable to compare the distribution shape by means of a Kendall-tau nonparametric test of the simulated cfu from PAM and the measured data by Pittet et al. (1999). Specifically, this is a measure of rank correlation or the similarity of the orderings of the data when ranked by each of the quantities. This approach is used for comparing the differences between individual observations with respect to each other to gain an insight into the overall data distribution.

Initial comparison shows a less-than-perfect fit ($P \sim 0.2$), and therefore, the data from both PAM and Pittet et al. were split into 4 groups corresponding to: lower quartile ($\leq 25\%$), lower-mid quartile ($25\% < x \leq 50\%$), upper-mid-quartile ($50\% < x \leq 75\%$), and upper quartile ($75\% < x \leq 100\%$).

Good comparison is shown particularly at lower (first quartile) values ($P = 1 \times 10^{-3}$), where a higher concentration of data exists. Both lower-mid and upper-mid quartiles compare well ($P = 0.01$ and $P = 0.04$). Higher values of cfus (upper quartile) become less frequent and the comparison is poorer ($P = 0.12$). The reader must note that detection levels by glove juice methods and subsequent culture techniques carried out by Pittet et al. (1999) have led to truncated data, which is likely the reason for less optimal comparison at this level. If these data were extrapolated, PAM potentially may approximate the behavior better in the upper quartiles ($P \sim 0.02$). However, pending greater sources of data, it is not unreasonable to conclude that at least through the first two quartiles or the first 50% of cfu colonization levels, PAM is a capable and realistic model.

Application of PAM to single- and four-bed rooms

Air change rate. Results from PAM are all normalized with respect to the mean contamination level on HCWs' hands after *direct care* in the single room at 6 ac/h. This can be considered the 'base case' and enables comparison between rooms, ventilation, and care types.

Figure 8 depicts predicted normalized cfu on HCW hands, Y , compared against the average of *direct care* for each subsequent type of care within the single room. Additionally, the comparison is made between a ventilation rate of 4 and 6 ac/h. Initially, there appears only to be a small reduction in hand contamination from 4 to 6 ac/h when comparing medians, and comparison of the upper quartile shows small differences depending on care type. However, comparison of extrema using a Kruskal-Wallis nonparametric test reveals that predicted hand contamination levels under

Fig. 7 Cumulative probability of hand hygiene category subdivided by care type

Modeling environmental contamination in hospital rooms

a ventilation rate of 4 ac/h are consistently higher throughout ($P < 0.05$).

Room type. In Figure 9, we consider two design options: four patients located in four single rooms or colocated in one-four-bed room. In each case, the simulation assumes that one patient is infectious and that the HCW provides care to all four patients in turn. The model assumes the worst case scenario where the first patient attended to is the infectious one (Figure 9a,b). All other parameters in the model, including hand washing are as set out in the methodology. Figure 9c–h shows the normalized contamination on HCW hands (Y values) for progression through the series of four patients in single- and four-bed rooms with no airborne cross-transmission between the rooms. The results show that cfu values are likely to be monotonically decreasing as the HCW progresses between patients in the single rooms. Environmental contamination due to the patient is only present in room 1, and hand antisepsis removes contamination in the majority of cases and minimizes further environmental contamination in subsequent rooms. In the case of the multi-bed room, the results are quite different. Rather than an expected decrease due to hand hygiene, the aerial spread of microorganisms to neighboring bed bays allows for subsequent accretion of pathogenic material by the HCW regardless of hand hygiene. This accretion is also likely to happen without the HCW awareness; they may take additional precautions if they know that patient 1 is infectious, but are not likely to modify care for other patients in the same way.

Discussion

The study conducted here demonstrates the potential for quantifying the effect of room design on potential infection risk by means of an indirect metric, namely hand contamination.

Bioaerosol deposition patterns

CFD modeling of the application scenarios revealed that a ventilation rate of 6 ac/h showed little significant improvement over 4 ac/h on deposition quantities or spatial variation in three of the four considered scenarios in the four-bed room. A decrease in spread locus was noticed particularly when the infectious patient was placed closest to the outlet vent, highlighting the greater downward momentum on particles exerted by comparatively higher local air velocities at 6 ac/h. This indicates that both the ventilation diffuser locations and ventilation rate may be important in influencing deposition as well as extraction of airborne microorganisms. It is recognized that exact cfu/cm² values cannot be obtained via this method due to the absence of knowledge regarding the concentration of the infec-

tious source. Here, we used a normalization metric to consider the relative spatial deposition. It is also important to note that the CFD simulations were steady-state models of the airflow that did not account for movement of people and only considered the deposition of small (2.5 μ m) diameter particles. We made these assumptions here based on validation experiments for the CFD models (King et al., 2013). In reality, infectious particles will be released in a size distribution that will include smaller and larger particles which will change the spatial deposition patterns; larger particles are likely to increase deposition close to the patient. A CFD model incorporating a polydisperse particle release based on known particle size data from respiratory (Han et al., 2013; Xie, 2008) and environmental (Hathway et al., 2013) sources could enable an estimation of the resulting spatial contamination, which can then be applied in PAM. However, without experimental validation of the CFD model, these results would have to be treated with caution.

Ventilation method and transient flows due to activity are also factors. Under the HTM 03-01UK guidance (Department of Health, 2007), minimum air change rates of 6ACH are specified, but how and if these are achieved can vary. Hospital ventilation strategies in the UK often incorporate both natural and mechanical ventilation methods. While verification of mechanical flow rates is largely feasible, in naturally ventilated environments, measurement is more challenging. Although the small number of studies (Escombe et al. 2007, Qian et al. 2010, Gilkeson et al. 2013) suggest that high ventilation rates are achievable, these may not have predominant or established airflow pathways in some cases. When combined with activity such as human movement, opening and closing doors, changes in buoyancy due to heat sources, and use of fans for comfort, these variations in airflow patterns may change the dispersion of airborne microorganisms and further confound surface contamination patterns. An observation and sampling study conducted on a multi-bed respiratory ward (Hathway et al., 2013) found that airborne microorganisms and particles varied with the different activities on a ward, with increases during healthcare worker activity and personal care, but little change with visitors on the ward. Nevertheless, the approach presented here gives a realistic mechanism for exploring potential deposition at design stage and identifying design options that are likely to minimize contamination.

Observational study

The first hand data accrued from the observational study is of fundamental importance for the modeling of human hand-to-surface contact events, allowing insight into the different types of care and how these also the behavior of nurses and doctors. These data

then formed the basis of a stochastic model of HCW behavior as they moved from one surface to another and consequently forms the driving force behind the subsequent model for pathogen accretion. While the data are only from one hospital with a single-bed ward environment, comparison with other studies suggests the data are realistic and representative of typical health care in other hospital environments. However, it should be acknowledged that in applying the model to other hospital wards, it may be necessary to make adjustments to the location of surfaces and contact patterns. For example, in the current study, the position of the patient charts and information in the single rooms was treated as a far-bed surface based on the practice in the observation study, while in the four-bed room, it was treated as near-bed based on Smith et al.(2012). In other hospitals, the position of charts may vary depending on room design, local practices, and care needs. Similarly, in wards where care routines differ substantially from those considered here, it may be necessary to conduct a further observational study to create new hand-to-surface contact patterns that are more representative of the environment.

Probabilistic model

The pathogen accretion model (PAM) was developed from the growing understanding of hand contamination from surface contacts. This model focuses on the physical process of accruing pathogens onto either the skin or gloved surfaces of HCWs' hands as they perform episodes of standard patient care. The model provides a framework which allows for the quantitative comparison of hospital room design including single- vs. four-bed accommodation by means of HCW hand contamination. Application of PAM to the scenario rooms showed that differences were not clear cut and the positioning of the infectious patient had most effect on the final results. The spatial deposition of particles is influenced by the location of the ventilation supply inlet relative to the source. Locating a susceptible patient closer to the supply air is likely to reduce the risk of environmental contamination due to bioaerosol release from a neighboring patient. Locating the infectious patient in a four-bed room without an unobstructed air pathway from the bed to the ventilation outlet caused the highest level of surface contamination of all scenarios tested. These findings concur with experiments and simulations conducted in King et al. (2013).

It is crucial to highlight that this is a flexible framework model, built from the increasing understanding of the mechanics behind pathogen transmission; however, the results are dependent on several data inputs to the model which all have a degree of uncertainty. Initial validation was successful against the limited available data in the published literature, but it is

Modeling environmental contamination in hospital rooms

acknowledged that full validation of the model is very challenging as the microbiome, ventilation design, physical layout, and personnel variation of every hospital is highly specific. Data for the surface contamination patterns and the HCW hand-surface contact patterns were derived from CFD models and the observational study, respectively, as part of the study. While this leads to a reasonable degree of confidence in these data in the particular scenarios examined, both parameters are influenced by a number of factors as outlined above. The other model elements relied on published data to provide suitable inputs. As far as possible, these were applied as distribution functions to account for variability; however, the influence of factors such as temperature, humidity, and surface porosity are not explicitly considered in the model and cannot be determined from the current results. With further data, it may be possible to include these factors, for example, into the transfer efficiency parameters.

It should also be emphasized that the current model does not simulate the pathogen accretion process over a particular time period. The CFD deposition pattern is used to generate a likely surface contamination pattern for a given room, and the PAM then simulates the contact sequence and likely resulting accretion. The resulting hand contamination is presented in the study as a normalized parameter to enable relative comparison between scenarios, as the model does not include transient factors that may influence the actual microbial concentration on HCW hands. In reality, microbial viability on surfaces and on hands will be a factor, and this is influenced by temperature and humidity as well as surface properties. Hand hygiene may also influence microbial viability; alcohol gels are known to exert residual microbiocidal effects due to remaining residue on HCWs' hands (Bogusz et al., 2013) which would also influence the actual microbial concentrations. The aerosol release of microorganisms will also be a continuous and transient process, with surfaces never having a steady-state concentration due to ongoing deposition interspersed with cleaning activities. Although this means that the model cannot explicitly model infection risk, the current formulation enables exploration of the likely importance of different design and care factors and incorporates the combined effects of airflows and human activities. In particular, it enables direct and quantitative comparison between different ward designs under the same care conditions. The framework also allows for increasingly precise specification of surface contamination levels, transfer parameters, and HCW contact patterns with input of further data from sampling and observation studies.

Conclusions

The aim of this study was to provide a mathematical model which quantifies the relative contamination

levels of healthcare workers' hands from surfaces within hospital rooms. This is achieved through a multidisciplinary approach coupling CFD simulations with clinical observation of HCW movement and Markov chain Monte Carlo modeling of hand contamination. An observational study of patient care in a single-bed hospital ward showed that hand hygiene choice and frequency varied strongly. HCWs performing short episodes of care had a predilection for alcohol rub. In other care types, the usage of alcohol rub or soap and water was 50/50. HCW surface contact patterns in rooms were modeled by a Markov chain and fed into a mathematical model to calculate the pathogen colonization level on hands after patient care.

A parametric study indicates that hand contamination levels depend highly on care type ($P < 0.0001$), the number of surface contacts ($P < 0.001$), and the distribution of surface pathogens ($P = 0.05$). Highest hand contamination was predicted during *Personal care* despite this having the highest levels of hand hygiene. This is due to the greater number of contacts on the more highly contaminated near-bed surfaces. Increasing the ventilation rate is likely to have a small benefit on environmental contamination in a single-bed room, while the relative location of infectious patients and ventilation supply and extract grilles had a significant effect in a four-bed room ($P = 0.05$). Comparison of four patients housed in single rooms against a four-bed room suggests contamination on the HCWs' hands is likely to decrease monotonically after care in single rooms, but is likely to increase during contact with subsequent patients in four-bed rooms.

The results support the hypothesis that single-patient rooms reduce the risk of HCAI, highlighting that this benefit may extend to risk of infection due to environmental contamination not just the more obvious airborne and direct contact transmission routes. The findings also suggest that ventilation design and room layout may affect environmental contamination and subsequent contact transmission risks in multi-bed environments. This has implications for those designing wards as well as operational aspects in terms of the most suitable location for infectious or susceptible patients.

This study makes a significant contribution to the body of evidence that support the NHS in making decisions about hospital design and whether or not to incorporate single rooms.

Acknowledgements

This work was carried out as part of a PhD studentship supported by the UK Engineering and Physical Sciences Research Council (EPSRC), EP/G029768/1 and Arup. The observational study was approved by the South East Wales Research Ethics Committee (11/WA/0200). The authors would like to thank Sue Bale, Liz Waters for valuable input into the preparation of this manuscript and all the staff at the Ysbyty Aneurin Bevan for facilitating the observational study.

Summary: We describe the epidemiology and control of a hospital outbreak of multi-drug-resistant tuberculosis (MDR-TB). A human immunodeficiency virus (HIV)-negative patient with drug-sensitive tuberculosis developed MDR-TB during a period of unsupervised therapy. She was admitted to an isolation room in a ward with HIV-positive patients, but the room, unbeknown to hospital staff, was at positive-pressure relative to the main ward. Seven HIV-positive contacts developed MDR-TB. The diagnosis in the second patient was delayed, partly because acid-fast bacilli in his sputum were assumed to be *Mycobacterium avium-intracellulare*. All the available *Mycobacterium tuberculosis* isolates were indistinguishable by molecular typing. Nearly 1400 staff and patient contacts were offered screening, but the screening programme detected only one of the cases. Despite therapy, the index patient and two of the contacts died. HIV-positive patients are more likely than others to develop tuberculosis after exposure, and the disease may progress more rapidly. In these patients the possibility that acid-fast bacilli may represent *M. tuberculosis* must always be considered. Patients with tuberculosis (suspected or proven) should not be nursed in the same wards as immunosuppressed patients, and should be isolated. MDR-TB cases must be isolated in negative-pressure rooms. Hospital side-rooms may be positive-pressure as a fire safety measure; infection control teams must be aware of the airflows in all isolation rooms, and must be consulted during the design of hospital buildings. Good communication between infection control teams and clinicians is important, and all medical and nursing staff must be aware of the principles of management of patients with proven or suspected tuberculosis and MDR-TB.

Keywords: Tuberculosis; multidrug resistant tuberculosis; drug resistance; cross-infection; infection control; HIV; airflow; isolation; supervised therapy; contact tracing; typing.

Introduction

The steady decline in tuberculosis in Western countries has reversed in recent years with an excess of reported over-predicted cases, particularly in inner cities.¹⁻³ There are many reasons for this, including increasing immigration from countries with a high prevalence of tuberculosis, poverty and social deprivation, and inadequately resourced public health services.⁴ Furthermore, poorly supervised therapy and the addition of single drugs to failing regimens has led to the emergence of multi-drug-resistant tuberculosis (MDR-TB).⁵ Because these strains are less responsive to standard therapy, patients remain infectious for longer.

The emergence of human immunodeficiency virus (HIV) and acquired immunodeficiency syndrome (AIDS) has paralleled the re-emergence of tuberculosis. There have been several reports of outbreaks of tuberculosis in HIV patients in the USA, Spain, South America and London.⁶⁻¹⁶ In most cases these outbreaks have centred on hospitals where AIDS patients are nursed together, and increasingly involve multi-drug-resistant strains.

We report an outbreak of MDR-TB amongst HIV patients at St Thomas's Hospital in London, in which a major factor was inadequate isolation on a ward where HIV patients were being nursed.

Patients and methods

The outbreak

St Thomas's Hospital is a teaching hospital with approximately 800 inpatient beds, serving a large urban population. The HIV outpatient unit provides care for 700 regular attenders. The hospital has several wings of different ages and design; for many years patients with known or suspected tuberculosis have been nursed in side-rooms, with no known cases of cross-infection before 1995. Until recently, HIV-positive inpatients were admitted to East and South Wing wards, but latterly they were admitted to a particular ward ('Ward 1') in the North Wing

under the care of the respiratory physicians. This ward has 28 beds arranged in five bays, and four single rooms with adjacent bathrooms.

Patients

Patient 1

The first case was an HIV-seronegative female in her 20s, recently arrived from West Africa. In December 1994 she was admitted with open pulmonary tuberculosis with a fully sensitive strain of *Mycobacterium tuberculosis*. She was started on rifampicin, isoniazid and pyrazinamide, and improved. However, she failed to attend her outpatients appointment in February 1995, and in March she presented complaining of cough and night sweats. Her sputum showed large numbers of acid-fast bacilli (AFB), and the chest X-ray showed increased cavitation. She was admitted to a side-room on a ward in the East Wing (Ward 2), and ethambutol was added to her therapy. She was discharged in mid-April. Shortly afterwards her most recent isolate was reported to be resistant to rifampicin, isoniazid, clofazimine and rifabutin, and in May her treatment was changed to a combination of ethambutol, pyrazinamide and ciprofloxacin. By June she had deteriorated; she was admitted to a side-room on Ward 3 in the East Wing, and streptomycin was added. In September 1995 Ward 3 was refurbished and she was transferred to a side-room in Ward 1 in the North Wing. By January 1996 the organism had become resistant to pyrazinamide, cycloserine and ciprofloxacin. She remained on Ward 1 until April 1996 when she was transferred to another hospital. She later returned to St Thomas's and was nursed in a negative-pressure room. Despite therapy she died in December 1997.

Patient 2

A 34-year-old man with AIDS was an inpatient on Ward 1 for four weeks between October and November 1995, with a diagnosis of *Pneumocystis carinii* pneumonia. Culture of his sputum for mycobacteria at this time was negative. He was nursed in a side-room adjacent to that of Patient 1. In February 1996 he developed fever and cough, with sputum

containing numerous AFBs which were assumed to be *Mycobacterium avium-intracellulare*. He deteriorated and was re-admitted to Ward 1 in March 1996. Despite repeated requests, he kept the door open, frequently left the room and visited other patients. In mid-March his sputum sample taken in February yielded a mycobacterium species, identified as *M. tuberculosis* by gene probing (Accuprobe, Gen-probe Inc., San Diego, USA) and he was given rifampicin, isoniazid and pyrazinamide. One week later the organism was shown to be resistant to rifampicin and isoniazid. It was immediately concluded that Patient 2 had probably been infected by Patient 1. Urgent examination of airflows showed that the isolation rooms on Ward 1 were positive pressure relative to the main ward.

Subsequent cases and outcome

A further six patients with MDR-TB were identified over the following eight months (Table I). Four were identified in St Thomas's Hospital, and two elsewhere. The four who presented to St Thomas's Hospital were transferred to other hospitals with appropriate isolation facilities as soon as the diagnosis was suspected. All six patients were HIV-positive males. Five presented with respiratory or constitutional symptoms; one was asymptomatic, and was detected as part of the screening programme. Two patients, Patients 2 and 4, have subsequently died.

Contacts between patients

All the cases had been on a ward at the same time as Patient 1, and three also at the same time as Patient 2 while he was infectious with AFBs in his sputum. Patient 8 was not a patient at St Thomas's, but had counselled Patient 2 while he was infectious on Ward 1. Patient 3 had also been in contact with Patient 2 in the HIV clinic, and may have acquired his infection there. At least one, and possibly two infectious were acquired following exposure to a patient in a neutral pressure room. The duration of contact for each patient is

shown in Table I. Sixty-four HIV positive patients were known to have had inpatient contact with an infectious case, giving an overall clinical case attack rate of 11% (7/64) in this group (Table II).

Molecular typing of the *M. tuberculosis* isolates

Isolates from seven patients were typed by restriction fragment length polymorphism at the Royal Free Hospital and the Public Health Laboratory Service (PHLS) Mycobacterium Reference Unit, Dulwich.¹⁷ All isolates were indistinguishable, including the sensitive and resistant strains from Patient 1. The organism from Patient 8 failed to grow and was unavailable for typing, but *M. tuberculosis* and mutations within the *rpoB* gene associated with rifampicin resistance were detected in his sputum by the polymerase chain reaction (PCR) and solid-phase hybridization techniques; in view of his close contact with Patient 2, he was probably part of the outbreak.

Management of the outbreak

A committee was formed to define, investigate and manage the outbreak. The main elements of the management of the outbreak were as follows.

Transfer of known cases

As soon as the outbreak was identified, the two known cases were transferred to hospitals with adequate negative-pressure isolation rooms.

Review of isolation room airflow

Airflows in hospital side rooms were urgently reviewed. It was found that all the side-rooms in the North Wing wards were under positive pressure relative to the main wards. Side-rooms in the East Wing were in balance with the main wards. There were no negative-pressure rooms available in the Trust, so proposals for the conversion of the side-rooms on Ward 1 to negative pressure were brought forward. Four such rooms with >12 air-changes per hour and en-suite facilities were opened in January 1997.

Table 1 Secondary cases of MDR-TB: clinical and epidemiological information

	Contact with Patient 1 (days)	Contact with Patient 2 (days)	Interval to symptoms (weeks)	Delay to clinical diagnosis of MDR-TB (weeks)	CD4	Chest X-Ray appearances	Outcome
Patient 2	33	—	11	7	<50	Rt hilar and basal infiltrates	Died
Patient 3	2	<1 (outpatient)	53*	4	100	Rt lung infiltrates	Survived‡
Patient 4	20	6	10	2	<50	Lt hilar and basal infiltrates	Died
Patient 5	18	10	12	3	<50	Rt apical and hilar infiltrates	Survived‡
Patient 6	12	—	28†	<1	100	Lt upper zone cavitation	Survived‡
Patient 7	4	—	33	4	250	Miliary appearance	Survived‡
Patient 8	<1	<1 (visitor to ward)	24	<1	170	Clear	Survived‡

All were males infected with HIV.

* Precise date of initial exposure uncertain. Interval given refers to earliest possible exposure.

† Time to detection at screening clinic; patient was asymptomatic.

‡ Alive at the time of writing, 20 months after the recognition of the outbreak.

Table II Clinical case attack rates in inpatient HIV-positive contacts of Patients 1 and 2

Source of exposure	Number exposed	Number infected	Attack rate (%)
Patient 1—Ward 2	2	1	50
Patient 1—Ward 3	11	1	9
Patient 1—Ward 1	51	4	8
Patient 2—Ward 1	9	2	22
Patient 1 or 2	64	7	11

Review of Trust tuberculosis policy

The Trust policy for tuberculosis was reviewed. All patients with signs of chest disease are now assessed for risk of tuberculosis and MDR-TB before admission to hospital. Patients who present to outpatients or casualty with suspected tuberculosis are kept in isolation while an urgent auramine stain of sputum is performed; if MDR-TB is suspected and AFB are seen, the patient is transferred to a negative-pressure isolation facility. Patients with known or suspected drug-sensitive tuberculosis can continue to be nursed in neutral-pressure side-rooms as they have been for many years; the positive-pressure rooms are no longer used for tuberculosis isolation. Immunocompromised patients are no longer nursed on the same ward as those with known or suspected tuberculosis. A negative-pressure room was constructed in the outpatients for cough inducing procedures such as induced sputum collection and bronchoscopy, and dust/mist/fume particulate filter face masks were made available for nursing MDR-TB patients.

Contact tracing and screening programme

Because of the length of stay of Patient 1, a large number of other patients and staff were exposed to MDR-TB: 792 staff, 61 HIV-positive inpatients and 226 HIV-negative inpatients had possible exposure. Screening was offered to all surviving contacts, and to all surviving HIV-positive patients who had attended the HIV clinic between January and March 1996. Screening consisted of a health questionnaire and a tuberculin skin test; those who were immunodeficient or had symptoms were also offered a chest X-ray. One case (Patient 6)

was identified during screening of HIV-positive contacts, but so far no cases have been identified in any of the other groups.

Antibiotic prophylaxis

Prophylaxis with ethambutol and para-aminosalicylic acid was offered to immunodeficient contacts; they were informed of its unproven efficacy and possible side-effects. Only seven patients accepted prophylaxis, and none continued for more than two weeks.

Public relations, press release, telephone helplines

A press release was issued at the same time as the recall letters were posted, and telephone helplines were set up in the HIV unit. Interest by the media and public was intense but short-lived.

Internal enquiry and changes to infection control

The Trust commissioned an internal enquiry into the outbreak. Their report was completed in October 1996 and was made available to the public. Following the recommendations of the report, the infection control team was enlarged, its practices were reviewed, and communication links between the infection control nurses, microbiologists, clinicians and the community thoracic nursing team were strengthened. Other recommendations were incorporated in the revised tuberculosis policy and in the new isolation facilities, as previously described.

Discussion

Although the dangers of tuberculosis and MDR-TB are well recognized; this outbreak

illustrates the importance of following the correct management procedures for these patients.

Poor motivation, language barriers and social isolation may lead some patients to default from therapy and present later with MDR-TB. Supervised therapy has been shown to improve outcome and reduce the emergence of drug resistance.^{18,19} Patient 1 developed MDR-TB during a period of unsupervised therapy. She was admitted to hospital and single drugs added sequentially to her treatment; subsequent isolates showed further resistance. She remained infectious in hospital for many months, and was eventually transferred to a ward with HIV patients. Staff were unaware that the side-rooms on this ward were at positive pressure relative to the main ward. The problem was further compounded by the reluctance of Patient 2 to be isolated. It was this combination of inadequate isolation and proximity with HIV patients that led to the outbreak.

In the last decade, several similar outbreaks of tuberculosis and MDR-TB have been described in hospitals or other institutions, mostly in the USA.^{6–16,20} One outbreak involved 357 patients attending 41 different hospitals.¹² Most outbreaks have involved HIV patients, emphasizing their vulnerability to tuberculosis: once infected, these patients progress to disease more frequently and more rapidly than those who are HIV-negative.⁷ The chest X-ray appearance may be atypical, and the AFB in the sputum may be misinterpreted as mycobacteria other than *M. tuberculosis*, leading to delayed diagnosis. Mortality rates of 80–90% have been reported in these patients,²⁰ but rapid diagnosis and aggressive treatment can improve outcome.²¹ Factors contributing to these outbreaks include contact between HIV-positive patients or staff with tuberculous patients, delayed diagnosis resulting in inadequate therapy and prolonged infectiousness, and inadequate isolation. In some outbreaks, inadequate airflow in isolation rooms have also played a part.⁸ This outbreak demonstrated all of these factors and underlined how easily tuberculosis can become drug resistant and how readily it can be transmitted to patients infected with HIV.

Even though this was a relatively small outbreak, we identified nearly 1400 staff and patient contacts. Tracing and screening the contacts was a major undertaking, involving many hospital departments over several months. We identified no secondary cases in HIV-negative contacts, but infection in these patients may not manifest for many years, if at all.

Hospital staff were unaware that the isolation rooms in the North Wing (built 20 years ago) were engineered to be at positive pressure relative to the main wards to protect against fire hazards. It is essential for infection control teams to know the airflow of all isolation rooms in their institutions, and to be consulted on infection control aspects of new building work.

During the outbreak, molecular techniques were increasingly used for the rapid diagnosis of tuberculosis and MDR-TB. These techniques are useful, but only when applied appropriately; they are not a substitute for clinical skills in making the initial diagnosis. The outbreak also stimulated us to rewrite our tuberculosis policy, emphasizing the dangers of MDR-TB and the susceptibility of HIV patients. However, policies by themselves do not guarantee good practice; it is the responsibility of senior medical and nursing staff to ensure that those working with or for them are aware of the proper management of patients with tuberculosis.

In conclusion, patients who have open tuberculosis must not be nursed near patients with HIV. The airflow characteristics of all isolation rooms should be known by infection control and clinical staff, and positive-pressure rooms must not be used for containment isolation. HIV patients with AFBs in their sputum should be managed as if they might have tuberculosis until the true diagnosis is made, and the risk of drug resistance must be assessed. Patients who might have MDR-TB must be nursed in negative-pressure rooms. Antituberculous therapy must be supervised when there is any doubt about the patient's adherence to therapy, and single drugs should not be added to failing treatment regimens. Good communication between microbiologists, infection control staff, physicians and nurses is essential; local infection

control policies for tuberculosis should be developed, disseminated and adhered to by all staff.

Dispatches

Nosocomial Transmission of Multidrug-Resistant *Mycobacterium tuberculosis* in Spain

Before 1990, outbreaks of multidrug-resistant tuberculosis (MDRTB) were uncommon (1); since then, more than 10 outbreaks have been reported, all in hospitals and prisons in the eastern United States (2-7). Persons traditionally considered at risk for MDRTB (foreign-born TB patients and those inadequately treated for TB) have not been associated with these outbreaks. Instead, the presence of patients with active TB near immunocompromised patients in HIV-dedicated wards has led to MDRTB-infected HIV patients whose TB cases often go unrecognized. The patients receive inadequate treatment in facilities without effective procedures for isolating acid-fast bacilli; these circumstances favor nosocomial transmission. Health officials in other geographic areas where HIV and TB are major public health threats have been alerted to this emerging problem, and surveillance systems have been designed (8).

Spain has the highest reported incidence rate of AIDS in Europe (143.4 cases per million in 1994) (9). Although in Spain TB is not notifiable at the national level, reported rates in the autonomous community of Madrid for 1994 were among the highest in Europe (33.5/100,000) (10). During a 45-month period starting in September 1991, a number of patients and one health care worker became infected with MDRTB in a 120-bed, infectious disease reference hospital in urban Madrid. In May 1995, the Field Epidemiology Training Program of the Spanish Ministry of Health was invited to assist the Madrid Department of Health and hospital officials in investigating the outbreak. This report describes the findings of the epidemiologic and molecular laboratory investigation and analyzes risk factors associated with the outbreak. The study was designed in three parts: 1) a description of the reported MDRTB cases, including a laboratory investigation of isolates; 2) a case-control study comparing HIV-infected patients who also had MDRTB to HIV-infected patients who did not have MDRTB; and 3) a study of tuberculin conversion among hospital employees.

We reviewed the medical records and laboratory specimen testing results of a series of patients with MDRTB in the HIV-dedicated ward of the hospital for January 1991 through June 1995.

Cases were defined as patients with culture-confirmed TB and drug resistance to at least rifampin and isoniazid and with no previous history of inadequate treatment. Demographic and clinical variables were collected to characterize the cluster. Drug susceptibility testing and DNA subtyping analysis were performed with resistant strains available at the time of the study. Drug susceptibility testing was performed by the method of proportions in Middlebrook 7H11 medium distributed in petri plate compartments (reference).

All 48 reported cases of isoniazid and rifampin resistance were among HIV-infected patients hospitalized in the HIV-dedicated ward from September 15, 1991, to May 1995. One patient was an HIV-infected nurse who worked on the ward from 1990 to 1994. The mean age of patients was 34.1; 81.3% were male, and 66.6% were intravenous-drug users (Table 1). Of the 47 (97.9%) who died, the mean interval from diagnosis to death was 77.6 days.

The epidemiologic curve suggests a propagated transmission pattern of MDRTB among HIV ward patients, starting in 1991 and continuing until June 1995 (Figure 1). By the first 6 months of 1995, 65% of *Mycobacterium tuberculosis* strains seen among HIV ward patients were multidrug-resistant.

Table 1. MDRTB patient characteristics

Variable	Number (n = 48)	%
Sex		
Male	39	81.3
Female	9	18.7
Mean age	34.1	(6.8) ^a
HIV status		
Infected	48	100.0
HIV risk group		
Intravenous drug users	32	66.6
Homosexual	10	20.8
Others	6	12.6

Death	47	95.9
Discharge	1	4.1
Mean survival after MDRTB diagnosis (in days)	77.6	(107.8) ^a

^a Standard deviation.

Dispatches

*1995 data are for first 6 months only.

Figure 1. Hospital outbreak, Madrid, Spain, 1995.

At the beginning of the outbreak, no consistent antibiogram pattern was observed among isolates. However, beginning in 1993, strains were consistently resistant to isoniazid, streptomycin, ethambutol, and rifampin (HSEr); of the 26 patients with an MDRTB diagnosis since the last trimester of 1993, 24 (92.3%) had HSEr isolates. DNA subtyping analysis was performed on 12 of these HSEr isolates that were available. Eleven of the 12 strains had the same band patterns (Figure 2). Two additional isolates with a different antibiogram pattern had different banding patterns.

Subtyping of *M. tuberculosis* strains was performed (11) by analyzing DNA located between two copies of repetitive sequence IS6110. A 10- μ l sample of the extracted DNA was amplified in a reaction mixture containing 0.5 pM of each of the four primers (Ris1, Ris2, Pntb1, and Pntb2), 200 μ M dNTPs, 50 mM Tris-HCl, 50 mM KCl (pH 8.8), 2.5 mM MgCl₂, 0.1% Triton x-100, and 0.5% Taq polymerase. The samples were denatured by incubation at 95°C for 10 min and amplified by 30 cycles of denaturation at 94°C for 1 min, primer alignment at 56°C for 2 min, and primer extension at 72°C for 1 min. The amplification products were analyzed by electrophoresis in 2% agarose gel stained with ethidium bromide and observed with an ultraviolet transilluminator.

HIV-infected patients hospitalized on the HIV-dedicated ward between September 15, 1991, and December 31, 1994, who had TB diagnosed in 1994 with a known drug-susceptibility pattern were included in a case-control study. Case patients' isolates were resistant to isoniazid, rifampin, streptomycin, and ethambutol; control patients' isolates were sensitive to the same antimicrobial drugs.

*All strains of resistance pattern HSEr (isoniazid, streptomycin, ethambutol, rifampin) had similar DNA subtyping.

Figure 2. Evolution of MDRTB strain* over time, hospital outbreak, Madrid, Spain, 1995.

A time-person line diagram was prepared for each of the case patients and control patients, including all hospitalization dates, ward and room number, potentially infectious days, and possible days exposed to infective patients. Prior admission was defined as all admissions to the HIV-dedicated ward since the MDRTB patient was diagnosed (9/15/91) until the end of the period (12/31/94). TB patients were classified as "potentially infective" from the 2 week-period before sputum or culture results were positive for *M. tuberculosis* until the time sputum results were negative or the patient died. TB-negative patients were classified as "possibly exposed" if they were hospitalized on the HIV-dedicated ward during the time a potentially infective patient was also present, beginning on September 15, 1991, until 2 weeks before TB diagnosis.

Thirty-five patients (18 with cases and 17 controls) met the established study case/control definition. Case patients and control patients were not significantly different with respect to age, sex, HIV risk factors, interval between HIV and TB diagnoses or count of CD4 lymphocytes at the time of TB diagnosis (Table 2).

Before the hospitalization during which TB was diagnosed, 76.4% of the case-patients had been hospitalized on the HIV-dedicated ward of the hospital versus 23.5% of control patients (OR = 7.8 [1.4,50.5]) (Table 3). Of the five case patients with no prior hospitalization, three were family members of previously hospitalized HIV-infected patients who had visited the HIV ward frequently during the outbreak period.

Dispatches

Case patients and controls were compared with respect to possible exposure to a potentially infective wardmate beginning on 9/15/91 until 2 weeks prior to the diagnosis of TB. Case patients were more likely to have been exposed to potentially infective wardmates (72.2% with a median of 26.4 days) than control patients (41.2% with a median of 7.6 days). When we stratified possible ward exposure by days (0 days vs. 1 to 30 days vs. 30 days), we observed a dose-response effect, and the chi-square for linear trend was statistically significant (Table 3). Case patients were more likely to die during their initial hospitalization for MDRTB (94.4%) than were control patients (29.4%) during their hospitalization for TB (OR = 40.8 [3.6, 1842]) (Table 3).

A TB screening clinic visit was offered to all hospital employees after the outbreak was identified. Of the 591 active employees, 565 (95.6%) participated. Of these, 288 (51%) had not participated in previous hospital employee screening

programs conducted in 1990 and 1994. The overall prevalence of TB infection among participating employees was 450 (80%) of 565; only 115 (20%) of the current employees tested were tuberculin-negative.

Employees currently working at the hospital, who had a documented negative (< 6 mm) tuberculin test between January 1993 and June 1995 were eligible for this skin test conversion study. Many of the employees had received BCG vaccine. For those who had not received BCG vaccine, conversion was defined as an induration of 10 mm or greater with a change of at least 6 mm of induration since the last negative tuberculin test (12). For BCG vaccinees, conversion was defined as a 15-mm induration change since the last negative (< 6 mm) skin test.

Employees were defined as occupationally exposed if they worked in parts of the hospital where exposure to patients or *M. tuberculosis* was likely (the HIV-dedicated ward, HIV outpatient clinic,

radiology unit, the mycobacteriology laboratory, and the internal medicine ward). Employees were asked to quantify the cumulative number of months spent in these high-risk areas, regardless of their usual place of work, during the 30-month study period.

According to the Mantoux technique, 2 tuberculin units of purified protein derivative (PPD) tuberculin RT-23 were administered in the anterior forearm of the screened employees, and the results were read within 48 to 72 h. Of the participants, 92 (16.3%) were eligible for the conversion study. The incidence of conversion during the 30-month period was 24 of 92 (26%). Employees who had occupational exposure to high-risk areas had higher conversion rates than employees who did not have occupational exposure to high-risk areas (RR = 5.0 [2.7, 9.6]) (Table 4). The conversion had a dose-response effect, that is, the more months the person is occupationally exposed to high risk-areas, the higher the risk for conversion.

This is the first nosocomially transmitted MDRTB outbreak reported in

Spain, which, with recent outbreaks in the United Kingdom (13) and Italy, is among the first in Europe. Its characteristics are similar to the other reported outbreaks on that it occurred in an HIV-dedicated ward among non-foreign-born patients who had not been treated for TB; it had a high mortality rate within 3 months of onset during which mycobacteria laboratory surveillance recognized similar antibiogram resistant patterns; and identification of MDRTB isolates was followed by DNA subtyping, which confirmed that the same strain was responsible for the outbreak. Risk factors identified include admission to the HIV-dedicated ward and more "possible exposure" days to potentially infective wardmates; additionally, skin test conversion rates among employees were directly related to working in high risk areas of the hospital. The consistency of these findings with those reported in similar outbreaks and the fact that the same isolate was cultured over an extensive period among many different patients on a hospital ward without proper room isolation techniques support the conclusion that nosocomial transmission was the leading cause of the outbreak.

CDC's recommended guidelines for hospital TB prevention and control (14) were not fully implemented in the hospital. Acid-fast bacilli room isolation techniques were not in place; moreover, no ventilation system was available to provide negative pressure to prevent bacilli from passing from the MDRTB patients' rooms to the hallway or to provide the six air interchanges per hour recommended for removing bacilli from room air. Surgical masks used in the HIV-dedicated ward during the outbreak as protective masks are not

recommended for this purpose because of filtering and facial sealing problems. Observational visits to the HIV-dedicated ward revealed that MDRTB patients without masks were walking, talking, and smoking in the halls and in the lounge next to the unprotected patients, families, and staff.

Complete follow-up of employees is an essential component of a hospital control program (14). Because 80% of the employees in this outbreak were tuberculin-positive, chest radiographs became an important component for disease screening;

yearly surveillance of the tuberculin-negative employees will help determine if the interventions in place to prevent future outbreaks have worked in this setting.

Once the case-control study findings were analyzed, a TB control committee was established. All MDRTB patients were placed in a separate area of the hospital. Hospital staff were informed about the outbreak and alerted about future possible cases and the patient management and treatment schemes. The mycobacteria laboratory expanded the antibiogram service to include all second-line antibiotics used by the hospital clinicians. Clinicians have elaborated a treatment flow chart for MDRTB patients. Masks that fulfilled the sealage and filtering criteria (15) were purchased, and mask use was aggressively implemented. An employee health clinic was also instituted, with a prophylaxis and chest X-ray follow-up program for the 410 infected employees, along with a computerized follow-up surveillance system which included all employees graded by occupational risk category. Plans were made to screen tuberculin-negative employees every 3 months to identify those who had recently seroconverted. Family, community members and wardmates of all patients whose MDRTB had been diagnosed within the previous 6 months were notified of their risk and were scheduled for follow-up evaluations. The HIV-dedicated ward will be transformed into an acid-fast bacilli isolation zone, with an exclusive ventilation system that provides 11 individual rooms, each with 12 air interchanges per hour and negative pressure relative to the hallway.

Health officials in Europe need to be updated about this emerging problem, especially in areas

Dispatches

of high HIV and TB prevalence. Basic universal TB control and prevention measures (16,17) should be implemented by all general community hospitals in Spain, especially those with HIV-dedicated wards in areas where TB is prevalent. TB surveillance of health care employees is necessary to identify emerging problems as well as to protect employees, patients, and visitors.

Nosocomial transmission of multidrug-resistant *Mycobacterium tuberculosis*

W.R. Jarvis

*Hospital Infections Program, Centers for Disease Control,
National Center for Infectious Diseases, U.S. Public Health Service,
Atlanta, GA (USA)*

Concomitant with the resurgence of tuberculosis in the United States have been increasing reports of nosocomial transmission of TB. From January 1990 through September 1992, the Centers for Disease Control (CDC) investigated eight nosocomial outbreaks of multidrug-resistant tuberculosis (MDR-TB). Over 200 patients were infected; approximately 75 % of these patients died. Risk factors for infection included human immunodeficiency virus infection or acquired immunodeficiency syndrome and recent hospitalization on the same ward as other MDR-TB patients. Restriction fragment length polymorphism (RFLP) analysis of *M. tuberculosis* isolates revealed unique strains were transmitted in each hospital. In three hospitals, health care workers (HCW) assigned to wards with MDR-TB patients were shown to be more likely to have tuberculin skin test (TST) conversions than HCW assigned to wards without MDR-TB patients. These outbreaks demonstrate the serious morbidity and mortality associated with nosocomial MDR-TB and emphasize the importance of adhering to current CDC guidelines for preventing the transmission of tuberculosis in healthcare settings, with special focus on HIV-related issues.

Introduction

Before 1990, reports of nosocomial transmission of drug-susceptible or MDR-TB were uncommon in United States hospitals. During 1953 to 1985, the number of reported patients with TB in the U.S. steadily declined and elimination of TB became a goal of the U.S. Public Health Service (PHS). However, between 1985 and 1992, the number of reported patients with TB has increased, with nearly 40,000 excessive cases over what would have been expected if reported TB had decreased at the same rate as be-

tween 1980-1984 (Jereb *et al.*, 1990). Several factors are responsible for this increase, but HIV infection and AIDS have clearly played an important role.

In addition, before 1990, MDR-TB, i.e., *M. tuberculosis* strains resistant to isoniazid (INH) and rifampin (RIF), with or without resistance to other antituberculosis agents, were uncommon in the U.S. Most MDR-TB reported was thought to result from TB patients with drug-susceptible strains who acquired drug resistance as a result of noncompliance with their therapy. Thus, primary drug resistance, i.e., the first infection with *M. tuberculosis* being with MDR strains, was very uncommon.

Most nosocomial TB reported in the U.S. between 1970 and 1991 involved ≥ 1 source-patient with active TB, who was not known to have TB and was not on therapy, or was on therapy for either a very short time (< 2 days) or had a drug-resistant strain (Hutton *et al.*, 1992). In many reports, aerosol-producing medical procedures, such as bronchoscopy, endotracheal intubation, wound manipulation, respiratory tract manipulation or autopsy, were associated with transmission.

MDR-TB outbreaks

Between 1990 and 1992, the CDC has investigated eight nosocomial outbreaks of MDR-TB (table I) (Edlin *et al.*, 1992a; Pearson *et al.*, 1992; Beck-Sague *et al.*, 1992; Kent *et al.*, 1992; Valway *et al.*, 1992; Coronado *et al.*, 1992a,b; Jereb *et al.*, 1992; Stroud *et al.*, 1992). These outbreaks have demonstrated a change in the epidemiology of nosocomial TB in health care facilities. These outbreaks have involved primary MDR-TB infection in immunocompromised patients. Outbreaks have occurred in multiple states and involved between 7 and 10 patients. All MDR-

Table 1. Centers for Disease Control investigated nosocomial multidrug-resistant tuberculosis outbreaks, United States, 1989-1992.

Facility	Location	Time period	Total cases	Resistance pattern	% HIV infection	% Mortality	Interval, TB diagnosis to death (mean, weeks)
Hospital A	Miami	1988-1991	65	INH, RIF (EMB, ETA)	93	72	7
Hospital B	New York City	1989-1991	35	INH, SM (RIF, EMB)	100	89	16
Hospital C	New York City	1989-1992	70	INH, RIF, SM (EMB, ETA, KM, RBT)	95	77	4
Hospital D	New York City	1990-1991	29	INH, RIF (EMB, ETA)	91	83	4
Hospital E	New York State	1990-1991	7	INH, RIF, SM (EMB, ETA, KM, RBT)	14	43	4
Hospital F	New York City	1990-1991	16	INH, RIF, SM (EMB, ETA, KM, RBT)	82	82	4
Hospital I	New Jersey	1990-1992	13	INH, RIF (EMB)	100	85	4
Hospital J	New York City	1990-1992	18	INH, RIF, SM (EMB, ETA)	88	88	4

INH = isoniazid, RIF = rifampin, EMB = ethambutol, ETA = ethionamide, KM = kanamycin, SM = streptomycin, RBT = rifabutin.

TB strains have been resistant to at least INH and RIF, except for one outbreak where the predominant strain was resistant to INH and streptomycin. In addition, most strains have been resistant to from one to five other antituberculous agents. In each of the outbreaks, except for one outbreak (hospital E) that involved transfer of an infectious MDR-TB patient from a prison, the majority of infected patients had HIV infection or AIDS. In all but one outbreak (hospital E), mortality in patients exceeded 70 %. The interval from TB diagnosis to death ranged from 4-16 weeks (median 8 weeks).

Risk factors for nosocomial MDR-TB

In case-control studies, numerous risk factors for MDR-TB infection were identified (table II). These included having an HIV infection or AIDS, prior hospitalization and exposure to another infectious MDR-TB patient. MDR-TB patients did not have a prior history of TB or TB treatment and were more likely to have had prior opportunistic infections and lower CD4-T-lymphocyte counts, suggesting that the infections were likely primary infection rather than reactivation. Exposure to an acid-fast bacillus (AFB) sputum-smear and culture-positive MDR-TB patient placed patients at greater risk of acquiring MDR-TB than exposure to an AFB sputum smear-negative, culture-positive MDR-TB patient.

Other factors contributing to the outbreaks include: delayed recognition of TB in patients because of atypical presentation or low clinical suspicion; delayed initiation of effective treatment regimens; length of time required to perform and report culture and drug-susceptibility results; prolonged period of infectiousness; delayed institution, inadequate duration of, and/or inadequate facilities for AFB isolation.

In most episodes, the MDR-TB patient presented with pulmonary symptoms and fever (Coronado *et al.*, 1992b). However, because few patients had classical signs of TB, i.e., cavitory lesions or miliary patterns on chest x-ray, neither tuberculin skin tests (TSTs) nor AFB sputum smears were performed in a timely fashion. Most MDR-TB patients had abnormal chest x-rays, however, the infiltrates were often interstitial and varied in location. When cultures were obtained, there were delays in obtaining *M. tuberculosis* culture (median 7 weeks) and drug susceptibility (additional median 7 weeks) results. This contributed to delays in institution of effective antituberculosis therapy. Patients were diagnosed a median of six weeks after onset of symptoms and died a median of seven weeks after onset of symptoms. The median time from diagnosis until death was eight weeks. Thus, MDR-TB patients were often culture-positive during their entire hospitalization until death. A subsequent study has shown that with earlier diagnosis and therapy, clinical outcome can be improved (Edlin *et al.*, 1992b).

Table II. Risk factors for nosocomial multidrug-resistant *M. tuberculosis* infection, 1989-1992.

Human immunodeficiency virus infection/acquired immunodeficiency syndrome (AIDS)
Duration of AIDS
Prior opportunistic infection
Previous hospitalization
Hospitalization (exposure) on the same ward as another infectious MDR-TB patient
Exposure to an acid-fast bacillus sputum smear-positive MDR-TB patient
Proximity to infectious MDR-TB patient
Lower CD ₄ -T lymphocyte count

Because of delays in clinical suspicion of TB and delays in diagnosis, institution of AFB isolation was often delayed. In addition, many patients either did not stay in their AFB isolation rooms (patients visited lounges, walked hallways masked improperly, or went to common bathroom facilities), AFB isolation was discontinued prematurely (before clinical improvement and three negative AFB sputum smears), and/or AFB isolation facilities did not meet current CDC recommendations (i.e., air flow systems with negative pressure in relation to hallway and other rooms, six air exchanges per hour, and air exhaust directly outside). These factors contributed to nosocomial MDR-TB transmission to other patients and HCW.

Molecular epidemiologic investigations

In each of the outbreaks, infecting MDR-TB isolates were obtained and genetically typed using RFLP (Cave *et al.*, 1991; Crawford *et al.*, 1992). RFLP typing confirmed a unique common strain (which usually varied between hospitals) being transmitted in each hospital. RFLP was a more consistent marker than antimicrobial susceptibility pattern. These molecular typing data confirmed the epidemiologic data that MDR-TB was being transmitted nosocomially.

Risk of MDR-TB infection/disease in HCW

HCW also were at risk of MDR-TB infection. In comparative studies, HCW on the outbreak wards were at greater risk of TST conversion than HCW on control wards or at an AIDS outpatient clinic (Beck-Sague *et al.*, 1992). In three of the hospitals, TST conversions were identified in 24/108 (22 %), 13/39 (33 %), and 6/12 (50 %) HCW tested. At least 16 HCW have developed active MDR-TB; seven of those HCW are HIV-positive. At least five HCW have died with MDR-TB; four are known to be HIV-positive. In most of the hospitals, HCW were not wearing adequate respiratory protection i.e. partic-

ulate respirators, when they entered infectious MDR-TB patients' rooms; this included wearing no mask or wearing a mask improperly.

Infection control interventions and their efficacy

Thus, in each of these hospitals, MDR-TB outbreaks occurred when current CDC guidelines for preventing TB transmission in health care facilities were incompletely implemented (Centers for Disease Control, 1990). Follow-up investigations at several of these MDR-TB outbreak hospitals reveal varying degrees of implementation of the guidelines. At one hospital, which has implemented most of the guidelines, nosocomial MDR-TB transmission to patients and HCW has been terminated on the outbreak ward (Otten *et al.*, 1992; Wenger *et al.*, 1992). At another hospital, where the CDC guidelines have been "less fully implemented" (i.e. rapid identification, isolation in rooms even if not negative pressure), MDR-TB transmission to patients has been significantly reduced (Maloney *et al.*, 1992). A recent study by Stroud *et al.* suggests that improved clinician education to suspect TB, rapid diagnosis, and appropriate isolation of patients significantly reduces the risk of patient-to-patient MDR-TB transmission (personal communication). These data support the efficacy of the 1990 CDC guidelines and illustrate the importance of implementing these guidelines to prevent nosocomial MDR-TB transmission.

Status of U.S. hospitals to infection control programs

A recent survey of U.S. hospitals shows that; (1) MDR-TB patients were admitted to hospitals in at least 40 states; (2) HCW TST were usually applied upon employment but follow-up or repeat TST varied widely afterwards; (3) the number of AFB isolation rooms in each hospital varied widely, ranging from 0 to 99 (median 6) rooms; and (4) hospitals reported nosocomial TB transmission to patients

and/or HCW (Rudnick *et al.*, 1992). These data show that MDR-TB is widespread in many areas of the U.S. and that enhancement of HCW TST programs, AFB isolation facilities, and TB infection control practices are necessary to meet the challenge of the changing epidemiology of MDR-TB.

Recommendations

These outbreaks serve as a reminder of the importance of adequate diagnostic and infection control practices if MDR-TB outbreaks are to be terminated or prevented (table III). It is essential that clinicians maintain a high index of clinical suspicion of TB. TB can occur concomitantly with other pathogens, and thus any AFB-positive respiratory specimen should be considered *M. tuberculosis* until proven otherwise. Newer diagnostic tests, such as genetic probes, can facilitate rapid diagnosis (Cleary *et al.*, 1992). Other diagnostic tests, such as fluorescence microscopy and radiometric culture, and drug susceptibility testing can facilitate earlier diagnosis, more rapid institution of effective therapy, and early institution of AFB isolation.

Any patient with suspected or confirmed TB should be placed in AFB isolation. Effective isolation includes: negative pressure ventilation, at least

six air exchanges per hour, and air exhausted to the outside (Centers for Disease Control, 1990). To insure adequate AFB isolation, the direction of air flow should be frequently monitored. Patients in AFB isolation should remain in their rooms with the doors closed. If the patient must leave the room (medical emergency or essential procedures), the patient should wear a mask. Similarly, persons entering the AFB isolation room should wear respiratory protection. MDR-TB patients should not be removed from AFB isolation until they have both evidence of clinical improvement and the number of organisms on sequential sputum AFB smears is decreasing. When a patient is likely to be infected with drug-resistant organisms, AFB precautions should be applied until the patient is improving *and* has three successive negative AFB sputum smears.

Because of the risk of TB transmission to HCW, an active HCW TST program is essential. *All* HCW (including paid and unpaid hospital workers, medical students, attending staff, volunteers, those that have received BCG, etc.) should have baseline TST. Periodically, retest TST-negative HCW; in non-outbreak situations, TST should be conducted at least annually; where an outbreak has occurred, in high risk areas or groups, and in those with known TB contacts, TST should be conducted more frequently (≤ 6 months). In hospital A, where MDR-TB trans-

Table III. Measures necessary to prevent nosocomial tuberculosis transmission.

Early identification

- high index of suspicion
- rapid diagnostic work-up

Use rapid diagnostic techniques

- fluorescent microscopy for smears
- radiometric methods for identification and drug susceptibility testing

Prompt initiation of adequate AFB Isolation

- negative pressure rooms
- ≥ 6 air exchanges per hour
- exhaust air directly outside
- keep patient in room
- doors closed
- do not remove MDR-TB-patients from isolation until both clinical improvement *and* three successive negative AFB smears
- persons entering the room should wear respiratory protection
- appropriate follow-up of discharged patients

Prompt initiation of effective antituberculosis therapy

Monitor adequacy of therapy

- frequent acid-fast bacillus (AFB) smears and culture
-

mission was terminated, TST every 3-4 months of ward HCW was essential for evaluating the efficacy of introduced control measures (Otten *et al.*, 1992; Wenger *et al.*, 1992). All HCW with positive TST should be promptly evaluated for active disease; if active disease is ruled out, evaluate for preventive therapy (Villarino *et al.*, 1992). Of utmost importance, TST data must be collected and analysed so that high risk areas, procedures, and personnel can be identified and the efficacy of infection control practices assessed.

Conclusion

The emergence of nosocomial outbreaks of MDR-TB in U.S. hospitals is a serious public health problem requiring rapid response. The CDC and other PHS agencies have developed a PHS TB Task Force and a CDC TB Working Group to quickly initiate action to control this serious problem. A PHS TB Action Plan has been developed with a step-by-step approach to reducing TB and controlling nosocomial TB transmission. A CDC meeting of outside experts was held in October 1992 to review and assess the current 1990 CDC TB guidelines. The consensus was that the guidelines needed some revision, but that, in general, the 1990 CDC guidelines were adequate but not widely implemented in U.S. hospitals. Because of the serious morbidity and mortality to both patients and HCW resulting from nosocomial MDR-TB transmission, the current CDC guidelines should be fully implemented immediately in hospitals so that MDR-TB transmission in healthcare facilities can be prevented.

Multiple-drug-resistant tuberculosis: clinical and laboratory issues

J.E. McGowan, Jr.

*Clinical Microbiology Laboratory (Box 26248), Grady Memorial Hospital,
and Emory University School of Medicine, Atlanta, GA 30335 (USA)*

Introduction

During the past few years, tuberculosis (TB) has become a subject of concern in the United States to both healthcare workers and the public (Cowley, Leonard, and Hager, 1992). In part, this concern results from the recent appearance of *Mycobacterium tuberculosis* strains resistant to the usual first line drugs used to treat TB. This review details several factors determining the current pattern of TB in the United States, the clinical importance of multidrug-resistant TB (MDR-TB), and the increased importance that MDR-TB brings to preventing nosocomial spread of the disease. The steps needed to control TB in the hospital setting will be discussed, and the impact of these measures on the laboratory then will be highlighted.

Changes in the pattern of tuberculosis in the United States

In the United States, TB did not receive the respect it deserves during the 1980s (McGowan, 1992). There were many reasons for this. First, TB

was thought to be a disappearing disease, the subject of an elimination effort created by the Centers for Disease Control (CDC) (Centers for Disease Control, 1989). Second, TB by the 1980s had become primarily a disease of the disadvantaged — cases of TB became a rarity except in United States hospitals serving the homeless and the helpless. As these hospitals and their patients tend to be ignored by the health authorities and the public, TB was lost to medical attention, especially in comparison to new problem infections like acquired immunodeficiency syndrome (AIDS). Third, virtually all TB isolates were susceptible to the two major drugs used for treatment, isoniazid and rifampin. The tuberculocidal action of these drugs in combination made treatment shorter and easier than ever before. When resistance to these drugs was found in occasional strains, these usually emerged from initially susceptible strains in patients who were non-compliant with therapy, or were found in patients with infections acquired in countries other than the United States. Thus, the threat of TB seemed diminished. As a result, during this period, TB control programs at the federal, state, and local levels were cut back or eliminated (Glassroth, 1992; Bloom and Murray, 1992).

EVALUATION OF INFECTION CONTROL MEASURES IN PREVENTING THE NOSOCOMIAL TRANSMISSION OF MULTIDRUG-RESISTANT MYCOBACTERIUM TUBERCULOSIS IN A NEW YORK CITY HOSPITAL

ABSTRACT

OBJECTIVE: To evaluate the efficacy of Centers for Disease Control and Prevention (CDC)-recommended infection control measures implemented in response to an outbreak of multidrug-resistant (MDR) tuberculosis (TB).

DESIGN: Retrospective cohort studies of acquired immunodeficiency syndrome (AIDS) patients and healthcare workers. The study period (January 1989 through September 1992) was divided into period I, before changes in infection control; period II, after aggressive use of administrative controls (eg, rapid placement of TB patients or suspected TB patients in single-patient rooms); and period III, while engineering changes were made (eg, improving ventilation in TB isolation rooms).

SETTING: A New York City hospital that was the site of one of the first reported outbreaks of MDR-TB among AIDS patients in the United States.

PARTICIPANTS: All AIDS patients admitted during periods I and II. Healthcare workers on nine inpatient units with TB patients and six without TB patients.

RESULTS: The epidemic (38 patients) waned during period II and only one MDR-TB patient presented during period III. The MDR-TB attack rate among AIDS patients hospitalized on the same ward on the same days as an infectious MDR-TB patient was 8.8% (19 of 216) during period I, decreasing to 2.6% (5 of 193; $P=0.01$) during period II. In a small group of healthcare workers with tuberculin skin test data, conversions during periods II through III were higher on wards with than without TB patients (5 of 29 versus 0 of 15; $P=0.15$), although the difference was not statistically significant.

CONCLUSIONS: Transmission of MDR-TB among AIDS patients decreased markedly after enforcement of readily implementable administrative measures, ending the outbreak. However, tuberculin skin-test conversions among healthcare workers may not have been prevented by these measures. CDC guidelines for prevention of nosocomial transmission of TB should be implemented fully at all US hospitals (*Infect Control Hosp Epidemiol* 1995;16:141-147).

INTRODUCTION

Nosocomial transmission of tuberculosis (TB) to healthcare workers (HCWs) is a well-documented risk, usually associated with highly infectious patients with unsuspected disease.^{1,2} In 1989, nosocomial transmission of drug-sensitive TB to human immunodeficiency virus (HIV)-infected patients was reported in

Italy³ and investigated by the Centers for Disease Control and Prevention (CDC) in Puerto Rico.⁴ In 1990, Jackson Memorial Hospital in Miami and Roosevelt Hospital in New York City reported to the CDC outbreaks of multidrug-resistant (MDR) tuberculosis (TB). Nosocomial transmission was suspected but confirmed only after completion of detailed epidemiol-

ologic and laboratory studies.^{5,6} Subsequently, the CDC documented nosocomial transmission of MDR-TB at six additional US hospitals and a New York state prison.⁷⁻¹³ These outbreaks were associated with incomplete implementation of CDC TB infection control guidelines.¹⁴⁻¹⁶

Many TB infection control measures are of unproven efficacy. In the wake of recent nosocomial outbreaks, the adequacy of CDC TB infection control guidelines has been questioned. An important component of the National Action Plan to Combat MDR-TB, published in 1992, is an assessment of TB infection control strategies.¹⁷ Data on the efficacy of such strategies has been used in the revision of CDC TB infection control guidelines.¹⁸

Our initial report described the epidemic of MDR-TB among acquired immunodeficiency syndrome (AIDS) patients at Roosevelt Hospital⁶ during an era when CDC-recommended TB infection control guidelines were poorly implemented at many US hospitals. Nosocomial transmission on inpatient-care units was implicated strongly and explained 13 of 18 outbreak patients; the remaining five patients may have acquired disease in other areas of the hospital (eg, outpatient clinics, radiology department) or community settings. Evaluation of patient-to-HCW transmission was hampered by insufficient tuberculin skin-test data.¹⁹ The objectives of our currently reported study were to assess changes in infection control policy and procedures made in response to the outbreak and to evaluate the impact that these changes had on transmission of MDR-TB from patient to patient and from patient to HCW.

METHODS

To ascertain changes in infection control measures, in September 1992 we interviewed infection control personnel, reviewed hospital isolation policies and practices, and inspected hospital facilities. A smoke dispenser was used to determine the direction of airflow in rooms used for TB isolation. On the basis of infection control precautions used, the study period (January 1989 to September 1992) was divided into three 15-month intervals: period I (January 1989 to March 1990), period II (April 1990 to June 1991), and period III (July 1991 to September 1992).

Case-Patients

To facilitate comparison, we used the definitions and methodology employed in our previous study⁶ whenever possible. A case-patient was defined as any patient meeting the 1987 CDC AIDS case definition²⁰ who had a diagnosis of active TB at Roosevelt Hospital during the study period, and whose *Mycobacterium tuberculosis* isolate was resistant to at least isoniazid

and streptomycin (MDR-TB). The date of diagnosis was defined as the date of collection of the first specimen culture positive for MDR-TB. Hospital mycobacteriology and infection control records were reviewed to identify case-patients; medical records were reviewed to obtain demographic, clinical, and microbiologic data. Case-patients were considered to be infectious for 15 days before and after having a positive acid-fast bacillus (AFB) smear from sputum or bronchoalveolar lavage fluid.

Cohort Study Among AIDS Patients

A cohort study was performed among all AIDS patients identified in the hospital's AIDS center program data base who were admitted during periods I or II. AIDS patients who had TB at the time of first admission, or who developed TB not meeting the case definition, were excluded. The risk of same-ward exposure (hospitalization on the same ward on the same days as an infectious case-patient) was compared for periods I and II. Days of same-ward exposure were determined from a hospital computer data base with information on ward and room assignments. For case-patients, same-ward exposures <14 days before the date of MDR-TB diagnosis were excluded. A small number of computer-identified same-ward exposures of 1-day duration were excluded because comparisons with hospital charts showed that such exposures often had not occurred (ie, they were due to errors in the hospital computer data base); however, these comparisons proved the data base to be reliable for exposures of ≥ 2 days.

Laboratory Studies

Case-patient *M tuberculosis* isolates were tested by the hospital laboratory for resistance to at least isoniazid, rifampin, streptomycin, and ethambutol. At the CDC, antimicrobial resistance testing was repeated, and restriction fragment length polymorphism (RFLP) analysis was performed on available case-patient *M tuberculosis* isolates.^{6,21}

TB Infection Among Healthcare Workers

We reviewed hospital employee health records to obtain demographic, clinical, and tuberculin skin-test information on HCWs. Skin tests were performed using the Mantoux technique (intradermal injection of 0.1 mL of intermediate-strength purified protein derivative). Employee health personnel or the authors performed and read all skin tests. Tuberculin skin-test conversion (defined for this study as ≥ 10 mm increase in induration) rates among healthcare workers during periods II and III were compared on nine units with and six units without TB patients. To exclude reactivity due to TB exposure during period I, only workers

† Among infectious case-patients (N = 11 for period I, N = 16 for periods II through III).

‡ Among case patients with same-ward exposure (N = 11 for period I, N = 17 for periods II through III).

§ Antituberculous drugs begun within 2 weeks of diagnosis, excluding those to which the isolate was resistant in vivo.

suspected TB often exceeded the number that had undergone these modifications. Isolation chambers were used for sputum induction and aerosolized pentamidine therapy, and dust-mist respirators (3M no. 8715, Minneapolis, MN) were used by HCWs during such procedures. Surgical masks (Technol. no. 47080-070, Fort Worth, TX) were used for routine care of patients on TB isolation precautions.

During the study period, 46 patients had TB resistant to isoniazid and streptomycin; 38 (83%) also had AIDS and, therefore, met the case definition (Figure). The proportion of total TB patients meeting the case definition was similar during periods I (16 [16.3%] of 98) and II (21 [17.4%] of 121; $P = 1.0$), but decreased significantly during period III (1 [1.3%] of 76; $P < 0.001$ compared with periods I and II combined).

Compared with case-patients who had MDR-TB diagnosed in period I, period II and III case-patients were older and more likely to be black, but these differences were not statistically significant (Table 1). Also, for period I versus periods II and III, the proportions of case-patients that were infectious were similar. However, placement of infectious patients in TB isolation on the day of admission rose significantly from 0% to 44%, and the median time from admission to TB isolation decreased from 6 to 2 days (Table 1).

Use of antituberculosis therapy and mortality did not differ significantly during the two intervals (Table 1).

The Risk of Nosocomial Transmission to AIDS Patients

The cohort of 1,356 AIDS patients admitted during periods I or II included 32 case-patients (six case-patients were admitted after diagnosis of MDR-TB and, therefore, were not included in the cohort study). Case-patients were similar to other cohort patients in numbers of days hospitalized during periods I and II (median, 33.5 versus 28.0, respectively; $P = 0.6$).

The MDR-TB attack rate was 0.5% (4 of 863) for AIDS patients without same-ward exposure, 8.8% (19 of 216) for those with period I exposures only, 2.6% (5 of 193) for those with period II exposures only, and 4.8% (4 of 84) for those with exposures in both periods I and II. The one case-patient presenting in period III had no same-ward exposures during period III.

Among the 216 AIDS patients with same-ward exposure during period I only, the attack rate decreased as exposure distance (ie, number of rooms from the infectious patient) increased, but did not show a progressive increase as the total days of exposure increased (Table 2). Most exposures

* 84 patients (four of whom were case-patients) with same-ward exposure during both periods I and II are not tabulated.

† $P < 0.05$ compared with the attack rate (4/863 [0.5%]) among those without exposure in either period.

‡ Data tabulated only for infectious patients exposing ≥4 case patients.

occurred on wards A and B. Of 27 infectious MDR-TB patients, five exposed ≥4 case-patients during period I (Table 2, patients A through E).

Although approximately equal numbers of AIDS patients had same-ward exposures in periods I and II, the MDR-TB attack rate was significantly lower during period II (19 of 216 versus 5 of 193; $P = 0.01$). Among 193 AIDS patients exposed during period II only, attack rates were not related to exposure distance or to total days exposed, but were associated highly with exposure to patients F and G (Table 2). Of five case-patients exposed during period II only, four were exposed to both patients F and G during July 1990, and the fifth was exposed to patient F during June 1990.

TABLE 3

LOGISTIC REGRESSION MODEL: EFFECT OF SAME-WARD EXPOSURE ON RISK OF MDR-TB AMONG 1,356 AIDS PATIENTS ADMITTED DURING PERIODS I AND II, ROOSEVELT HOSPITAL, JANUARY 1989 THROUGH JUNE 1991

Factor	Odds Ratio	P Value
No exposure	1.0	–
Period I exposures		
Exposure distance		
Same room	15.3	<0.001
1 room	3.9	0.01
2 to 3 rooms	1.1	0.9
4 to 5 rooms	1.5	0.5
≥6 rooms	0.2	0.01
Patient A	6.2	0.01
Patient C	10.9	<0.001
Period II exposures		
Patient G	40.0	<0.001
Other patients	0.7	0.4

A logistic regression model was used to assess the independent importance of exposure distance and exposure to specific infectious patients. To assess the importance of exposure duration, each variable was evaluated both as a dichotomous variable coding for the presence or absence of the exposure and a continuous variable coding for the number of days of such exposure; however, the continuous variables were less predictive of risk, and none were incorporated into the model (Table 3). During period I, the risk of MDR-TB was related independently to exposure distance and exposure to patients A and C; during period II, risk was related only to exposure to patient G. Interaction terms between patients (A and C) and exposure distance (same room or one room away) were not statistically significant and were not incorporated into the model.

A separate analysis was performed to evaluate the importance of exposure to case-patients who were culture-positive but smear-negative from pulmonary specimens. Forty-six AIDS patients in the cohort were hospitalized on the same ward at the same time as such patients; only one of the 46 (who also had exposure to smear-positive case-patients) contracted MDR-TB. We also explored the possibility of transmission from eight patients with isoniazid-streptomycin-resistant TB but not meeting the case definition because they did not have AIDS; the MDR-TB attack rate was 0 of 120 after same-ward exposure to such patients.

Laboratory Results

Among the 38 case-patient *M tuberculosis* isolates (all were resistant to isoniazid and streptomycin by

definition), 26 (68%) were rifampin resistant and 15 (39%) were ethambutol resistant; of 18 tested, 2 (11%) were amikacin resistant; of 19 tested, none were ciprofloxacin resistant.

Of 35 *M. tuberculosis* isolates available for RFLP typing, 32 (91%) had an identical pattern (outbreak pattern), two (6%) shared a unique pattern identified during a nosocomial outbreak at another New York City hospital, and one (3%) had a distinct pattern. Of the 32 patients with outbreak pattern isolates, three also had a second isolate collected on a different occasion with a different RFLP pattern. When only RFLP-typed isolates were considered, among 26 from patients with same-ward exposure, all had the outbreak pattern; among nine from patients without same-ward exposure, six had the outbreak pattern ($P=0.01$). All five case-patients with same-ward exposures only during period II had an isolate with the RFLP outbreak pattern.

TB Infection Among Healthcare Workers

Although most HCWs had at least one tuberculin skin test performed during periods II and III, paired (baseline and follow-up) tuberculin skin tests were available for only 29 (16%) of 181 HCWs on nine wards with TB patients and 15 (14%) of 110 workers on six wards without TB patients. Most workers with paired tests had a baseline test in period II and a follow-up test in period III; therefore, it was not possible to calculate separate conversion rates for the two periods. During periods II and III, the HCW tuberculin skin-test conversion rate was higher on the TB-care wards than on other wards, although the difference was not statistically significant (5 of 29 versus 0 of 15; $P=0.15$).

None of the HCWs with skin-test conversion had evidence of active disease. However, four other HCWs developed isoniazid-streptomycin-resistant TB; of three isolates tested by RFLP, all had the Roosevelt Hospital outbreak strain. All four worked during period I, and two also worked during period II. Two were HIV positive, one was HIV negative, and one was not tested for HIV but had a normal CD4+ lymphocyte count. No active TB was identified among those who worked only during periods II and III.

DISCUSSION

Our initial report documented nosocomial MDR-TB transmission among AIDS patients.⁶ Continued surveillance revealed a decline in the number of case-patients, forming a typical "epidemic curve." The usual reasons for such a pattern (ie, the epidemic having been caused by a point source or ended because of exhaustion of susceptibles) do not apply to this outbreak: our investigation suggested transmis-

sion from several source patients and documented continuing same-ward exposure of susceptible AIDS patients. Although reduced transmission in the community and in other New York City hospitals may have played a role, most of the decline probably was due to improvements in infection control at Roosevelt Hospital.

In response to the outbreak, administrative infection control precautions were stressed during period II. Patient-to-patient MDR-TB transmission declined, and only one case-patient presented during period III. This result documents the efficacy of early identification, isolation, and treatment of infectious TB patients. However, MDR-TB was transmitted to at least five patients during period II, after administrative measures were stressed but before environmental changes were made. Transmission probably was from a particularly infectious patient; patient F exposed all five case-patients, but patient G (who exposed 4 of 5) was associated more strongly statistically. Regardless of the source patient, this continued nosocomial transmission during period II underscores the importance of full implementation of CDC guidelines.

The last case-patient was diagnosed months before installation of exhaust fans to improve ventilation in TB isolation rooms. However, before installation of these fans, most rooms had air exhausted directly to the outside; although this feature did not prevent the outbreak, it may have contributed to ending it.

During period I, risk of acquiring MDR-TB was independently conferred by same-ward exposures at short distances to any infectious case-patient, and exposures at any distance to two specific patients (A or C). During period II, AIDS patients continued to be hospitalized in proximity to infectious MDR-TB patients, but attack rates after such exposure were reduced substantially. In addition to the protection afforded by earlier placement of infectious patients in TB isolation rooms, period II case-patients may have been less infectious on average, in part due to earlier antimycobacterial treatment.

These findings are in accord with those of two other CDC follow-up studies at hospitals that have experienced MDR-TB outbreaks.^{22,23} Both studies showed that use of CDC-recommended infection control measures resulted in termination of the outbreaks. At neither of these two hospitals were UV lamps installed. At Roosevelt Hospital, installation of UV lamps began during the month of diagnosis of the last case-patient; therefore, we are unable to assess whether UV lamps were protective.

Ten of 38 MDR-TB patients could not be explained by documented same-ward exposures, six had no Roosevelt Hospital admissions prior to diagnosis, and four had previous admissions but no same-

ward exposures. The results of RFLP typing suggested that two patients had acquired MDR-TB at another New York City hospital. The mode of acquisition for the other eight (six of whom had isolates with the RFLP outbreak pattern on at least one occasion) is uncertain. We were unable to evaluate the possibility of acquisition in the community or in areas of the hospital other than patient-care wards.

The rate of tuberculin skin-test conversion on TB-care wards during periods II and III was high, but data were not available on a sufficient number of workers to evaluate risk adequately. The minority with both a baseline and follow-up skin test may not have been representative of other workers. Because HCWs must enter TB isolation rooms routinely and work in proximity to infectious patients, the combination of administrative controls, engineering controls, and personal protective equipment (eg, respirators) may be needed to safeguard this group.

We conclude that, at Roosevelt Hospital, inexpensive and readily implementable administrative measures, such as rapid identification and isolation of known and suspected TB patients, greatly reduced patient-to-patient transmission of MDR-TB and ended the outbreak. Although active disease did not occur among healthcare workers who worked only during periods II and III, tuberculin skin-test conversions among workers may not have been prevented by these administrative measures. It is possible that earlier complete implementation of CDC guidelines, especially use of negative-pressure TB isolation rooms and provision of particulate respirators to workers, would have reduced nosocomial transmission further. Full implementation of CDC guidelines^{16,18} at hospitals caring for TB patients is recommended for maximum protection of both patients and HCWs.

Efficacy of Control Measures in Preventing Nosocomial Transmission of Multidrug-Resistant Tuberculosis to Patients and Health Care Workers

Susan A. Maloney, MD, MHS; Michele L. Pearson, MD; Marcia T. Gordon, RN; Rachel Del Castillo, RN; John F. Boyle, PhD; and William R. Jarvis, MD

■ **Objective:** To assess the efficacy of control measures in decreasing nosocomial transmission of multidrug-resistant tuberculosis.

■ **Design:** Retrospective cohort study.

■ **Setting:** A teaching hospital in New York City.

■ **Population:** 40 patients hospitalized with multidrug-resistant tuberculosis (case-patients) and health care workers receiving tuberculin skin testing.

■ **Interventions:** Centers for Disease Control and Prevention (CDC) 1990 guidelines for preventing transmission of tuberculosis, including 1) prompt isolation and treatment of patients with tuberculosis; 2) rapid diagnostic techniques for processing *Mycobacterium tuberculosis* specimens; 3) negative-pressure isolation rooms; and 4) molded surgical masks for health care workers.

■ **Measurements:** Proportion of case-patients with nosocomially acquired tuberculosis and rate of tuberculin skin test conversion among health care workers before and after implementation of control measures.

■ **Results:** The proportion of patients with multidrug-resistant strains of *M. tuberculosis* decreased after the interventions (10 of 70 [14%] compared with 30 of 95 [32%] patients before the intervention; relative risk [RR], 0.5; 95% CI, 0.2 to 0.9). Before onset of multidrug-resistant tuberculosis, case-patients in the intervention period were as likely to be hospitalized on high-risk wards containing patients with tuberculosis (4 of 10 compared with 17 of 30 patients; RR, 0.7; $P = 0.5$) but were less likely to be exposed to another case-patient with tuberculosis (1 of 10 compared with 20 of 30 patients; RR, 0.2; $P = 0.003$). Tuberculin skin test conversion rates for health care workers assigned to wards housing patients with tuberculosis were lower in the intervention period than in the preintervention period (4 of 78 [5%] compared with 15 of 90 [17%] conversions; $P = 0.02$), decreasing to levels observed for workers assigned to other wards (4 of 78 [5%] compared with 9 of 228 [4%] conversions; $P = 0.7$).

■ **Conclusions:** Implementing control measures reduced nosocomial transmission of multidrug-resistant strains to patients and health care workers.

Nosocomial transmission of *Mycobacterium tuberculosis*, particularly transmission of multidrug-resistant strains, to patients and health care workers is a major public health problem (1–12). From 1990 through 1992, the Centers for Disease Control and Prevention (CDC) investigated eight outbreaks of multidrug-resistant tuberculosis in U.S. hospitals (1–6; CDC, unpublished data). More than 300 patients with multidrug-resistant tuberculosis were identified during these investigations; most (87%) were infected with human immunodeficiency virus (HIV). Their clinical course was characterized by rapid progression from infection to active tuberculosis and their mortality rate was high (9). Additionally, more than 100 health care workers at hospitals where outbreaks of multidrug-resistant tuberculosis had occurred had conversion of their tuberculin skin tests, suggesting recently acquired *M. tuberculosis* infection. At least 17 of these newly infected health care workers developed active multidrug-resistant *M. tuberculosis*, and at least 7 of them died with multidrug-resistant tuberculosis (10).

Because of the explosive and fatal nature of these recent nosocomial outbreaks of multidrug-resistant tuberculosis, questions have been raised about the most effective interventions and control measures necessary to prevent institutional transmission of tuberculosis (13–15). We evaluated the efficacy of control measures for decreasing the transmission of these multidrug-resistant *M. tuberculosis* strains in one of the hospitals that had had an outbreak.

Methods

In May 1991, we investigated an outbreak of multidrug-resistant tuberculosis at Cabrini Medical Center, a teaching hospital in New York City. In that investigation, epidemiologic and laboratory data showed the occurrence of nosocomial transmission of multidrug-resistant tuberculosis to patients and health care workers (5). Risk factors for acquisition of multidrug-resistant tuberculosis by patients included age, HIV seropositivity, and hospital admission to Cabrini Medical Center within 7 months before onset of multidrug-resistant tuberculosis. Additionally, health care workers assigned to the medical or HIV wards (primary wards housing patients with tuberculosis) were identified as being at increased risk for tuberculin skin test conversion. Conditions facilitating tuberculosis transmission included delayed identification, isolation, or treatment of patients with infectious tuberculosis; lapses in tuberculosis isolation practices; and inadequate isolation facilities for patients with tuberculosis. In response to the outbreak, control measures similar to those recommended in the CDC's 1990 tuberculosis guidelines were instituted to prevent further nosocomial transmission of tuberculosis (16).

Control Measures

Numerous measures were introduced to decrease transmission of multidrug-resistant tuberculosis, including source controls, en-

Ann Intern Med. 1995;122:90-95.

‡ Cough-inducing procedures = sputum induction or aerosolized pentamidine administration.

§ 3M 1800+ Aseptex, 3M Inc., St. Paul, Minnesota.

Environmental controls, and respiratory protection for health care workers (Table 1). Source control measures included improved isolation precautions and expanded treatment regimens for patients with suspected or confirmed tuberculosis and included routine use of acid-fast bacilli smears to determine length of isolation and to establish treatment efficacy. To expedite the identification of patients with infectious tuberculosis and the determination of the antimicrobial susceptibility of *M. tuberculosis* isolates, laboratory procedures were also modified. Thus, personnel and workday hours devoted to processing of mycobacterial isolates were expanded; a hospital-wide computerized database of patients with tuberculosis was developed; a gene probe was introduced; and the reporting of acid-fast bacilli smear results to requesting physicians was standardized.

Environmental modifications included installing exhaust fans in isolation rooms to increase the number of acid-fast bacilli isolation rooms with negative pressure and included using portable Aeroguard (HR Incorporated, Bellevue, Washington) chambers to do cough-inducing procedures, such as sputum induction or aerosolized pentamidine administration. Finally, to further decrease the risk for occupational acquisition of tuberculosis, the respiratory protection worn by health care workers was changed from nonmolded to molded surgical masks (3M 1800+ Aseptex, 3M Incorporated, St. Paul, Minnesota).

To assess compliance with these control measures, we examined the hospital's isolation facilities, reviewed patient charts for documentation of initiation and discontinuation of acid-fast bacilli isolation precautions, interviewed infection control and laboratory personnel, observed isolation practices on hospital wards containing patients with tuberculosis, and evaluated the ventilation system in acid-fast bacilli isolation rooms by testing air-flow direction using smoke tubes.

Epidemiologic Studies

A case-patient was defined as any Cabrini Medical Center patient whose *M. tuberculosis* isolate was resistant to at least isoniazid and rifampin and as any patient whose clinical course was consistent with active tuberculosis during the study period (1 January 1990 to 11 August 1992). Case-patients and all other patients with tuberculosis were identified by reviewing Cabrini Medical Center laboratory and infection control records during the study period. Medical records of all potential case-patients were reviewed to verify a clinical course consistent with tuberculosis.

To determine whether a decrease had occurred in the incidence of multidrug-resistant tuberculosis after the institution of control measures, we compared the proportion of patients with tuberculosis who had multidrug-resistant strains before (preintervention period) and after (intervention period) the implementation of control measures. The preintervention period (January 1990 to June 1991) was defined as the time from the onset of the

outbreak until the formal institution of recommended control measures; the intervention period (July 1991 to 11 August 1992) was defined as the time during and after the institution of recommended control measures until our follow-up study.

Patient-to-Patient Transmission

To investigate possible patient-to-patient transmission of multidrug-resistant tuberculosis, we evaluated case-patient medical records to determine if case-patients had been hospitalized at Cabrini Medical Center within 7 months before onset of tuberculosis. For those case-patients who had been previously hospitalized, we determined whether they had been hospitalized on the same ward at the same time or whether they had a documented nosocomial exposure to another patient with culture-confirmed multidrug-resistant tuberculosis during a previous hospitalization. Data collected included age, sex, race, HIV serologic status, previous opportunistic infections, dates and results of acid-fast bacilli smears and mycobacterial cultures, *M. tuberculosis* antimicrobial susceptibilities, dates of admission and discharge, hospital room assignments, dates of isolation for tuberculosis, nursing documentation of proper application of isolation precautions, antituberculous medications prescribed, clinical course, and outcome.

Patient-to-Health Care Worker Transmission

To evaluate whether the risk for transmission of multidrug-resistant tuberculosis from patients to health care workers had been reduced, we compared conversion rates of tuberculin skin tests in health care workers during the preintervention and intervention periods. During both periods, the tuberculin skin testing program at Cabrini Medical Center required annual testing of all hospital employees and additional testing of health care workers after a known tuberculosis exposure. A tuberculin skin test conversion was defined as induration of 10 mm or more to purified protein derivative in a Cabrini Medical Center employee with a documented tuberculin skin test result that was negative within the previous 24 months. Employees without negative skin test results at baseline were excluded from our analyses. Conversion rates were compared by period, by job category (frequent direct patient contact compared with infrequent or no direct patient contact), and by ward assignment (primary wards housing patients with tuberculosis [medical and HIV wards] compared with wards infrequently housing patients with tuberculosis).

Health care workers with direct patient contact included physicians, nurses, nursing aides, respiratory therapists, and social workers; workers without direct patient contact included administrative staff, clerks, dietitians, housekeepers, engineers, and laboratory personnel. Health care workers with tuberculin skin-test conversions or active tuberculosis or both were identified by reviewing employee health and infection control records during

Figure 1. Distribution of patients with multidrug-resistant tuberculosis by date of first positive culture. The numbers 1 to 4 with arrows indicate the dates of introduction of 1) improved patient isolation, expanded criteria for isolation of patients (June to July 1991), and molded surgical masks (July 1991); 2) improved laboratory services (15 July 1991); 3) acid-fast bacilli isolation rooms on wards with negative pressure systems (September 1991); and 4) negative-pressure chambers for aerosolized pentamidine administration and sputum induction (October 1991). The months are abbreviated using the first letter of the month.

the study period. Data collected included age, sex, race, history of bacille Calmette-Guérin (BCG) vaccination or tuberculosis exposure or both, country of origin, job title, duration of employment, and work location at time of tuberculin skin-test conversion.

Statistical Analysis

Data were collected on standardized forms, entered into Epi Info Version 5.01b software, and analyzed (17). Categorical variables were compared by the Fisher exact or chi-square test, and relative risks (RRs) were calculated. Continuous variables were compared by the Student *t*-test or the Kruskal-Wallis rank-sum test.

Results

Case-Patients

Forty patients met the case definition (Figure 1). Case-patients in the preintervention and intervention periods were similar in age, race, sex, HIV serologic status, and diagnosis of AIDS (data not shown). However, case-patient mortality decreased in the intervention compared with the preintervention period (4 of 10 [40%] compared with 25 of 30 [83%] deaths; $P = 0.01$). Further, in the preintervention period, 20 of 25 (80%) case-patient deaths were attributed to tuberculosis, whereas in the intervention period, only 1 of 4 deaths was attributed to tuberculosis (the 3 remaining case-patient deaths occurring in the intervention period were attributed to complications of AIDS [$n = 2$] and to suicide [$n = 1$]).

The proportion of patients with multidrug-resistant *M. tuberculosis* infection decreased in the intervention compared with the preintervention period (10 of 70 [14%] compared with 30 of 95 [32%] patients; RR, 0.5 [95% CI, 0.2 to 0.9; $P = 0.02$]). Because hospitalization at Cabrini Medical Center within 7 months before onset of tuber-

culosis, particularly on the HIV ward, was identified as a risk factor for development of multidrug-resistant tuberculosis, we next examined the location and duration of hospitalization for case-patients before onset of tuberculosis. A similar number of case-patients in the intervention and preintervention periods had a history of previous hospitalization at Cabrini Medical Center (6 of 10 compared with 24 of 30 patients; RR, 0.8; $P = 0.2$) (Figure 1). Further, case-patients in the intervention and preintervention periods were equally likely to have been admitted to the HIV ward (4 of 10 compared with 17 of 30 patients; RR, 0.7; $P = 0.5$) and were hospitalized for a similar number of days (median, 5 compared with 15 days; $P = 0.2$) before onset of tuberculosis. However, case-patients diagnosed during the intervention period were less likely than those diagnosed during the preintervention period to have had an identified nosocomial exposure to another case-patient during a previous hospitalization (1 of 10 compared with 20 of 30 patients; RR, 0.2; $P = 0.003$).

The one identified exposure of a case-patient to a patient with multidrug-resistant tuberculosis during the intervention period occurred approximately 6 months after the implementation of control measures. The putative source-patient was not isolated at the time of admission, and when finally isolated, the patient was intermittently noncompliant with isolation precautions (walking in hallways without a mask). Of the remaining 5 case-patients in the intervention period with previous hospitalizations, 1 was the partner and housemate of a case-patient, 1 had a history of tuberculosis and poor compliance with medications, 1 had a prolonged hospitalization that included preintervention and intervention periods and had been hospitalized on the same ward as a case-patient during

the preintervention segment of the hospitalization, and 2 had no identified source of exposure.

Health Care Workers

Of 1567 tuberculin skin tests administered to health care workers with previously negative skin test results, we identified 48 (3.0%) skin-test conversions. Overall, tuberculin skin-test conversion rates during the preintervention and intervention periods were similar (26 of 840 [3.1%] compared with 22 of 727 [3.0%] conversions; $P=0.9$).

Health care workers who had tuberculin skin-test conversions had a median age of 34 years (range, 23 to 58 years), 34 (71%) were women, 12 (25%) were black, and approximately half (56%) were born in the United States. Only 4 (8%) were known to have received BCG vaccination; none had a known history of tuberculosis. Before tuberculin skin test conversion, these health care workers had been in their current positions a median of 5.0 years (range, 0 to 21 years), and most workers (36 of 48 [75%]) had direct patient care responsibilities.

Health care workers with tuberculin skin-test conversions during the preintervention or intervention periods were similar in age, sex, race, and BCG vaccination status. However, health care workers with tuberculin skin test conversions during the preintervention period were more likely than those with conversions during the intervention period to be assigned to the medical or HIV wards (primary wards housing patients with tuberculosis) (Table 2).

Because overall conversion rates for tuberculin skin tests were similar for the two time periods, we next examined conversion rates by job category and ward location. During the preintervention period, health care workers with direct patient contact had higher skin-test conversion rates than did health care workers without direct patient contact (22 of 342 [6.4%] compared with 4

Table 2. Characteristics of Health Care Workers with Tuberculin Skin Test Conversions*

Characteristic	Preintervention Period (n = 26)	Intervention Period (n = 22)	P Value
Median age, y	34	34.5	0.9
Female sex, n (%)	19 (73)	15 (68)	0.7
Race or ethnicity, n (%)			
Black	8 (21)	4 (18)	0.5
White	7 (27)	5 (23)	
Hispanic	8 (31)	7 (32)	
Asian	3 (11)	6 (27)	
History of BCG vaccination, n(%)	3 (11)	1 (4)	0.6
Assignment to medical or HIV wards, n (%)	15 (58)	4 (18)	0.006

of 409 [1.0%] conversions; RR, 6.6; $P < 0.001$). During the intervention period, skin test conversion rates among health care workers with and without direct patient contact were similar (14 of 296 [4.7%] compared with 8 of 354 [2.3%]; RR, 2.1; $P=0.08$) (Figure 2).

When we compared tuberculin skin-test conversion rates for specific wards, a change in the risk for conversion also occurred between the preintervention and intervention periods (Table 3). Before the institution of control measures, conversion rates in health care workers assigned to primary wards housing patients with tuberculosis were higher than those in workers assigned to other wards; however, in the intervention period, conversion rates among workers assigned to wards housing patients with tuberculosis decreased to levels seen in workers assigned to other hospital wards. In contrast, conversion rates for tuberculin skin tests among health care workers

Figure 2. Tuberculin skin test conversion rates in health care workers with and without direct patient contact. Health care workers with direct patient contact included physicians, nurses, nurses' aides, respiratory therapists, and social workers. Health care workers without direct patient contact included administrative staff, clerks, dieticians, housekeeping personnel, engineers, and laboratory personnel. TST = tuberculin skin test.

Table 3. Ward-specific Tuberculin Skin Test Conversion Rates in Health Care Workers*

Variable	Preintervention Period	Intervention Period	Relative Risk	P Value
Primary wards housing patients with tuberculosis (medical and HIV), n/n (%)	15/90 (16.7)	4/78 (5.1)	3.2	0.02
Other wards, n/n (%)	7/254 (2.8)	9/228 (4.0)	0.7	0.5
Relative risk	6.0	1.3		
P value	<0.001	0.7		

* HIV = human immunodeficiency virus.

assigned to other wards infrequently housing patients with tuberculosis were similar during the two time periods (Table 3).

Active tuberculosis developed in two health care workers. The first had cutaneous anergy and contracted active tuberculosis after an exposure during the preintervention period. This health care worker (a housekeeper) was HIV seropositive, had an *M. tuberculosis* isolate that matched the restriction fragment length polymorphism pattern for the hospital's epidemic strain of tuberculosis, was treated with a multidrug regimen for tuberculosis, and died of tuberculosis. The second health care worker had a documented skin-test conversion and contracted active tuberculosis during the intervention period. This health care worker, a physician with unknown HIV serologic status, had an upper lobe infiltrate on chest radiograph; no *M. tuberculosis* isolate was available. This health care worker was treated with isoniazid, rifampin, and pyrazinamide and survived.

Discussion

Recent reports of outbreaks of multidrug-resistant tuberculosis have documented the risk for nosocomial transmission of multidrug-resistant tuberculosis to patients and workers in medical facilities (1–10). At one hospital that had had an outbreak, Cabrini Medical Center, transmission of multidrug-resistant tuberculosis occurred at a time when the CDC guidelines were not being fully implemented (5). In response to the outbreak, various control measures were instituted to decrease transmission of tuberculosis.

Our data suggest that after the introduction of these control measures, the risk for nosocomial transmission of multidrug-resistant tuberculosis from patient to patient decreased. Decreases occurred in the proportion of patients with tuberculosis who had multidrug-resistant *M. tuberculosis* isolates and in the number of case-patients who might have acquired their disease nosocomially despite the similar placement of case-patients on wards housing patients with tuberculosis and despite a similar duration of hospitalization before onset of tuberculosis. At Cabrini Medical Center, the implementation of these control measures was supported by expanded staffing of the mycobacteriology laboratory and by the introduction of a standardized reporting system. Moreover, modifications such as rapid identification and treatment of case-patients with an expanded drug regimen were probably responsible for the reduction in mortality associated with multidrug-resistant tuberculosis seen in the intervention period, despite the similar demographic characteristics of

case-patients and the similar severity of underlying disease.

Our results also suggest that the introduced control measures were effective in reducing transmission of multidrug-resistant tuberculosis from patients to health care workers. After control measures were introduced, health care workers with and without frequent direct patient contact had similar rates of tuberculin skin-test conversion. More importantly, the skin-test conversion rate among workers assigned to primary wards housing patients with tuberculosis decreased by 70%, returning to a rate similar to that of health care workers assigned to other hospital wards. The observed decreases in skin-test conversion rates could not be attributed to other differences (for example, age, race, or BCG vaccination status) between workers, factors that may confound conversion rates (18, 19). These data suggest that the combination of source and environmental controls together with the use of molded surgical masks were all effective in reducing tuberculin skin-test conversion rates among health care workers at this hospital. At present, the efficacy of these molded surgical masks is unknown, and the contribution of their use to the reduction in risk for tuberculin skin-test conversion remains unclear. Recently, however, other models of molded surgical masks have been shown to filter mycobacterial organisms with more than 95% efficiency (20).

Tuberculin skin-testing programs serve two important functions in health care settings: 1) monitoring tuberculosis transmission among health care workers and 2) targeting health care workers who need prophylactic therapy or treatment of active tuberculosis. Therefore, all workers who might have had contact with infectious patients who have tuberculosis should be included in an annual tuberculin skin testing program. As our data show, hospital-wide conversion rates for tuberculin skin tests may be insensitive in determining tuberculosis transmission within an institution. Instead, calculation of job- and ward-specific (for example, nursing and bronchoscopy personnel, HIV ward) conversion rates for tuberculin skin tests may be a superior means of identifying high-risk groups for whom more frequent skin testing and adequate respiratory protection should be targeted.

Although our findings strongly suggest that nosocomial transmission was reduced as a result of the introduced control measures, our study had inherent limitations. First, results of acid-fast bacilli smears were not available throughout the entire study period, making it difficult to systematically assess the infectiousness of case-patients on the basis of smear-positivity data. Second, we used the tuberculin skin test, not the person, as the unit of analysis

for our evaluation of skin-test data because health care worker-specific data for all tests were not available for analysis. However, because tuberculin skin testing was done annually and because each period (preintervention and intervention) was between 12 and 18 months in duration, the test unit is probably also a good approximation of the number of health care workers tested. We were also unable to assess potential community acquisition of tuberculosis among health care workers and how such transmission may have affected conversion rates of tuberculin skin tests. However, no clustering of conversions was noted by residence zip code and, in the absence of multiple, concurrent community outbreaks of multidrug-resistant tuberculosis, the rate of community acquisition should have been constant. Therefore, it is unlikely that community transmission of tuberculosis substantially affected the differences seen in skin-test conversion rates during the two periods. Third, it could not be determined with absolute accuracy whether some skin-test conversions occurred in the preintervention or the intervention period unless an occupational exposure was identified. However, the substantial reduction in skin test conversion rates among health care workers after the introduction of control measures provides strong evidence for a decreased risk for occupationally acquired tuberculosis infection. Fourth, because the implementation of control measures was associated with a decrease in the number of case-patients, the effectiveness of these control measures in the presence of a high concentration of infectious patients with multidrug-resistant tuberculosis during a prolonged period could not be fully evaluated. Finally, because several interventions were instituted simultaneously or consecutively, we were unable to determine the independent importance of any single control measure in decreasing nosocomial transmission of multidrug-resistant tuberculosis.

Nosocomial outbreaks of multidrug-resistant tuberculosis have been associated with significant morbidity and mortality among patients and health care workers (1-8). Our data show that full implementation of a multifaceted approach, similar to that described in the CDC 1990 guidelines (16), can effectively reduce the risk for transmission of multidrug-resistant tuberculosis in health care settings and can reduce morbidity and mortality in affected patients. To reduce the risk for nosocomial transmission of tuberculosis to patients and health care workers, similar infection control programs should be implemented at all U.S. hospitals caring for patients with tuberculosis.

MAJOR ARTICLE

The Influence of High-Efficiency Particulate Air Filtration on Mortality and Fungal Infection among Highly Immunosuppressed Patients: A Systematic Review

Tim Eckmanns,¹ Henning Rüden,¹ and Petra Gastmeier²

¹Institute of Hygiene and Environmental Medicine, Charité—University Medicine Berlin, Berlin, and ²Institute of Microbiology and Hospital Hygiene, Medical University Hanover, Hanover, Germany

Background. Patients with hematological malignancies who are treated with intensive chemotherapy or who receive bone marrow transplants are exposed to an increased risk of developing nosocomial fungal infections. The aim of this systematic review was to compare the effectiveness of high-efficiency particulate air (HEPA) filtration with that of non-HEPA filtration in decreasing the rates of mortality and fungal infection among patients with diagnosed hematological malignancies and neutropenia or among patients with bone marrow transplants.

Methods. Articles identified in a Medline search, guidelines, and books, as well as the bibliographies of review articles, monographs, and the articles identified by Medline, were researched. Randomized trials and observational studies comparing HEPA filtration with conventional room ventilation were selected for inclusion in the present review.

Results. Sixteen trials (9 with death as an outcome and 10 with fungal infection as an outcome) that compared HEPA filtration with non-HEPA filtration were selected for meta-analyses. We discovered no significant advantages of HEPA filtration in the prevention of death among patients with hematological malignancies with severe neutropenia in randomized controlled trials (RCTs; relative risk [RR], 0.86 [95% confidence interval {CI}, 0.65–1.14]) and in studies of a lower standard (non-RCTs; RR, 0.87 [95% CI, 0.60–1.25]).

Conclusions. The placement in protected areas of patients with hematological malignancies with severe neutropenia or patients with bone marrow transplants appears to be beneficial, but no definitive conclusion could be drawn from the data available.

Fungal infections are a major complication of severe neutropenia brought on by the treatment of hematological malignancies [1], and they are associated with high mortality rates [2, 3]. High environmental *Aspergillus* spore counts constitute a major risk for infection after inhalation of the spores [4, 5]. Therefore, patients with acute lymphocytic leukemia, acute nonlymphocytic leukemia, aplastic anemia, or cancer who are being

treated with chemotherapy or are receiving bone marrow transplants (BMTs), thereby developing severe neutropenia, are often placed in rooms with high-efficiency particulate air (HEPA) filtration, with or without laminar airflow (LAF) [6]. HEPA filtration leads to a significant decrease in the number of microorganisms in the air, whereas LAF increases air change in the cleanest zone, which is why both measures are frequently combined. Krüger et al. [6], in a survey of various practices of infectious disease prevention and management during hematopoietic stem cell transplantation, found that only 16.5% of the patients receiving autologous BMTs and 5.3% of the patients receiving allogeneic BMTs did not receive special accommodation.

To be highly protected, patients are confined to a room, and persons who enter the room have to wear masks and gowns. This may be why there were some studies that reported a high frequency of mental dis-

turbance among patients with BMTs during the course of their isolation [7, 8].

In 4 guidelines from the Centers for Disease Control and Prevention (CDC), the installation of HEPA filters according to category BIII or IB is recommended [9–12]. However, the guidelines refer to only a small number of studies and, in part, only to outbreaks. There are more studies that examine the influence of protective environment on fungal infection and mortality than are mentioned in the recommendations.

There has been a trend toward relaxing the degree of patient isolation, in the absence of definitive data to support its use [13]. Because the protective environment regimen is expensive and is a burden on patients, and because there is still no systematic review of HEPA filtration available, we conducted a systematic review to investigate whether HEPA filtration reduces the risk of death and fungal infection for patients with hematological malignancies who have severe neutropenia or for patients with bone marrow transplants.

METHODS

Literature search. The type of literature that we selected for the present review included literature on randomized trials, cohort studies, case-control studies, and nonrandomized controlled trials (non-RCTs). In these trials and studies, the effectiveness of HEPA filtration, with or without LAF, was compared with that of standard ventilation of patient hospital rooms with no air filtration, with regard to identification of decreasing rates of death and fungal infection among patients with hematological malignancies who have neutropenia due to their illness or its treatment (i.e., chemotherapy or BMTs [no stem cell transplantation]) or among patients without cancer who have BMTs (no stem cell transplantation) for other reasons. Every study included both an intervention group of patients who were treated in rooms with HEPA filtration with or without LAF and a control group of patients who were treated in patient hospital rooms with standard ventilation. Each study had to have at least 1 type of outcome enabling measurement of mortality or fungal infection.

A Medline search of the literature published from 1 January 1966 through 30 June 2005 was performed. One or more of the following search terms were used: “LAF,” “laminar airflow,” “HEPA,” “high-efficiency particulate,” and “protect* environment” (where “*” denoted a wild card). The term or terms were then combined with ≥ 1 of the following search terms: “BMT,” “marrow transplant*” (where “*” denoted a wild card), and “chemotherapy.” In addition, we searched for guidelines [9–12], related sections of books [14–16], and bibliographies of review articles, monographs, and articles identified in our initial search of the literature. We also established personal contact with experts in the field.

Literature selection. All the references that were identified

were initially selected on the basis of their titles and/or abstracts. Full reports from potentially relevant publications were obtained and checked for eligibility for inclusion in the review. Decisions about whether to include trials were based on the completeness of the trials. Only randomized controlled trials (RCTs), non-RCTs, cohort studies, and case-control studies were considered. Because of differences in study design, RCTs were analyzed separately, and the results of observational studies and non-RCTs were dealt with in other analyses [17, 18]. In some of the studies, additional prevention measures were investigated, because these studies were 3- and 4-arm studies. Studies were only considered for inclusion if the HEPA (intervention) and non-HEPA (control) groups had similar additional intervention measures.

On the basis of outcome and study design, the studies that were identified were categorized into 4 groups, as follows: (1) RCTs with death due to all causes as an outcome; (2) RCTs with fungal infection (invasive aspergillosis and non-*Candida* fungal infection) as an outcome; (3) non-RCTs with death due to all causes as an outcome; and (4) non-RCTs with fungal infection as an outcome. Because of the 2 different outcomes assessed, it was decided to perform 2 meta-analyses for each study design. If a study assessed both outcomes, then it was included in 2 meta-analyses.

Data collection and analysis. Two investigators assessed the methodology used in each trial individually and then extracted the information required. Differences in the data extracted were resolved together by the investigators. From each study, we extracted source details (authors, country and city where the study was performed, and year of publication), study information (design and outcome[s] assessed), patient information (number of patients evaluated, diagnosis received, therapy received, and age), intervention (type of protected area and additional intervention used), duration of follow-up, time in the protected area, and outcome (fungal infection and/or death).

The random-effects method was used to derive a summary estimate, as implemented in Stata software (version 7.0; Stata) [19]. Protective effects (with 95% confidence intervals [CIs] and heterogeneity testing) were calculated.

RESULTS

Literature search. Figure 1 shows the route of identification of relevant articles. Of a preliminary total of 923 articles identified by a Medline search and an additional 25 articles identified by a hand search, only 64 were retained after the titles and abstracts were read, and then only 16 were retained after the full articles were evaluated. Although the 923 articles were identified through an extensive search strategy, the majority of articles focused on topics other than air filtration and patients with neutropenia. The 48 studies that were excluded were mainly

Figure 1. Route of references collected from Medline, guidelines, books, and bibliographies

nonsystematic reviews, descriptions of outbreaks, and studies that dealt with the problem on a technical level. Appropriate numerical data or figures were missing from some studies.

An advantage for the use of air filtration was suggested by one study that did address our question and criteria but did not contain valid data [20]. The other study of a similar nature suggested no advantage [21].

There are 2 additional important reasons for the exclusion of preselected articles. First, some studies that examine the influence of air filtration on fungal infection and death among immunosuppressed patients contain contradictions between the text and a figure [20] or a figure and a table (see [21] for a contradiction regarding death as an outcome). Because the studies in question were older, we decided not to ask their authors for clarification, and we therefore did not consider the studies for inclusion in the review. Second, 2 research centers (Seattle and Houston) in the United States were the main sources of the discussion of the use of air filtration for immunosuppressed patients in the 1970s and 1980s. There were 5 studies (31%) from Seattle alone in our meta-analyses. However, because there were patients who were included in >1 study, one study was of no use in the meta-analysis (i.e., the patients in the study of Freireich et al. [22] were a subgroup of the patients in the study of Rodriguez et al. [23], and, therefore, the study of Freireich et al. [22] was excluded). Another study was only partially useful, because the patients who had aplastic anemia diagnosed in the study of Buckner et al. [24] were a subgroup of the patients in the study of Storb et al. [25].

Literature selection. Six RCTs [24–29] and 3 non-RCTs [23, 30, 31] were considered for 2 meta-analyses with death as the outcome. The meta-analyses included 774 and 231 patients, respectively. Four RCTs [21, 24, 27, 32] and 6 non-RCTs [23, 33–37] were suitable for 2 meta-analyses with fungal infection as the outcome; the meta-analyses included 238 and 759 patients, respectively. Three of the studies [23, 24, 27] included both death and fungal infection as outcomes.

Table 1, which presents data from RCTs, and table 2, which presents data from non-RCTs, provide an overview of the basic features of the included studies that were heterogeneous with regard to various parameters. The publication dates of the studies span 28 years (from 1973 to 2001). The participants in the trials were patients with different kinds of acute leukemia and aplastic anemia, as well as patients who had received an unspecified BMT. In the trials, patient treatment consisted of chemotherapy (6 trials [37.5%]) [21, 23, 26, 27, 32, 37] and allogeneic and autologous BMT (9 trials [56.3%]) [24, 25, 28–31, 33–35]. In one trial, patient treatment consisted of both chemotherapy and allogeneic and autologous BMT [36]. Follow-up duration and additional measures differed partially. Time in a protected area was mentioned in only 6 studies (37.5%) [21, 24, 25, 27, 32, 33]. In 5 of these 6 studies, the time in a protected area was 50 days; in the other study [32], this time was 29 days. One study investigated mainly children [31], whereas the other studies investigated mainly adults. In the study of Rhame et al. [34], the protected area was established through in-room HEPA units, and, in the study of Oren et al. [37], the protected area was established through the use of HEPA filtration without LAF. All other protected areas were provided with HEPA filtration with LAF. In no study was the sample size calculated.

In the study of Rodriguez et al. [23], patients were only randomized to a protected environment when a unit was available. If all the units were occupied, patients were treated in rooms without HEPA filtration. Because of this severe methodological flaw in randomization, this study was considered to be a non-RCT. Some of the patients included in the study of Navari et al. [33] were not randomized. This study was also counted as a non-RCT. Of the remaining 6 non-RCTs, 5 were cohort studies, and the study of Schmeiser et al. [30] was an interventional trial.

In some studies, only subgroups of patients were considered for the meta-analyses, because comparison of protected and nonprotected areas was possible only for the subgroups considered (table 1 and table 2). In the study of Yates et al. [26], information about death as an outcome in relation to a protected environment was available solely for 1 subgroup of the patients included. These data were used in the meta-analysis. In the study of Buckner et al. [24], which had death as an outcome, only patients with acute leukemia were considered for inclusion, because the more extensive study of Storb et al. [25] included patients with aplastic anemia.

Data analysis. Table 3 shows results of the single trials and the pooled relative risks (RRs) for studies with death as the outcome. The mortality rates in the 9 studies varied between 8% and 86%. Five of 9 studies suggested a decrease in the mortality rate. Four of 6 RCTs showed some advantage associated with the use of HEPA filtration with LAF (pooled RR, 0.86 [95% CI, 0.65–1.14]).

Table 1. Characteristics of 8 randomized controlled trials included in the meta-analyses.

Authors, year of publication [reference]	Location	Outcome	Clinical condition(s) of participants	Therapy received	Portion of participants considered ^a	Follow-up duration	Additional therapy received
Levine et al., 1973 [27]	Bethesda, MD	Fungal infection and death	Acute leukemia	Chemotherapy	Patients in 2 of 3 study arms	50 days	Topical or official antiseptics and antibiotics
Yates et al., 1973 [26]	Buffalo, NY	Death	Acute myeloid leukemia	Chemotherapy	A portion of the patients evaluated	Not mentioned	Partial gut sterilization
Schimpff et al., 1975 [21]	Baltimore, MD	Fungal infection	Acute myeloid leukemia	Chemotherapy	Patients in 2 of 3 study arms	120 days	Oral nonabsorbable antibiotics
Buckner et al., 1978 [24] ^b	Seattle, WA	Fungal infection and death	Aplastic anemia plus acute leukemia; acute leukemia only	BMT	For fungal infection as the outcome, all participants; for death as the outcome, a portion of the participants	6 months to 4 years	Oral nonabsorbable antibiotics ^c
Lohner et al., 1979 [32]	Brussels, Belgium	Fungal infection	Acute leukemia, agranulocytosis, lymphosarcoma	Chemotherapy	All	Not mentioned	Oral nonabsorbable antibiotics
Storb et al., 1983 [25]	Seattle, WA	Death	Aplastic anemia	BMT	All	16 months to 11 years	Oral nonabsorbable antibiotics ^c
Petersen et al., 1987 [29]	Seattle, WA	Death	All diseases that make BMT necessary	BMT	All	100 days	Prophylactic systemic antibiotics
Petersen et al., 1988 [28]	Seattle, WA	Death	All diseases that make BMT necessary	BMT	Patients in 2 of 4 study arms	30 days	Prophylactic systemic antibiotics or nonabsorbable antibiotics

NOTE. BMT, bone marrow transplantation.
^a For inclusion in the meta-analyses.
^b When death was the study outcome, we considered only patients with acute leukemia, because the other patients were included in the study of Storb et al. [25], which was published 5 years after the study of Buckner et al. [24].
^c Received only by patients in the intervention group.

Table 2. Characteristic of 8 nonrandomized controlled trials included in the meta-analyses.

Authors, year of publication [reference]	Location	Outcome	Clinical condition(s) of participants	Therapy received	Portion of study participants considered ^a	Follow-up duration	Additional therapy received
Rodriguez et al., 1978 [23] ^b	Houston, TX	Fungal infection and death	Acute leukemia	Chemotherapy	All	10 months to 4 years	Oral antibiotics and systemic antibiotics
Navari et al., 1984 [33] ^c	Seattle, WA	Fungal infection	Aplastic anemia	BMT	Patients in 2 of 3 study arms	100 days	None
Rhame et al., 1984 [34]	Minneapolis, MN	Fungal infection	All diseases that make BMT necessary	BMT	All	Not mentioned	Oral nonabsorbable antibiotics ^d
Sherertz et al., 1987 [35]	Gainesville, FL	Fungal infection	All diseases that make BMT necessary	BMT	All	>50 days	None
Schmeiser et al., 1988 [30] ^e	Ulm, Germany	Death	All diseases that make BMT necessary	BMT	All	Not mentioned	Total decontamination
Gamillscheg et al., 1991 [31]	Graz, Austria	Death	Aplastic and sideroblastic anemia; hematological and solid malignancies	BMT	All	10 months to 12 years	Total decontamination
Withington et al., 1998 [36]	Christchurch, New Zealand	Fungal infection	All diseases that make BMT necessary	BMT and chemotherapy	Patients from 2 of 3 study periods	Not mentioned	Prophylactic intranasal amphotericin (selective)
Oren et al., 2001 [37]	Haifa, Israel	Fungal infection	AML and ALL	Chemotherapy	Patients in 2 of 3 study arms from 1 of 3 periods	Not mentioned	None

NOTE. ALL, acute lymphatic leukemia; AML, acute myeloid leukemia; BMT, bone marrow transplantation.

^a For inclusion in the meta-analyses.

^b Patients were only randomized to be placed in a protected environment when a unit was available. If all units were occupied, patients were placed in hospital rooms with standard ventilation. Hence, this study was counted as a nonrandomized controlled trial.

^c Some of the patients who were included in the study were not randomized.

^d Received only by patients in the intervention group.

^e The study is an interventional trial.

NOTE. CI, confidence interval; HEPA, high-efficiency particulate air; LAF, laminar airflow; non-RCT, nonrandomized controlled trial; RCT, randomized controlled trial; RR, relative risk.

^a Pooled RR determined by the DerSimonian and Laird method.

The results for fungal infection as the outcome are shown in table 4. The rate of fungal infection was 2%–18%. Three of the RCTs reported no fungal infection among patients in the intervention group. Most (9 of 10) studies pointed to a decrease in the rate of fungal infection in association with the use of HEPA filtration or LAF. In 1 of the 4 RCTs with fungal infection as the outcome, an increased risk was noted (pooled RR, 0.57 [95% CI, 0.13–2.53]).

Forrest plots of the 6 RCTs that had death as an outcome and the 4 RCTs that had fungal infection as an outcome are shown in figure 2; the corresponding funnel plots are shown in figure 3. The funnel plots show no publication bias for death as an outcome, but they show a huge bias for fungal infection as an outcome.

All meta-analyses were calculated using the random-effects method, because the clinical heterogeneity of the studies suggests that the effect differs with each study. However, the test for statistical heterogeneity was not significant for any of the 4 meta-analyses ($P > .05$).

DISCUSSION

Of the 923 articles identified by a systematic search of the literature, only 16 were useful for analysis.

Rates of fungal infection and death. All the meta-analyses indicated a decrease in the rates of death or fungal infection in protected areas, but the result was significant only for non-RCTs for which fungal infection was an outcome. The statistical homogeneity was considerable (the results of tests of hetero-

geneity of the meta-analyses were all not significant). Even if all studies—RCTs and non-RCTs—with death as an outcome are included in one analysis, the result of the test of heterogeneity is not statistically significant ($P = .27$).

The huge differences in rates of infection and death between the studies are, in part, a consequence of study design, but there is, in fact, no satisfactory explanation. Only 3 of 10 studies with fungal infection as an outcome already had fungal infection noted in the intervention group. That would mean that all fungal infections that occurred during hospitalization were acquired in the hospital. This is unlikely, because the sinuses of the patients could have been colonized before admission to the hospital.

The funnel plot of the 4 RCTs with fungal infection as an outcome revealed publication bias. Studies that showed a small effect and no influence of ventilation on fungal infection are missing.

Heterogeneity of the studies. Although there is only little overall statistical heterogeneity in the results, the clinical heterogeneity is huge. We considered different kinds of studies. The patients in the trials had different underlying diseases, and their treatment programs were variable. Fungal infection as an outcome is the least common denominator for a range of outcome definitions. During the 28-year period during which the publications appeared (from 1973 to 2001), much with regard to study design, treatment, and technical equipment had, of course, changed. It is difficult to combine data from studies conducted during such a long period. Because only the 2 newest

studies [36, 37] provide definitions of nosocomial aspergillosis, it now becomes clear why we cannot provide information regarding its definition.

In 4 studies [23–25, 31], the duration of follow-up for the different patients was between months and years, with the authors having set specific dates for follow-up analyses. The long follow-up times explain why, for 3 of these studies [23, 24, 31], mortality rates were 60%–86%. Because 2 of the 3 studies in the analysis were non-RCTs with death as an outcome, the mean mortality rate in non-RCTs was high (59%).

In the cohort study of Gamillscheg et al. [31], which had a historical control group, it was not considered appropriate to set a fixed date for follow-up analysis for all patients. It is more surprising that the control group with a much longer follow-up (2–12 years, compared with 10 months to 2 years of follow-up in the intervention group) had a lower mortality rate (55% vs. 64%).

Two important explanations for this heterogeneity in the mortality rate are probably the duration and severity of neutropenia. Only a small number of the studies mentioned the severity and duration of neutropenia, although immunosuppression was the constant underlying theme in all the studies.

In 3 studies, decontamination (with oral nonabsorbable antibiotics) was part of the intervention. A meta-analysis conducted by Cruciani et al. [38] indicated that routine gut de-

contamination was not effective in preventing infection-related death; we may, therefore, assume that the reduction in mortality and/or fungal infection was the result of isolation and not decontamination.

In 2 of the 16 studies, only HEPA filtration, without LAF, was used [34, 37]. Environmental studies [4, 39] showed differences between LAF and HEPA filtration. The reduction in the number of fungal infections in these 2 studies did not differ from that noted in other non-RCTs with fungal infection as an outcome.

Limitations of all the studies. Another important point is that none of the studies was blinded. In each study, the medical team, as well as the patients, were aware of whether or not the patients were situated in a protected area. No studies involved the appropriate control subjects, who should have been situated in rooms with air conditioning but without HEPA filters. Of course, in these trials, the benefit of freedom of movement for the patients, which supports well-being, would be lost.

The only existing information about ventilation concerns HEPA filtration with or without LAF. However, of course, problems like pressure, location of filters (terminal HEPA), and protection of individual rooms only or protection of the whole unit are of concern.

Other studies. Two multicenter studies supported the benefit of a protected environment [40, 41]. Fischer et al. [40] an-

Figure 2. Forrest plot of relative risks (RRs) and 95% confidence intervals (CIs) for mortality (A) in 6 randomized controlled trials (RCTs) of air filtration and for fungal infection (B) in 4 RCTs of air filtration.

alyzed 183 patients from 15 European health care centers who had severe combined immunodeficiency and who had received BMTs. The RR for cumulative 2-year survival in a protected environment was 0.51 (95% CI, 0.37–0.69). This was a very specific group of patients who were not comparable to other patients who had also received BMT. Passweg et al. [41] analyzed 5065 patients (from 222 research teams) with leukemia who received BMT. The RR of survival after 1 year was 0.85 (95% CI, 0.78–0.92). This RR is similar to our results. Because of the large number of patients included in the study, the result is significant. It is not, however, possible to reproduce the allocation of the patients in the different centers, although this is an important factor for the outcome.

The epidemiological profile of *Aspergillus* infection in patients undergoing BMT at the Fred Hutchinson Cancer Research Center (Seattle, WA) between 1980 and 1987 and between 1987 and 1993 was analyzed in 2 retrospective cohort studies [42, 43]. During the first study period, the risk of *Aspergillus* infection was not significantly altered by methods of infection prevention, including the provision of a protective environment [42]. During the second study period, Wald et al. [43] analyzed the RR of infection for patients within 40 days after transplantation was performed. Transplantations performed outside protected environments were associated with a significantly increased risk of aspergillosis.

Existing guidelines. In 4 CDC guidelines, the installation of HEPA filters according to categories BIII or IB is recommended for immunosuppressed patients. These 4 guidelines present different categories for the use of HEPA filtration, although most of the references provided in the guidelines do not allow these conclusions. The recommendation in guidelines from 2000 for the prevention of opportunistic infections among hematopoietic stem cell transplant recipients [10] refers to 3 references [9, 34, 44] (table 5), with only one reference presenting data that provide evidence of a reduction in risk occurring in association with the use of special ventilation.

In the Healthcare Infection Control Practices Advisory Committee's 1997 guidelines for preventing nosocomial pneumonia, only staff education is included in category IA to prevent nosocomial aspergillosis [9]. This shows that definitive scientific studies are not available for any other measures. The guideline

Figure 3. Funnel plot of precision (1/SE) against relative risk (RR) for mortality (A) in 6 randomized controlled trials (RCTs) of air filtration and for invasive fungal infection (B) in 4 RCTs of air filtration [17, 18]. Note: Panel A shows no publication bias, because the study with the biggest effect is shown exactly on the line of the overall RR, and because the smaller studies are symmetrical around the overall RR (symmetrical plot). Panel B shows an asymmetrical plot (publication bias); small studies have an RR of <1, and the study with the biggest effect has an RR of >1 (overall RR, slightly <1).

Table 5. Different guidelines of the Centers for Disease Control and Prevention (CDC) that recommend the installation of high-efficiency particulate air (HEPA) filters, categories of use, and the content of references included in the guidelines.

[60], Barnes et al. [47], and Overberger et al. [61] conducted studies during hospital renovation Murray et al. [45] and Streifel et al. [46] focused on technical data regarding the use of ventilation for controlling microbes

NOTE. HEPA, high-efficiency particulate air.
^a B: Strong or moderate evidence for efficacy, but only limited clinical benefit; generally recommended. III: Evidence from opinions of respected authorities based on clinical experience, descriptive studies, or reports of expert committees.
^b IB: Strongly recommended for implementation and supported by certain experimental, clinical, or epidemiological studies and a strong theoretical rationale.
^c IC: Required by state or federal regulation, or representing an established association standard.

refers to 8 references [24, 35, 44–49], with only 2 providing evidence that there is a reduction.

The 2004 guidelines for preventing health care–associated pneumonia [11] refer to 5 references, with 2 providing evidence that there is a reduction. The 2003 guidelines for environmental infection control in health care facilities refer to 17 references [9, 24, 35, 45–48, 52–61], including 2 studies that provide evidence in favor of the installation of HEPA filters.

Conclusion. Many experts recommend the general housing of patients in hospital rooms with HEPA filtration, although this approach is expensive. Even if it is feasible for the highest-risk patient groups for a limited period, it cannot be applied for all patients who are at risk for longer periods.

Therefore, the objective of this study was to deliver and present a systematic overview of data on the prevention of fungal infection and death by use of appropriate ventilation systems. In 1984, Armstrong stated, “The only place for protected environments today appears to be in a limited number of centers where carefully studies should be conducted” [62, p. 689]. Research scientists have rather missed the chance for conducting such studies. Only 2 additional RCTs have been performed since this statement appeared; both RCTs revealed no benefit of installing a protected environment. Because most centers now have special rooms for patients with neutropenia, a multicenter double-blinded RCT is not practicable, from the ethical viewpoint.

The results of these meta-analyses suggest that patients with hematological malignancies with severe neutropenia or patients with bone marrow transplants receive some benefit if they are placed in a protected environment. Nevertheless, the evidence is still somewhat ambiguous. Even if it does seem to be beneficial to place in protected areas patients with hematological malignancies and severe neutropenia or patients with bone marrow transplants, at present, no final conclusion can be drawn from the data available.

3TC, lamivudine; **CD4**, cluster of differentiation 4; **DTG**, dolutegravir; **FDA**, United States Food and Drug Administration; **FTC**, emtricitabine; **HIV**, human immunodeficiency virus; **ITT-E**, intention-to-treat exposed; **NRTI**, nucleoside/nucleotide reverse transcriptase inhibitor; **RCT**, randomised controlled trial; **RNA**, ribonucleic acid; **TAF**, tenofovir alafenamide fumarate; **TDF**, tenofovir disoproxil fumarate; **XTC**, emtricitabine.

FOOTNOTES

*Data extracted from a systematic literature review of DTG+3TC real-world evidence. Overlap between cohorts cannot be fully excluded.

**The reported rate reflects the sum-total of resistance cases calculated from GEMINI I and II (n=1/716, through 144 weeks), STAT (n=0/131, through 52 weeks), and D2ARLING (n=0/106, through 24 weeks).⁵⁻⁷

†GEMINI I and II are two identical 148-week, phase III, randomised, double-blind, multicentre, parallel-group, non-inferiority, controlled clinical trials testing the efficacy of DTG/3TC in treatment-naïve patients. Participants with screening HIV-1 RNA ≤500,000 copies/mL were randomised 1:1 to once-daily DTG/3TC (n=716, pooled) or DTG + TDF/FTC (n=717, pooled). The primary endpoint of each GEMINI study was the proportion of participants with plasma HIV-1 RNA <50 copies/mL at Week 48 (ITT-E population, snapshot algorithm).¹³

‡STAT is a phase IIIb, open-label, 48-week, single-arm pilot study evaluating the feasibility, efficacy, and safety of DTG/3TC in 131 newly diagnosed HIV-1 infected adults as a first line regimen. The primary endpoint was the proportion of participants with plasma HIV-1 RNA <50 copies/mL at Week 24.⁶

§D2ARLING is a randomised, open-label, phase IV study designed to assess the efficacy and safety of DTG/3TC in treatment-naïve people with HIV with no available baseline HIV-1 resistance testing. Participants were randomised in a 1:1 ratio to receive DTG/3TC (n=106) or DTG + TDF/XTC (n=108). The primary endpoint was the proportion of participants with plasma HIV-1 RNA <50 copies/mL at Week 48.⁷ Results at week 24 of the study.

||The reported rate reflects the sum-total of resistance cases calculated from TANGO (n=0/369, through 196 weeks) and SALSA (n=0/246, through 48 weeks).^{8,9}

¶TANGO is a randomised, open-label, trial testing the efficacy of DOVATO in virologically suppressed patients. Participants were randomised in a 1:1 ratio to receive DOVATO (n=369) or continue with TAF-containing regimens (n=372) for up to 200 weeks. At Week 148, 298 of those on TAF-based regimens switched to DOVATO. The primary efficacy endpoint was the proportion of subjects with plasma HIV-1 RNA ≥50 copies/mL (virologic non-response) as per the FDA Snapshot category at Week 48 (adjusted for randomisation stratification factor).^{8,13}

#SALSA is a phase III, randomised, open-label, non-inferiority clinical trial evaluating the efficacy and safety of switching to DTG/3TC compared with continuing current antiretroviral regimens in virologically suppressed adults with HIV. Eligible participants were randomised 1:1 to switch to once-daily DTG/3TC (n=246) or continue current antiretroviral regimens (n=247). The primary endpoint was the proportion of subjects with plasma HIV-1 RNA ≥50 copies/mL at Week 48 (ITT-E population, snapshot algorithm).⁹

Brief Report

Exploring the role of infection preventionists in antimicrobial stewardship programs through several lenses: A brief report

Matthew Weissenbach MPH, CPH, CIC^{a,*}, Donna Haidunen PhD, RN, CIC, CPH^a,

Key Words:

Antibiotic stewardship
Antimicrobial stewardship
Multidisciplinary collaboration
Barriers
Survey

This study explored perceptions of the role of infection preventionists (IPs) in antimicrobial stewardship programs (ASPs) among IPs, pharmacists, infectious diseases physicians, and hospital executives. Expert telephone interviews, using a validated survey tool, were conducted from November 1, 2016 to December 12, 2016 (n = 28). Participants with clinical responsibilities reported modest expectations of the IP in ASPs. Competing IP job responsibilities and limited ASP role clarity were cited as common barriers to IP engagement.

Antimicrobial resistance is one of the greatest public health challenges of our time. In 2013, the Centers for Disease Control and Prevention published a comprehensive analysis outlining the top 18 threats of antimicrobial resistance in the United States.¹ It is estimated that 20%–50% of all antimicrobials prescribed in acute care facilities throughout the United States are inappropriate or unnecessary.^{2,3} Antimicrobial stewardship programs (ASPs) have demonstrated a decrease in the development of antimicrobial resistance and are critical components of ensuring patient safety.⁴ Previous research has shown that infection preventionists (IPs) are important contributors to hospital ASPs.^{5,6} Although ASPs warrant a multidisciplinary team model, the role of the IP is not well defined.⁷ The objectives of this study were (1) to assess multidisciplinary perspectives of IPs' contributions to ASPs; and (2) identify perceived barriers to optimal participation of IPs in ASPs.

METHODS

Expert telephone interviews, using a validated survey tool, were conducted from November 1, 2016 to December 12, 2016. Two IP leaders and 2 (non-IP) ASP leaders were recruited to assist with validation of the survey instruments prior to use and establish content validity. The interview was conducted with each leader as if they were actual participants. Subsequently, a copy of the interview

questions was provided to these individuals for review and feedback. Survey materials were assessed by this group for content appropriateness, item formatting, usability, and clarity. Expert feedback from the survey instrument validation efforts was incorporated prior to use in participant interviews. Reliability was assessed through calculation of Cronbach's alpha using analysis of variance 2-factor without replication within Microsoft Excel (Microsoft, Redmond, WA), resulting in a value of 0.468. This mixed-methods study used participant interviews and a survey framework to collect data on (1) facility demographics and ASP characteristics; (2) IP role characterization in ASP; (3) barriers to optimal IP engagement in ASPs; (4) metrics for measuring ASP success; and (5) participant demographics from a convenience sample of health care personnel within the professional networks of the research team to include IPs, infectious diseases (ID) physicians, pharmacists, and hospital executives. A truncated, 1-section survey was developed for use with participating hospital executives to assess perspectives on the state of their own ASP, perceived ownership of ASP among clinical roles, and antimicrobial stewardship as an organizational priority. The study was approved by the University of South Florida institutional review board. To facilitate validation of the surveys, 2 infection prevention and control (IPC) leaders and 2 (non-IP) ASP leaders assessed content appropriateness, item formatting, and clarity. Characteristics of each ASP, IPC involvement, and barriers were analyzed using descriptive statistics including frequencies and rates. Qualitative feedback from participants underwent content analysis for themes highlighting ASP characteristics and IPC engagement. Interview notes and audio recordings were reviewed, and codes were assigned to classify observations and aid in data summation and analysis.

E-mail address: mweissen@health.usf.edu (M. Weissenbach).

Conflicts of interest: None to report.

Thematic summaries for IPC involvement and experienced barriers were defined to categorize perceptions on IPC engagement.

RESULTS

The study sample was comprised of 28 individuals across 10 states including 8 IPs, 6 ID physicians, 10 pharmacists, and 4 hospital executives. The vast majority (86%) of participants held a master's or doctoral degree.

Sixty-three percent of participants indicated representation from IPs on the antimicrobial stewardship committee. The majority of the IP participants spent either no time (12%) or up to 5 hours per week (63%) on ASP activities, whereas 25% reported ≥ 5 hours per week.

Table 1 summarizes barriers to IP involvement in ASP activities. Forty-two percent of participants indicated that IPs have deficiencies in antimicrobial stewardship knowledge. When asked whether political/social tensions hindered IP involvement, 38% indicated yes and were mostly physicians (21%). The most common barriers cited were antimicrobial stewardship as a lower priority (58%), time constraints (54%), IP staffing levels (46%), and communication difficulties (46%). Interestingly, several participants cited that antimicrobial stewardship is not part of the IP role (33%) and some (21%) suggested no barriers exist.

The qualitative content analysis revealed 3 major themes. First, most non-IP clinician peer groups expect IP involvement in ASP to focus mostly on contributing data on rates of *Clostridium difficile* infection and multidrug-resistant pathogens. Second, there was little expectation that the IP contributes to the ASP through patient-level review, consultation, or intervention. Finally, hospital executives viewed IP involvement as “necessary” and “supportive” to the mission of their ASP, but not as critical as the ID physician or pharmacist.

Table 1
Barriers to IP involvement in ASPs by participant role (n = 24)

Barriers	n (%)
Deficiencies in antimicrobial stewardship knowledge	10 (42)
IP	4 (16)
Pharmacist	3 (13)
Physician	3 (13)
Political/social tensions in the hospital	9 (38)
IP	3 (13)
Pharmacist	1 (4)
Physician	5 (21)
Time constraints	13 (54)
IP	5 (21)
Pharmacist	5 (21)
Physician	3 (13)
AMS is a lower priority relative to competing activities or demands	14 (58)
IP	4 (17)
Pharmacist	4 (17)
Physician	6 (25)
IP staffing levels	11 (46)
IP	4 (17)
Pharmacist	4 (17)
Physician	3 (13)
Communication difficulties between concerned groups	11 (46)
IP	3 (13)
Pharmacist	3 (13)
Physician	5 (21)
Outside of IP role definition “It's not my job”	8 (33)
IP	2 (8)
Pharmacist	2 (8)
Physician	4 (17)
No barriers exist	5 (21)
IP	2 (8)
Pharmacist	2 (8)
Physician	1 (4)

For n = 24, items were multiselectable, resulting in some participants selecting no barriers and some more than 1 barrier.

AMS, antimicrobial stewardship; ASPs, antimicrobial stewardship programs; IP, infection preventionist.

DISCUSSION

The optimal engagement of IPs in ASPs is being challenged by varying expectations among ASP clinician peer groups. Additionally, the absence of a role definition for IPs in ASPs is likely hindering IPs from contributing in consistent, meaningful ways. The revised 2017 Competency Self-Assessment and Professional Development Plan as part of the IP Competency Model from the Association for Professionals in Infection Control and Epidemiology outlines a future-oriented IPC domain that encourages participation of IPs in ASPs.⁸ The Certification Board of Infection Control and Epidemiology also indicates antimicrobial stewardship as an IPC strategy within its examination content outline.⁹ In concordance with Manning and Pogorzelska-Maziarz,⁷ summary analysis of our qualitative feedback revealed that current IP engagement in ASPs is predominately focused on provision of data tied to health care–associated infections and multidrug-resistant organisms. However, our study results also suggest that IPs are currently contributing to ASPs in some undefined ways. Clarifying the role and responsibilities of IPs in ASPs would help to define and recognize specific contributions.

This study was limited by the small sample size and may not be representative of all US acute care hospital stakeholders eligible for participation in this study. Adding more items to the survey instrument in future studies may raise the value of Cronbach's alpha, and thus increase instrument reliability. All participant data were self-reported, and it is possible that not all participants were fully aware of the spectrum of ASP activity occurring within their institution. Despite these limitations, this study provides valuable insights on the current state of IPC engagement in ASPs from the perspective of several hospital stakeholders who share common interests and responsibilities in antimicrobial stewardship.

CONCLUSIONS

To our knowledge, this is the first evaluation of perceptions among multidisciplinary hospital-based peer groups of the IP role in ASP. Additional studies should further explore the barriers identified by IPs and other ASP clinicians. Removing these barriers and establishing more definitive roles may better facilitate IPs to become integral contributors to ASPs.

Guidelines for Environmental Infection Control in Health-Care Facilities

Recommendations of CDC and the Healthcare Infection Control Practices Advisory Committee (HICPAC)

Prepared by

Lynne Schulster, Ph.D.¹

Raymond Y.W. Chinn, M.D.²

¹*Division of Healthcare Quality Promotion
National Center for Infectious Diseases*

²*HICPAC member
Sharp Memorial Hospital
San Diego, California*

The material in this report originated in the National Center for Infectious Diseases, James M. Hughes, M.D., Director; and the Division of Healthcare Quality Promotion, Steven L. Solomon, M.D., Acting Director.

Summary

*The health-care facility environment is rarely implicated in disease transmission, except among patients who are immunocompromised. Nonetheless, inadvertent exposures to environmental pathogens (e.g., *Aspergillus* spp. and *Legionella* spp.) or airborne pathogens (e.g., *Mycobacterium tuberculosis* and varicella-zoster virus) can result in adverse patient outcomes and cause illness among health-care workers. Environmental infection-control strategies and engineering controls can effectively prevent these infections. The incidence of health-care--associated infections and pseudo-outbreaks can be minimized by 1) appropriate use of cleaners and disinfectants; 2) appropriate maintenance of medical equipment (e.g., automated endoscope reprocessors or hydrotherapy equipment); 3) adherence to water-quality standards for hemodialysis, and to ventilation standards for specialized care environments (e.g., airborne infection isolation rooms, protective environments, or operating rooms); and 4) prompt management of water intrusion into the facility. Routine environmental sampling is not usually advised, except for water quality determinations in hemodialysis settings and other situations where sampling is directed by epidemiologic principles, and results can be applied directly to infection-control decisions.*

This report reviews previous guidelines and strategies for preventing environment-associated infections in health-care facilities and offers recommendations. These include 1) evidence-based recommendations supported by studies; 2) requirements of federal agencies (e.g., Food and Drug Administration, U.S. Environmental Protection Agency, U.S. Department of Labor, Occupational Safety and Health

Administration, and U.S. Department of Justice); 3) guidelines and standards from building and equipment professional organizations (e.g., American Institute of Architects, Association for the Advancement of Medical Instrumentation, and American Society of Heating, Refrigeration, and Air-Conditioning Engineers); 4) recommendations derived from scientific theory or rationale; and 5) experienced opinions based upon infection-control and engineering practices. The report also suggests a series of performance measurements as a means to evaluate infection-control efforts.

Introduction

Parameters of the Report

This report, which contains the complete list of recommendations with pertinent references, is Part II of *Guidelines for Environmental Infection Control in Health-Care Facilities*. The full four-part guidelines will be available on CDC's Division of Healthcare Quality Promotion (DHQP) website. Relative to previous CDC guidelines, this report

- revises multiple sections (e.g., cleaning and disinfection of environmental surfaces, environmental sampling, laundry and bedding, and regulated medical waste) from previous editions of CDC's *Guideline for Handwashing and Hospital Environmental Control*;
- incorporates discussions of air and water environmental concerns from CDC's *Guideline for Prevention of Nosocomial Pneumonia*;
- consolidates relevant environmental infection-control measures from other CDC guidelines; and
- includes two topics not addressed in previous CDC guidelines --- infection-control concerns related to animals in health-care facilities and water quality in hemodialysis settings.

In the full guidelines, Part I, Background Information: Environmental Infection Control in Health-Care Facilities, provides a comprehensive review of the relevant scientific literature. Attention is given to engineering and infection-control concerns during construction, demolition, renovation, and repair of health-care facilities. Use of an infection-control risk assessment is strongly supported before the start of these or any other activities expected to generate dust or water aerosols. Also reviewed in Part I are infection-control measures used to recover from catastrophic events (e.g., flooding, sewage spills, loss of electricity and ventilation, or disruption of water supply) and the limited effects of environmental surfaces, laundry, plants, animals, medical wastes, cloth furnishings, and carpeting on disease transmission in health-care facilities. Part III and Part IV of the full guidelines provide references (for the complete guideline) and appendices, respectively.

Part II (this report) contains recommendations for environmental infection control in health-care facilities, describing control measures for preventing infections associated with air, water, or other elements of the environment. These recommendations represent the views of different divisions within CDC's National Center for Infectious Diseases and the Healthcare Infection Control Practices Advisory Committee (HICPAC), a 12-member group that advises CDC on concerns related to the surveillance, prevention, and control of health-care-associated infections, primarily in U.S. health-care facilities. In 1999, HICPAC's infection-control focus was expanded from acute-care hospitals to all venues where health care is provided (e.g., outpatient surgical centers, urgent care centers, clinics, outpatient dialysis centers, physicians' offices, and skilled nursing facilities). The topics addressed in this report are applicable to the majority of health-care facilities in the United States. This report is intended for use primarily by infection-control practitioners, epidemiologists, employee health and safety personnel, engineers, facility managers, information systems professionals, administrators, environmental service professionals, and architects. Key recommendations include

- infection-control impact of ventilation system and water system performance;
- establishment of a multidisciplinary team to conduct infection-control risk assessment;
- use of dust-control procedures and barriers during construction, repair, renovation, or demolition;
- environmental infection-control measures for special areas with patients at high risk;
- use of airborne-particle sampling to monitor the effectiveness of air filtration and dust-control measures;

- procedures to prevent airborne contamination in operating rooms when infectious tuberculosis (TB) patients require surgery;
- guidance regarding appropriate indications for routine culturing of water as part of a comprehensive control program for legionellae;
- guidance for recovering from water-system disruptions, water leaks, and natural disasters (e.g., flooding);
- infection-control concepts for equipment using water from main lines (e.g., water systems for hemodialysis, ice machines, hydrotherapy equipment, dental unit water lines, and automated endoscope reprocessors);
- environmental surface cleaning and disinfection strategies with respect to antibiotic-resistant microorganisms;
- infection-control procedures for health-care laundry;
- use of animals in health care for activities and therapy;
- managing the presence of service animals in health-care facilities;
- infection-control strategies for when animals receive treatment in human health-care facilities; and
- a call to reinstate the practice of inactivating amplified cultures and stocks of microorganisms onsite during medical waste treatment.

Topics outside the scope of this report include 1) noninfectious adverse events (e.g., sick building syndrome), 2) environmental concerns in the home, 3) home health care, 4) terrorism, and 5) health-care--associated foodborne illness.

Wherever possible, the recommendations in this report are based on data from well-designed scientific studies. However, certain of these studies were conducted by using narrowly defined patient populations or specific health-care settings (e.g., hospitals versus long-term care facilities), making generalization of findings potentially problematic. Construction standards for hospitals or other health-care facilities may not apply to residential home-care units. Similarly, infection-control measures indicated for immunosuppressed patient care are usually not necessary in those facilities where such patients are not present.

Other recommendations were derived from knowledge gained during infectious disease investigations in health-care facilities, where successful termination of the outbreak was often the result of multiple interventions, the majority of which cannot be independently and rigorously evaluated. This is especially true for construction situations involving air or water.

Other recommendations were derived from empiric engineering concepts and may reflect industry standards rather than evidence-based conclusions. Where recommendations refer to guidance from the American Institute of Architects (AIA), the statements reflect standards intended for new construction or renovation. Existing structures and engineered systems are expected to be in continued compliance with those standards in effect at the time of construction or renovation.

Also, in the absence of scientific confirmation, certain infection-control recommendations that cannot be rigorously evaluated are based on strong theoretic rationale and suggestive evidence. Finally, certain recommendations are derived from existing federal regulations.

Performance Measurements

Infections caused by the microorganisms described in this guideline are rare events, and the effect of these recommendations on infection rates in a facility may not be readily measurable. Therefore, the following steps to measure performance are suggested to evaluate these recommendations:

1. Document whether infection-control personnel are actively involved in all phases of a health-care facility's demolition, construction, and renovation. Activities should include performing a risk assessment of the necessary types of construction barriers, and daily monitoring and documenting of the presence of negative airflow within the construction zone or renovation area.
2. Monitor and document daily the negative airflow in AII rooms and positive airflow in PE rooms, especially when patients are in these rooms.
3. Perform assays at least once a month by using standard quantitative methods for endotoxin in water used to reprocess hemodialyzers, and for heterotrophic and mesophilic bacteria in water used to

prepare dialysate and for hemodialyzer reprocessing.

4. Evaluate possible environmental sources (e.g., water, laboratory solutions, or reagents) of specimen contamination when nontuberculous mycobacteria (NTM) of unlikely clinical importance are isolated from clinical cultures. If environmental contamination is found, eliminate the probable mechanisms.
5. Document policies to identify and respond to water damage. Such policies should result in either repair and drying of wet structural or porous materials within 72 hours, or removal of the wet material if drying is unlikely within 72 hours.

Updates to Previous Recommendations

Contributors to this report reviewed primarily English-language manuscripts identified from reference searches using the National Library of Medicine's MEDLINE, bibliographies of published articles, and infection-control textbooks. All the recommendations may not reflect the opinions of all reviewers. This report updates the following published guidelines and recommendations:

CDC. Guideline for handwashing and hospital environmental control. MMWR 1998;37(No. 24). Replaces sections on microbiologic sampling, laundry, infective waste, and housekeeping.

Tablan OC, Anderson LJ, Arden NH, et al., Hospital Infection Control Practices Advisory Committee. Guideline for prevention of nosocomial pneumonia. Infect Control Hosp Epidemiol 1994;15:587--627. Updates and expands environmental infection-control information for aspergillosis and Legionnaires disease; online version incorporates Appendices B, C, and D addressing environmental control and detection of *Legionella* spp.

CDC. Guidelines for preventing the transmission of *Mycobacterium tuberculosis* in health-care facilities. MMWR 1994;43(No. RR13). Provides supplemental information on engineering controls.

CDC. Recommendations for preventing the spread of vancomycin resistance: recommendations of the Hospital Infection Control Practices Advisory Committee (HICPAC). MMWR 1995;44(No. RR12). Supplements environmental infection-control information from the section, Hospitals with Endemic VRE or Continued VRE Transmission.

Garner JS, Hospital Infection Control Practices Advisory Committee. Guideline for isolation precautions in hospitals. Infect Control Hosp Epidemiol 1996;17:53--80. Supplements and updates topics in Part II --- Recommendations for Isolation Precautions in Hospitals (linen and laundry, routine and terminal cleaning, airborne precautions).

Mangram AJ, Horan TC, Pearson ML, Silver LC, Jarvis WR, Hospital Infection Control Practices Advisory Committee. Guideline for prevention of surgical site infection. Infect Control Hosp Epidemiol 1999;4:250--78. Updates operating room ventilation and surface cleaning/disinfection recommendations from the section, Intraoperative Issues: Operating Room Environment.

U.S. Public Health Service, Infectious Diseases Society of America, Prevention of Opportunistic Infections Working Group. USPHS/IDSA guidelines for the prevention of opportunistic infections in persons infected with human immunodeficiency virus. Infect Dis Obstet Gynecol 2002; 10:3--64. Supplements information regarding patient interaction with pets and animals in the home.

CDC, Infectious Diseases Society of America, American Society of Blood and Marrow Transplantation. Guidelines for preventing opportunistic infections among hematopoietic stem cell transplant recipients. Cytotherapy 2001;3:41--54. Supplements and updates the section, Hospital Infection Control.

Key Terms

Airborne infection isolation (AII) refers to the isolation of patients infected with organisms spread via airborne droplet nuclei $<5\ \mu\text{m}$ in diameter. This isolation area receives numerous air changes per hour (ACH) (≥ 12 ACH for new construction as of 2001; ≥ 6 ACH for construction before 2001), and is under negative pressure, such that the direction of the air flow is from the outside adjacent space (e.g., the corridor) into the room. The air in an AII room is preferably exhausted to the outside, but may be

recirculated provided that the return air is filtered through a high-efficiency particulate air (HEPA) filter. The use of personal respiratory protection is also indicated for persons entering these rooms when caring for TB or smallpox patients and for staff who lack immunity to airborne viral diseases (e.g., measles or varicella zoster virus [VZV] infection).

Protective environment (PE) is a specialized patient-care area, usually in a hospital, with a positive air flow relative to the corridor (i.e., air flows from the room to the outside adjacent space). The combination of HEPA filtration, high numbers of air changes per hour (≥ 12 ACH), and minimal leakage of air into the room creates an environment that can safely accommodate patients who have undergone allogeneic hematopoietic stem cell transplant (HSCT).

Immunocompromised patients are those patients whose immune mechanisms are deficient because of immunologic disorders (e.g., human immunodeficiency virus [HIV] infection or congenital immune deficiency syndrome), chronic diseases (e.g., diabetes, cancer, emphysema, or cardiac failure), or immunosuppressive therapy (e.g., radiation, cytotoxic chemotherapy, anti-rejection medication, or steroids). Immunocompromised patients who are identified as high-risk patients have the greatest risk of infection caused by airborne or waterborne microorganisms. Patients in this subset include persons who are severely neutropenic for prolonged periods of time (i.e., an absolute neutrophil count [ANC] of ≤ 500 cells/mL), allogeneic HSCT patients, and those who have received the most intensive chemotherapy (e.g., childhood acute myelogenous leukemia patients).

Recommendations for Environmental Infection Control in Health-Care Facilities

Rationale for Recommendations

As in previous CDC guidelines, each recommendation is categorized on the basis of existing scientific data, theoretic rationale, applicability, and possible economic effect. The recommendations are evidence-based wherever possible. However, certain recommendations are derived from empiric infection-control or engineering principles, theoretic rationale, or from experience gained from events that cannot be readily studied (e.g., floods).

The HICPAC system for categorizing recommendations has been modified to include a category for engineering standards and actions required by state or federal regulations. Guidelines and standards published by the AIA, American Society of Heating, Refrigeration, and Air-Conditioning Engineers (ASHRAE), and the Association for the Advancement of Medical Instrumentation (AAMI) form the basis of certain recommendations. These standards reflect a consensus of expert opinions and extensive consultation with agencies of the U.S. Department of Health and Human Services. Compliance with these standards is usually voluntary. However, state and federal governments often adopt these standards as regulations. For example, the standards from AIA regarding construction and design of new or renovated health-care facilities, have been adopted by reference by >40 states. Certain recommendations have two

category ratings (e.g., Categories IA and IC or Categories IB and IC), indicating the recommendation is evidence-based as well as a standard or regulation.

Rating Categories

Recommendations are rated according to the following categories:

Category IA. Strongly recommended for implementation and strongly supported by well-designed experimental, clinical, or epidemiologic studies.

Category IB. Strongly recommended for implementation and supported by certain experimental, clinical, or epidemiologic studies and a strong theoretic rationale.

Category IC. Required by state or federal regulation, or representing an established association standard. (Note: Abbreviations for governing agencies and regulatory citations are listed where appropriate. Recommendations from regulations adopted at state levels are also noted. Recommendations from AIA guidelines cite the appropriate sections of the standards.)

Category II. Suggested for implementation and supported by suggestive clinical or epidemiologic studies, or a theoretic rationale.

Unresolved issue. No recommendation is offered. No consensus or insufficient evidence exists regarding efficacy.

Recommendations --- Air

I. Air-Handling Systems in Health-Care Facilities

- A. Use AIA guidelines as minimum standards where state or local regulations are not in place for design and construction of ventilation systems in new or renovated health-care facilities. Ensure that existing structures continue to meet the specifications in effect at the time of construction (*I*). Category IC (AIA: 1.1.A, 5.4)
- B. Monitor ventilation systems in accordance with engineers' and manufacturers' recommendations to ensure preventive engineering, optimal performance for removal of particulates, and elimination of excess moisture (*I--8*). Category IB, IC (AIA: 7.2, 7.31.D, 8.31.D, 9.31.D, 10.31.D, 11.31.D, Environmental Protection Agency [EPA] guidance)
 1. Ensure that heating, ventilation, air conditioning (HVAC) filters are properly installed and maintained to prevent air leakages and dust overloads (*2,4,6,9*). Category IB
 2. Monitor areas with special ventilation requirements (e.g., AII or PE) for ACH, filtration, and pressure differentials (*1,7,8,10--26*). Category IB, IC (AIA: 7.2.C7, 7.2.D6)
 - a. Develop and implement a maintenance schedule for ACH, pressure differentials, and filtration efficiencies by using facility-specific data as part of the multidisciplinary risk assessment. Take into account the age and reliability of the system.
 - b. Document these parameters, especially the pressure differentials.
 3. Engineer humidity controls into the HVAC system and monitor the controls to ensure adequate moisture removal (*I*). Category IC (AIA: 7.31.D9)
 - a. Locate duct humidifiers upstream from the final filters.
 - b. Incorporate a water-removal mechanism into the system.
 - c. Locate all duct takeoffs sufficiently downstream from the humidifier so that moisture is completely absorbed.
 4. Incorporate steam humidifiers, if possible, to reduce potential for microbial proliferation within the system, and avoid use of cool-mist humidifiers. Category II
 5. Ensure that air intakes and exhaust outlets are located properly in construction of new facilities and

renovation of existing facilities (1,27). Category IC (AIA: 7.31.D3, 8.31.D3, 9.31.D3, 10.31.D3, 11.31.D3)

- a. Locate exhaust outlets >25 ft from air-intake systems.
- b. Locate outdoor air intakes ≥ 6 ft above ground or ≥ 3 ft above roof level.
- c. Locate exhaust outlets from contaminated areas above roof level to minimize recirculation of exhausted air.

6. Maintain air intakes and inspect filters periodically to ensure proper operation (1,11--16,27). Category IC (AIA: 7.31.D8)

7. Bag dust-filled filters immediately upon removal to prevent dispersion of dust and fungal spores during transport within the facility (4,28). Category IB

- a. Seal or close the bag containing the discarded filter.
- b. Discard spent filters as regular solid waste, regardless of the area from which they were removed (28).

8. Remove bird roosts and nests near air intakes to prevent mites and fungal spores from entering the ventilation system (27,29,30). Category IB

9. Prevent dust accumulation by cleaning air-duct grilles in accordance with facility-specific procedures and schedules and when rooms are not occupied by patients (1,10--16).

Category IC, II (AIA: 7.31.D10)

10. Periodically measure output to monitor system function; clean ventilation ducts as part of routine HVAC maintenance to ensure optimum performance (1,31,32). Category IC, II (AIA: 7.31.D10)

C. Use portable, industrial-grade HEPA filter units capable of filtration rates in the range of 300--800 ft³/min to augment removal of respirable particles as needed (33). Category II

1. Select portable HEPA filters that can recirculate all or nearly all of the room air and provide the equivalent of ≥ 12 ACH (34). Category II

2. Portable HEPA filter units placed in construction zones can be used later in patient-care areas, provided all internal and external surfaces are cleaned, and the filter replaced or its performance verified by appropriate particle testing. Category II

3. Situate portable HEPA units with the advice of facility engineers to ensure that all room air is filtered (34). Category II

4. Ensure that fresh-air requirements for the area are met (33,35). Category II

D. Follow appropriate procedures for use of areas with through-the-wall ventilation units (1). Category IC (AIA: 8.31.D1, 8.31.D8, 9.31.D23, 10.31.D18, 11.31.D15)

1. Do not use such areas as PE rooms (1). Category IC (AIA: 7.2.D3)

2. Do not use a room with a through-the-wall ventilation unit as an AII room unless it can be demonstrated that all required AII engineering controls are met (1,34). Category IC (AIA: 7.2.C3)

E. Conduct an infection-control risk assessment (ICRA) and provide an adequate number of AII and PE rooms (if required) or other areas to meet the needs of the patient population (1,2,7,8,17,19, 20,34,36--43). Category IA, IC (AIA: 7.2.C, 7.2.D)

F. When ultraviolet germicidal irradiation (UVGI) is used as a supplemental engineering control, install fixtures 1) on the wall near the ceiling or suspended from the ceiling as an upper air unit; 2) in the air-return duct of an AII area; or 3) in designated enclosed areas or booths for sputum induction (34). Category II

G. Seal windows in buildings with centralized HVAC systems, including PE areas (1,3,44). Category IB, IC (AIA: 7.2.D3)

H. Keep emergency doors and exits from PE rooms closed except during an emergency; equip emergency doors and exits with alarms. Category II

- I. Develop a contingency plan for backup capacity in the event of a general power failure (45). Category IC (Joint Commission on Accreditation of Healthcare Organizations [JCAHO]: Environment of Care [EC] 1.4)

1. Emphasize restoration of appropriate air quality and ventilation conditions in All rooms, PE rooms, operating rooms, emergency departments, and intensive care units (1,45).

Category IC (AIA: 1.5.A1; JCAHO: EC 1.4)

2. Deploy infection-control procedures to protect occupants until power and systems functions are restored (1,36,45). Category IC (AIA: 5.1, 5.2; JCAHO: EC 1.4)

- J. Do not shut down HVAC systems in patient-care areas except for maintenance, repair, testing of emergency backup capacity, or new construction (1,46). Category IB, IC (AIA: 5.1, 5.2.B, C)

1. Coordinate HVAC system maintenance with infection-control staff and relocate immunocompromised patients if necessary (1). Category IC (AIA: 5.1, 5.2)

2. Provide backup emergency power and air-handling and pressurization systems to maintain filtration, constant ACH, and pressure differentials in PE rooms, All rooms, operating rooms, and other critical-care areas (1,37,47). Category IC (AIA: 5.1, 5.2)

3. For areas not served by installed emergency ventilation and backup systems, use portable units and monitor ventilation parameters and patients in those areas (33). Category II

4. Coordinate system startups with infection-control staff to protect patients in PE rooms from bursts of fungal spores (1,3,37,47). Category IC (AIA: 5.1, 5.2)

5. Allow sufficient time for ACH to clean the air once the system is operational (Table 1) (1,33). Category IC (AIA: 5.1, 5.2)

- K. HVAC systems serving offices and administrative areas may be shut down for energy conservation purposes, but the shutdown must not alter or adversely affect pressure differentials maintained in laboratories or critical-care areas with specific ventilation requirements (i.e., PE rooms, All rooms, operating rooms). Category II

- L. Whenever possible, avoid inactivating or shutting down the entire HVAC system, especially in acute-care facilities. Category II

- M. Whenever feasible, design and install fixed backup ventilation systems for new or renovated construction of PE rooms, All rooms, operating rooms, and other critical-care areas identified by ICRA (1). Category IC (AIA: 1.5.A1)

II. Construction, Renovation, Remediation, Repair, and Demolition

- A. Establish a multidisciplinary team that includes infection-control staff to coordinate demolition, construction, and renovation projects and consider proactive preventive measures at the inception; produce and maintain summary statements of the team's activities (1,9,11--16,38,48--51). Category IB, IC (AIA: 5.1)

- B. Educate both the construction team and health-care staff in immunocompromised patient-care areas regarding the airborne infection risks associated with construction projects, dispersal of fungal spores during such activities, and methods to control the dissemination of fungal spores (11--16,27,50,52--56). Category IB

- C. Incorporate mandatory adherence agreements for infection control into construction contracts, with penalties for noncompliance and mechanisms to ensure timely correction of problems (1,11,13--16,27,50). Category IC (AIA: 5.1)

- D. Establish and maintain surveillance for airborne environmental disease (e.g., aspergillosis) as appropriate during construction, renovation, repair, and demolition activities to ensure the health and safety of immunocompromised patients (27,57--59). Category IB

1. Using active surveillance, monitor for airborne infections in immunocompromised patients (27,37,57,58). Category IB

2. Periodically review the facility's microbiologic, histopathologic, and postmortem data to identify additional cases (27,37,57,58). Category IB

3. If cases of aspergillosis or other health-care--associated airborne fungal infections occur, aggressively pursue the diagnosis with tissue biopsies and cultures as feasible (11,13--

E. Implement infection-control measures relevant to construction, renovation, maintenance, demolition, and repair (1,16,49,50,60). Category IB, IC (AIA: 5.1, 5.2)

1. Before the project gets under way, perform an ICRA to define the scope of the activity and the need for barrier measures (1,11,13--16,48--51,60). Category IB, IC (AIA: 5.1)

a. Determine if immunocompromised patients may be at risk for exposure to fungal spores from dust generated during the project (13--16,48,51).

b. Develop a contingency plan to prevent such exposures (13--16,48,51).

2. Implement infection-control measures for external demolition and construction activities (11,13--16,50,61,62). Category IB

a. Determine if the facility can operate temporarily on recirculated air; if feasible, seal off adjacent air intakes.

b. If this is not possible or practical, check the low-efficiency (roughing) filter banks frequently and replace as needed to avoid buildup of particulates.

c. Seal windows and reduce wherever possible other sources of outside air intrusion (e.g., open doors in stairwells and corridors), especially in PE areas.

3. Avoid damaging the underground water system (i.e., buried pipes) to prevent soil and dust contamination of the water (1,63). Category IB, IC (AIA: 5.1)

4. Implement infection-control measures for internal construction activities (1,11,13--16,48--50,64). Category IB, IC (AIA: 5.1, 5.2)

a. Construct barriers to prevent dust from construction areas from entering patient-care areas; ensure that barriers are impermeable to fungal spores and in compliance with local fire codes (1,45,48,49,55,64--66).

b. Seal off and block return air vents if rigid barriers are used for containment (1,16,50).

c. Implement dust-control measures on surfaces and divert pedestrian traffic away from work zones (1,48,49,64).

d. Relocate patients whose rooms are adjacent to work zones, depending on their immune status, the scope of the project, the potential for generation of dust or water aerosols, and the methods used to control these aerosols (1,64,65).

5. Perform those engineering and work-site related infection-control measures as needed for internal construction, repairs, and renovations (1,48,49,51,64,66). Category IB, IC (AIA: 5.1, 5.2)

a. Ensure proper operation of the air-handling system in the affected area after erection of barriers and before the room or area is set to negative pressure (39,47,50,64). Category IB

b. Create and maintain negative air pressure in work zones adjacent to patient-care areas and ensure that required engineering controls are maintained (1,48,49,51,64,66).

c. Monitor negative airflow inside rigid barriers (1,67).

d. Monitor barriers and ensure integrity of the construction barriers; repair gaps or breaks in barrier joints (1,65,66,68).

e. Seal windows in work zones if practical; use window chutes for disposal of large pieces of debris as needed, but ensure that the negative pressure differential for the area is maintained (1,13,48).

f. Direct pedestrian traffic from construction zones away from patient-care areas to minimize dispersion of dust (1,13--16,44,48--51,64).

g. Provide construction crews with 1) designated entrances, corridors, and elevators wherever practical; 2) essential services (e.g., toilet facilities) and convenience services (e.g., vending machines); 3) protective clothing (e.g., coveralls, footgear, and headgear) for travel to patient-care areas; and 4) a space or anteroom for changing clothing and storing

equipment (1,11,13--16,50).

h. Clean work zones and their entrances daily by 1) wet-wiping tools and tool carts before their removal from the work zone; 2) placing mats with tacky surfaces inside the entrance; and 3) covering debris and securing this covering before removing debris from the work zone (1,11,13--16,50).

i. In patient-care areas, for major repairs that include removal of ceiling tiles and disruption of the space above the false ceiling, use plastic sheets or prefabricated plastic units to contain dust; use a negative pressure system within this enclosure to remove dust; and either pass air through an industrial-grade, portable HEPA filter capable of filtration rates of 300--800 ft³/min., or exhaust air directly to the outside (16,50,64,67,69).

j. Upon completion of the project, clean the work zone according to facility procedures, and install barrier curtains to contain dust and debris before removing rigid barriers (1,11,13--16,48--50).

k. Flush the water system to clear sediment from pipes to minimize waterborne microorganism proliferation (1,63).

l. Restore appropriate ACH, humidity, and pressure differential; clean or replace air filters; dispose of spent filters (3,4,28,47).

F. Use airborne-particle sampling as a tool to evaluate barrier integrity (3,70). Category II

G. Commission the HVAC system for newly constructed health-care facilities and renovated spaces before occupancy and use, with emphasis on ensuring proper ventilation for operating rooms, AII rooms, and PE areas (1,70--72). Category IC (AIA: 5.1; ASHRAE: 1-1996)

H. No recommendation is offered regarding routine microbiologic air sampling before, during, or after construction, or before or during occupancy of areas housing immunocompromised patients (9,48,49,51,64,73,74). Unresolved issue

I. If a case of health-care--acquired aspergillosis or other opportunistic environmental airborne fungal disease occurs during or immediately after construction, implement appropriate follow-up measures (40,48,75--78). Category IB

1. Review pressure-differential monitoring documentation to verify that pressure differentials in the construction zone and in PE rooms are appropriate for their settings (1,40,78).

Category IB, IC (AIA: 5.1)

2. Implement corrective engineering measures to restore proper pressure differentials as needed (1,40,78). Category IB, IC (AIA: 5.1)

3. Conduct a prospective search for additional cases and intensify retrospective epidemiologic review of the hospital's medical and laboratory records (27,48,76,79,80). Category IB

4. If no epidemiologic evidence of ongoing transmission exists, continue routine maintenance in the area to prevent health-care--acquired fungal disease (27,75). Category IB

J. If no epidemiologic evidence exists of ongoing transmission of fungal disease, conduct an environmental assessment to find and eliminate the source (11,13--16,27,44,49--51,60,81). Category IB

1. Collect environmental samples from potential sources of airborne fungal spores, preferably by using a high-volume air sampler rather than settle plates (2,4,11,13--16,27,44,49,50,64,65,81--86). Category IB

2. If either an environmental source of airborne fungi or an engineering problem with filtration or pressure differentials is identified, promptly perform corrective measures to eliminate the source and route of entry (49,60). Category IB

3. Use an EPA-registered antifungal biocide (e.g., copper-8-quinolinolate) for decontaminating structural materials (16,61,66,87). Category IB

4. If an environmental source of airborne fungi is not identified, review infection-control measures, including engineering controls, to identify potential areas for correction or improvement (88,89). Category IB

5. If possible, perform molecular subtyping of *Aspergillus* spp. isolated from patients and the environment to compare their strain identities (90--94). Category II

- K. If air-supply systems to high-risk areas (e.g., PE rooms) are not optimal, use portable, industrial-grade HEPA filters on a temporary basis until rooms with optimal air-handling systems become available (1,13--16,27,50). Category II

III. Infection Control and Ventilation Requirements for PE rooms

- A. Minimize exposures of severely immunocompromised patients (e.g., solid-organ transplant patients or allogeneic neutropenic patients) to activities that might cause aerosolization of fungal spores (e.g., vacuuming or disruption of ceiling tiles) (37,48,51,73). Category IB
- B. Minimize the length of time that immunocompromised patients in PE are outside their rooms for diagnostic procedures and other activities (37,62). Category IB
- C. Provide respiratory protection for severely immunocompromised patients when they must leave PE for diagnostic procedures and other activities; consult the most recent revision of CDC's *Guideline for Prevention of Health-Care--Associated Pneumonia* for information regarding the appropriate type of respiratory protection. (27,37). Category II
- D. Incorporate ventilation engineering specifications and dust-controlling processes into the planning and construction of new PE units (Figure 1). Category IB, IC
 - 1. Install central or point-of-use HEPA filters for supply (incoming) air (1,2,27,48,56,70, 80,82,85,95--102). Category IB, IC (AIA: 5.1, 5.2, 7.2.D)
 - 2. Ensure that rooms are well-sealed by 1) properly constructing windows, doors, and intake and exhaust ports; 2) maintaining ceilings that are smooth and free of fissures, open joints, and crevices; 3) sealing walls above and below the ceiling; and 4) monitoring for leakage and making any necessary repairs (1,27,44,100,101). Category IB, IC (AIA: 7.2.D3)
 - 3. Ventilate the room to maintain ≥ 12 ACH (1,27,37,100,101,103). Category IC (AIA: 7.2.D)
 - 4. Locate air supply and exhaust grilles so that clean, filtered air enters from one side of the room, flows across the patient's bed, and exits from the opposite side of the room (1,27,100,101). Category IC (AIA: 7.31.D1)
 - 5. Maintain positive room air pressure (≥ 2.5 Pa [0.01-inch water gauge]) in relation to the corridor (1,3,27,100,101). Category IB, IC (AIA: Table 7.2)
 - 6. Maintain airflow patterns and monitor these on a daily basis by using permanently installed visual means of detecting airflow in new or renovated construction, or by using other visual methods (e.g., flutter strips or smoke tubes) in existing PE units. Document the monitoring results (1,13). Category IC (AIA: 7.2.D6)
 - 7. Install self-closing devices on all room exit doors in PE rooms (1). Category IC (AIA: 7.2.D4)
- E. Do not use laminar air flow systems in newly constructed PE rooms (99,101). Category II
- F. Take measures to protect immunocompromised patients who would benefit from a PE room and who also have an airborne infectious disease (e.g., acute VZV infection or tuberculosis).
 - 1. Ensure that the patient's room is designed to maintain positive pressure.
 - 2. Use an anteroom to ensure appropriate air-balance relationships and provide independent exhaust of contaminated air to the outside, or place a HEPA filter in the exhaust duct if the return air must be recirculated (1,100) (Figure 2). Category IC (AIA: 7.2.D1, A7.2.D)
 - 3. If an anteroom is not available, place the patient in AII and use portable, industrial-grade HEPA filters to enhance filtration of spores in the room (33). Category II
- G. Maintain backup ventilation equipment (e.g., portable units for fans or filters) for emergency provision of required ventilation for PE areas and take immediate steps to restore the fixed ventilation system (1,37,47). Category IC (AIA: 5.1)

IV. Infection-Control and Ventilation Requirements for AII Rooms

- A. Incorporate certain specifications into the planning and construction or renovation of AII units (1,34,100,101,104) (Figure 3). Category IB, IC
 - 1. Maintain continuous negative air pressure (2.5 Pa [0.01 inch water gauge]) in relation to the air pressure in the corridor; monitor air pressure periodically, preferably daily, with

audible manometers or smoke tubes at the door (for existing AII rooms), or with a permanently installed visual monitoring mechanism. Document the results of monitoring

(1,100,101). Category IC (AIA: 7.2.C7, Table 7.2)

2. Ensure that rooms are well-sealed by properly constructing windows, doors, and air-intake and exhaust ports; when monitoring indicates air leakage, locate the leak and make necessary repairs (1,99,100). Category IB, IC (AIA: 7.2.C3)

3. Install self-closing devices on all AII room exit doors (1). Category IC (AIA: 7.2.C4)

4. Provide ventilation to ensure ≥ 12 ACH for renovated rooms and new rooms, and ≥ 6 ACH for existing AII rooms (1,34,104). Category IB, IC (AIA: Table 7.2)

5. Direct exhaust air to the outside, away from air-intake and populated areas. If this is not practical, air from the room can be recirculated after passing through a HEPA filter (1,34).

Category IC (AIA: Table 7.2)

B. Where supplemental engineering controls for air cleaning are indicated from a risk assessment of the AII area, install UVGI units in the exhaust air ducts of the HVAC system to supplement HEPA filtration or install UVGI fixtures on or near the ceiling to irradiate upper room air (34). Category II

C. Implement environmental infection-control measures for persons with diagnosed or suspected airborne infectious diseases.

1. Use AII rooms for patients with or suspected of having an airborne infection who also require cough-inducing procedures, or use an enclosed booth that is engineered to provide 1)

≥ 12 ACH; 2) air supply and exhaust rate sufficient to maintain a 2.5 Pa (0.01-inch water gauge) negative pressure difference with respect to all surrounding spaces with an exhaust

rate of ≥ 50 ft³/min; and 3) air exhausted directly outside away from air intakes and traffic or exhausted after HEPA filtration before recirculation (1,34,105--107). Category IB, IC

(AIA: 7.15.E, 7.31.D23, 9.10, Table 7.2)

2. Although airborne spread of viral hemorrhagic fever (VHF) has not been documented in a health-care setting, prudence dictates placing a VHF patient in an AII room, preferably with an anteroom, to reduce the risk of occupational exposure to aerosolized infectious material in blood, vomitus, liquid stool, and respiratory secretions present in large amounts during the end stage of a patient's illness (108--110). Category II

a. If an anteroom is not available, use portable, industrial-grade HEPA filters in the patient's room to provide additional ACH equivalents for removing airborne particulates.

b. Ensure that health-care workers wear face shields or goggles with appropriate respirators when entering the rooms of VHF patients with prominent cough, vomiting, diarrhea, or hemorrhage (109).

3. Place smallpox patients in negative pressure rooms at the onset of their illness, preferably using a room with an anteroom, if available (36). Category II

D. No recommendation is offered regarding negative pressure or isolation for patients with *Pneumocystis carinii* pneumonia (111--113). Unresolved issue.

E. Maintain backup ventilation equipment (e.g., portable units for fans or filters) for emergency provision of ventilation requirements for AII rooms, and take immediate steps to restore the fixed ventilation system (1,34,47). Category IC (AIA: 5.1)

V. Infection-Control and Ventilation Requirements for Operating Rooms

A. Implement environmental infection-control and ventilation measures for operating rooms.

1. Maintain positive-pressure ventilation with respect to corridors and adjacent areas (1,114,115). Category IB, IC (AIA: Table 7.2)

2. Maintain ≥ 15 ACH, of which ≥ 3 ACH should be fresh air (1,116,117). Category IC (AIA: Table 7.2)

3. Filter all recirculated and fresh air through the appropriate filters, providing 90% efficiency (dust-spot testing) at a minimum (1,118). Category IC (AIA: Table 7.3)

4. In rooms not engineered for horizontal laminar airflow, introduce air at the ceiling and exhaust air

near the floor (1,115,119). Category IC (AIA: 7.31.D4)

5. Do not use ultraviolet (UV) lights to prevent surgical-site infections (115,120--126). Category IB

6. Keep operating room doors closed except for the passage of equipment, personnel, and patients, and limit entry to essential personnel (127,128). Category IB

B. Follow precautionary procedures for infectious TB patients who also require emergency surgery (34,129,130). Category IB, IC

1. Use an N95 respirator approved by the National Institute for Occupational Safety and Health without exhalation valves in the operating room (129,131). Category IC (Occupational

Safety and Health Administration [OSHA]; 29 Code of Federal Regulations [CFR] 1910.134,139)

2. Intubate the patient in either the AII room or the operating room; if intubating the patient in the operating room, do not allow the doors to open until 99% of the airborne contaminants are removed (Table 1) (34,117). Category IB

3. When anesthetizing a patient with confirmed or suspected TB, place a bacterial filter between the anesthesia circuit and patient's airway to prevent contamination of anesthesia equipment or discharge of tubercle bacilli into the ambient air (130,132). Category IB

4. Extubate and allow the patient to recover in an AII room (34,117). Category IB

5. If the patient has to be extubated in the operating room, allow adequate time for ACH to clean 99% of airborne particles from the air (Table 1), because extubation is a cough-producing procedure (34,117). Category IB

C. Use portable, industrial-grade HEPA filters temporarily for supplemental air cleaning during intubation and extubation for TB patients who require surgery (33,34,117). Category II

1. Position the units appropriately so that all room air passes through the filter; obtain engineering consultation to determine the appropriate placements (34). Category II

2. Switch the portable unit off during the surgical procedure. Category II

3. Provide fresh air as per ventilation standards for operating rooms; portable units do not meet the requirements for the number of fresh ACH (1,33,133). Category II

D. If possible, schedule TB patients as the last surgical cases of the day to maximize the time available for removal of airborne contamination. Category II

E. No recommendation is offered for performing orthopedic implant operations in rooms supplied with laminar airflow (118,120). Unresolved issue

F. Maintain backup ventilation equipment (e.g., portable units for fans or filters) for emergency ventilation of operating rooms, and take immediate steps to restore the fixed ventilation system (1,47,131,134). Category IB, IC (AIA: 5.1)

VI. Other Potential Infectious Aerosol Hazards in Health-Care Facilities

A. In settings where surgical lasers are used, wear appropriate personal protective equipment (PPE), including N95 or N100 respirators, to minimize exposure to laser plumes (129,135,136). Category IC (OSHA; 29 CFR 1910.134,139)

B. Use central wall suction units with in-line filters to evacuate minimal laser plumes (135--138). Category II

C. Use a mechanical smoke evacuation system with a high-efficiency filter to manage the generation of large amounts of laser plume, when ablating tissue infected with human papilloma virus (HPV) or performing procedures on a patient with extrapulmonary TB (34,136,137,139--141). Category II

Recommendations --- Water

I. Controlling the Spread of Waterborne Microorganisms

A. Practice hand hygiene to prevent the hand transfer of waterborne pathogens, and use barrier precautions (e.g., gloves) as defined by other guidelines (36,142--146). Category IA

B. Eliminate contaminated water or fluid environmental reservoirs (e.g., in equipment or solutions) wherever possible (142,147). Category IB

- C. Clean and disinfect sinks and wash basins on a regular basis by using an EPA-registered product as set by facility policies. Category II
- D. Evaluate for possible environmental sources (e.g., potable water) of specimen contamination when waterborne microorganisms (e.g., NTM) of unlikely clinical importance are isolated from clinical cultures (e.g., specimens collected aseptically from sterile sites or, if postprocedural, colonization after use of tap water in patient care) (148--151). Category IB
- E. Avoid placing decorative fountains and fish tanks in patient-care areas; ensure disinfection and fountain maintenance if decorative fountains are used in public areas of the health-care facility (152). Category IB

II. Routine Prevention of Waterborne Microbial Contamination Within the Distribution System

- A. Maintain hot water temperature at the return at the highest temperature allowable by state regulations or codes, preferably $\geq 124^{\circ}\text{F}$ ($\geq 51^{\circ}\text{C}$), and maintain cold water temperature at $< 68^{\circ}\text{F}$ ($< 20^{\circ}\text{C}$) (27, 153). Category IC (States; ASHRAE: 12:2000)
- B. If the hot water temperature can be maintained at $\geq 124^{\circ}\text{F}$ ($\geq 51^{\circ}\text{C}$), explore engineering options (e.g., installing preset thermostatic valves in point-of-use fixtures) to help minimize the risk of scalding (153). Category II
- C. When state regulations or codes do not allow hot water temperatures above the range of 105°F -- 120°F (40.6°C -- 49°C) for hospitals or 95°F -- 110°F (35°C -- 43.3°C) for nursing care facilities or when buildings cannot be retrofitted for thermostatic mixing valves, follow either of these alternative preventive measures to minimize the growth of *Legionella* spp. in water systems. Category II
 - 1. Periodically increase the hot water temperature to $\geq 150^{\circ}\text{F}$ ($\geq 66^{\circ}\text{C}$) at the point of use (153). Category II
 - 2. Alternatively, chlorinate the water and then flush it through the system (153--155). Category II
- D. Maintain constant recirculation in hot-water distribution systems serving patient-care areas (1). Category IC (AIA: 7.31.E.3)

III. Remediation Strategies for Distribution System Repair or Emergencies

- A. Whenever possible, disconnect the ice machine before planned water disruptions. Category II
- B. Prepare a contingency plan to estimate water demands for the entire facility in advance of significant water disruptions (i.e., those expected to result in extensive and heavy microbial or chemical contamination of the potable water), sewage intrusion, or flooding (45, 156). Category IC (JCAHO: EC 1.4)
- C. When a significant water disruption or an emergency occurs, adhere to any advisory to boil water issued by the municipal water utility (157). Category IB, IC (Municipal order)
 - 1. Alert patients, families, staff, and visitors not to consume water from drinking fountains, ice, or drinks made from municipal tap water, while the advisory is in effect, unless the water has been disinfected (e.g., by bringing to a rolling boil for ≥ 1 minute) (157). Category IB, IC (Municipal order)
 - 2. After the advisory is lifted, run faucets and drinking fountains at full flow for ≥ 5 minutes, or use high-temperature water flushing or chlorination (153, 157). Category IC, II (Municipal order; ASHRAE: 12:2000)
- D. Maintain a high level of surveillance for waterborne disease among patients after a boil water advisory is lifted. Category II
- E. Corrective decontamination of the hot water system might be necessary after a disruption in service or a cross-connection with sewer lines has occurred.
 - 1. Decontaminate the system when the fewest occupants are present in the building (e.g., nights or weekends) (27, 153). Category IC (ASHRAE: 12:2000)
 - 2. If using high-temperature decontamination, raise the hot-water temperature to 160°F -- 170°F (71°C --

-77°C) and maintain that level while progressively flushing each outlet around the system for ≥ 5 minutes (27,153). Category IC (ASHRAE: 12:2000)

3. If using chlorination, add enough chlorine, preferably overnight, to achieve a free chlorine residual of ≥ 2 mg/L (≥ 2 ppm) throughout the system (153). Category IC (ASHRAE: 12:2000)

a. Flush each outlet until chlorine odor is detected.

b. Maintain the elevated chlorine concentration in the system for ≥ 2 (but ≤ 24 hrs).

4. Use a thorough flushing of the water system instead of chlorination if a highly chlorine-resistant microorganism (e.g., *Cryptosporidium* spp.) is suspected as the water contaminant.

Category II

F. Flush and restart equipment and fixtures according to manufacturer's instructions. Category II

G. Change the pretreatment filter and disinfect the dialysis water system with an EPA-registered product to prevent colonization of the reverse osmosis membrane and downstream microbial contamination (158). Category II

H. Run water softeners through a regeneration cycle to restore their capacity and function. Category II

I. If the facility has a water-holding reservoir or water-storage tank, consult the facility engineer or local health department to determine whether this equipment needs to be drained, disinfected with an EPA-registered product, and refilled. Category II

J. Implement facility procedures to manage a sewage system failure or flooding (e.g., arranging with other health-care facilities for temporary transfer of patients or provision of services), and establish communications with the local municipal water utility and the local health department to ensure that advisories are received in a timely manner after release (45,156). Category IC (JCAHO: EC 1.4; Municipal order)

K. Implement infection-control measures during sewage intrusion, flooding, or other water-related emergencies.

1. Relocate patients and clean or sterilize supplies from affected areas. Category II

2. If hands are not visibly soiled or contaminated with proteinaceous material, include an alcohol-based hand rub in the hand hygiene process 1) before performing invasive procedures;

2) before and after each patient contact; and 3) whenever hand hygiene is indicated (146).

Category II

3. If hands are visibly soiled or contaminated with proteinaceous material, use soap and bottled water for handwashing (146). Category II

4. If the potable water system is not affected by flooding or sewage contamination, process surgical instruments for sterilization according to standard procedures. Category II

5. Contact the manufacturer of the automated endoscope reprocessor (AER) for specific instructions on the use of this equipment during a water advisory. Category II

L. Remediate the facility after sewage intrusion, flooding, or other water-related emergencies.

1. Close off affected areas during cleanup procedures. Category II

2. Ensure that the sewage system is fully functional before beginning remediation so contaminated solids and standing water can be removed. Category II

3. If hard-surfaced equipment, floors, and walls remain in good repair, ensure that these are dry within 72 hours; clean with detergent according to standard cleaning procedures.

Category II

4. Clean wood furniture and materials (if still in good repair); allow them to dry thoroughly before restoring varnish or other surface coatings. Category II

5. Contain dust and debris during remediation and repair as outlined in air recommendations (Air: IIG 4, 5). Category II

M. Regardless of the original source of water damage (e.g., flooding versus water leaks from point-of-use fixtures or roofs), remove wet, absorbent structural items (e.g., carpeting, wallboard, and wallpaper) and cloth furnishings if they cannot be easily and thoroughly cleaned and dried within 72

hours (e.g., moisture content $\leq 20\%$ as determined by moisture meter readings); replace with new materials as soon as the underlying structure is declared by the facility engineer to be thoroughly dry (2,47,159,160). Category IB

IV. Additional Engineering Measures as Indicated by Epidemiologic Investigation for Controlling Waterborne, Health-Care--Associated Legionnaires Disease

- A. When using a pulse or one-time decontamination method, superheat the water by flushing each outlet for ≥ 5 minutes with water at 160°F -- 170°F (71°C -- 77°C) or hyperchlorinate the system by flushing all outlets for ≥ 5 minutes with water containing ≥ 2 mg/L (≥ 2 ppm) free residual chlorine using a chlorine-based product registered by the EPA for water treatment (e.g., sodium hypochlorite [chlorine bleach]) (153,155,161--164). Category IB
- B. After a pulse treatment, maintain both the heated water temperature at the return and the cold water temperature per the recommendation (Water: II A) wherever practical and permitted by state codes, or chlorinate heated water to achieve 1--2 mg/L (1--2 ppm) free residual chlorine at the tap by using a chlorine-based product registered by the EPA for water treatment (e.g., sodium hypochlorite [bleach]) (153,165--169). Category IC (States; ASHRAE: 12:2000)
- C. Explore engineering or educational options (e.g., install preset thermostatic mixing valves in point-of-use fixtures or post warning signs at each outlet) to minimize the risk of scalding for patients, visitors, and staff. Category II
- D. No recommendation is offered for treating water in the facility's distribution system with chlorine dioxide, heavy-metal ions (e.g., copper or silver), monochloramines, ozone, or UV light (170--188). Unresolved issue

V. General Infection-Control Strategies for Preventing Legionnaires Disease

- A. Conduct an infection-control risk assessment of the facility to determine if patients at risk or severely immunocompromised patients are present (27,189,190). Category IB
- B. Implement general strategies for detecting and preventing Legionnaires disease in facilities that do not provide care for severely immunocompromised patients (i.e., facilities that do not have HSCT or solid-organ transplant programs) (see Appendix) (27,189,190). Category IB
 1. Establish a surveillance process to detect health-care--associated Legionnaires disease (27,189,190). Category IB
 2. Inform health-care personnel (e.g., infection control, physicians, patient-care staff, engineering) regarding the potential for Legionnaires disease to occur and measures to prevent and control health-care--associated legionellosis (166,191). Category IB
 3. Establish mechanisms to provide clinicians with laboratory tests (e.g., culture, urine antigen, direct fluorescence assay [DFA], and serology) for the diagnosis of Legionnaires disease (27,189). Category IB
- C. Maintain a high index of suspicion for health-care--associated Legionnaires disease, and perform laboratory diagnostic tests for legionellosis on suspected cases, especially in patients at risk who do not require a PE for care (e.g., patients receiving systemic steroids; patients aged ≥ 65 years; or patients with chronic underlying disease (e.g., diabetes mellitus, congestive heart failure, or chronic obstructive lung disease) (27,166,190,192--198). Category IA
- D. Periodically review the availability and clinicians' use of laboratory diagnostic tests for Legionnaires disease in the facility; if clinicians' use of the tests on patients with diagnosed or suspected pneumonia is limited, implement measures (e.g., an educational campaign) to enhance clinicians' use of the test(s) (193). Category IB
- E. If one case of laboratory-confirmed, health-care--associated Legionnaires disease is identified, or if two or more cases of laboratory-suspected, health-care-associated Legionnaires disease occur during a 6-month period, certain activities should be initiated (181,189,191,193,199,200). Category IB
 1. Report the cases to state and local health departments where required. Category IC (States)
 2. If the facility does not treat severely immunocompromised patients, conduct an epidemiologic investigation, including retrospective review of microbiologic, serologic, and postmortem data to look for previously unidentified cases of health-care--associated Legionnaires disease, and

begin intensive prospective surveillance for additional cases

([27,181,189,191,193,199,200](#)). Category IB

3. If no evidence of continued health-care--associated transmission exists, continue intensive prospective surveillance for ≥ 2 months after the initiation of surveillance ([27,181,189,191,193,199,200](#)). Category IB

F. If there is evidence of continued health-care--associated transmission (i.e., an outbreak), conduct an environmental assessment to determine the source of *Legionella* spp. (199--207). Category IB

1. Collect water samples from potential aerosolized water sources ([Box 1](#) and [Box 2](#)) (208). Category IB

2. Save and subtype isolates of *Legionella* spp. obtained from patients and the environment (163,199--207,209). Category IB

3. If a source is identified, promptly institute water system decontamination measures per recommendations (see Water IV) (164,210). Category IB

4. If *Legionella* spp. are detected in ≥ 1 culture (e.g., conducted at 2-week intervals during 3 months), reassess the control measures, modify them accordingly, and repeat the decontamination procedures; consider intensive use of techniques used in the initial decontamination, or a combination of superheating and hyperchlorination ([27,210,211](#)). Category IB

G. If an environmental source is not identified during a Legionnaires disease outbreak, continue surveillance for new cases for ≥ 2 months. Either defer decontamination pending identification of the source of *Legionella* spp. or proceed with decontamination of the hospital's water distribution system, with special attention to areas involved in the outbreak. Category II

H. No recommendation is offered regarding routine culturing of water systems in health-care facilities that do not have patient-care areas (i.e., PE or transplant units) for persons at high risk for *Legionella* spp. infection (see Appendix) (161,165,167, 198,212--214). Unresolved issue

I. No recommendation is offered regarding the removal of faucet aerators in areas for immunocompetent patients. Unresolved issue

J. Keep adequate records of all infection-control measures and environmental test results for potable water systems. Category II

VI. Preventing Legionnaires Disease in Protective Environments and Transplant Units

A. When implementing strategies for preventing Legionnaires disease among severely immunocompromised patients housed in facilities with HSCT or solid-organ transplant programs, incorporate these specific surveillance and epidemiologic measures in addition to the steps outlined previously (see Appendix).

1. Maintain a high index of suspicion for legionellosis in transplant patients even when environmental surveillance cultures do not yield legionellae (189,215). Category IB

2. If a case occurs in a severely immunocompromised patient, or if severely immunocompromised patients are present in high-risk areas of the hospital (e.g., PE or transplant units) and cases are identified elsewhere in the facility, conduct a combined epidemiologic and environmental investigation to determine the source of *Legionella* spp. (189,210). Category IB

B. Implement culture strategies and potable water and fixture treatment measures in addition to those previous outlined (Water: V). Category II

1. Depending on state regulations on potable water temperature in public buildings (216), hospitals housing patients at high risk for health-care--associated legionellosis should either

maintain heated water with a minimum return temperature of $\geq 124^{\circ}\text{F}$ ($\geq 51^{\circ}\text{C}$) and cold water at $< 68^{\circ}\text{F}$ ($< 20^{\circ}\text{C}$), or chlorinate heated water to achieve 1--2 mg/L (1--2 ppm) of free residual chlorine at the tap (153--155,165,167--169,217). Category II

2. Periodic culturing for legionellae in potable water samples from HSCT or solid-organ transplant units can be performed as part of a comprehensive strategy to prevent Legionnaires

disease in these units ([37,154,189,218](#)). Category II

3. No recommendation is offered regarding the optimal methodology (i.e., frequency or number of sites) for environmental surveillance cultures in HSCT or solid-organ transplant units.

Unresolved issue

4. In areas with patients at risk, when *Legionella* spp. are not detectable in unit water, remove, clean, and disinfect shower heads and tap aerators monthly by using a chlorine-based,

EPA-registered product. If an EPA-registered chlorine disinfectant is not available, use a chlorine bleach solution (500--615 ppm [1:100 v/v dilution]) ([153,187](#)). Category II

C. If *Legionella* spp. are determined to be present in the water of a transplant unit, implement certain measures until *Legionella* spp. are no longer detected by culture.

1. Decontaminate the water supply as outlined previously (Water: IV) ([27,37,153,164,210](#)). Category IB

2. Do not use water from the faucets in patient-care rooms to avoid creating infectious aerosols ([37,219](#)). Category IB

3. Restrict severely immunocompromised patients from taking showers ([37,219](#)). Category IB

4. Use water that is not contaminated with *Legionella* spp. for HSCT patients' sponge baths ([37,219](#)). Category IB

5. Provide patients with sterile water for tooth brushing, drinking, and for flushing nasogastric tubing during legionellosis outbreaks ([37,219](#)). Category IB

D. Do not use large-volume room air humidifiers that create aerosols (e.g., by Venturi principle, ultrasound, or spinning disk) unless they are subjected to high-level disinfection and filled only with sterile water ([27,37,201,220](#)). Category IB

VII. Cooling Towers and Evaporative Condensers

A. When planning construction of new health-care facilities, locate cooling towers so that the drift is directed away from the air-intake system, and design the towers to minimize the volume of aerosol drift ([153,203,221](#)). Category IC (ASHRAE 12-2000)

B. Implement infection-control procedures for operational cooling towers ([153,203,222](#)). Category IC (ASHRAE 12-2000)

1. Install drift eliminators ([153,203,222](#)). Category IC (ASHRAE 12-2000)

2. Use an effective EPA-registered biocide on a regular basis ([153](#)). Category IC (ASHRAE 12-2000)

3. Maintain towers according to manufacturers' recommendations, and keep detailed maintenance and infection-control records, including environmental test results from legionellosis outbreak investigations ([153](#)). Category IC (ASHRAE 12-2000)

C. If cooling towers or evaporative condensers are implicated in health-care--associated legionellosis, decontaminate the cooling-tower system ([199,203,221,223](#)). Category IB

VIII. Dialysis Water Quality and Dialysate

A. Adhere to current AAMI standards for quality-assurance performance of devices and equipment used to treat, store, and distribute water in hemodialysis centers (both acute and maintenance [chronic] settings) and for the preparation of concentrates and dialysate ([224--235](#)). Category IA, IC (AAMI: American National Standards Institute [ANSI]/AAMI RD5:1992, ANSI/AAMI RD47:1993)

B. No recommendation is offered regarding whether more stringent requirements for water quality should be imposed in hemofiltration and hemodiafiltration. Unresolved issue

C. Conduct microbiologic testing specific to water in dialysis settings ([229,230,236--238](#)). Category IA, IC (AAMI: ANSI/AAMI RD5:1992, ANSI/AAMI RD47:1993, RD62:2001)

1. Perform bacteriologic assays of water and dialysis fluids at least once a month and during outbreaks by using standard quantitative methods ([236--238](#)). Category IA, IC (AAMI: ANSI/AAMI RD62:2001)

- a. Assay for heterotrophic, mesophilic bacteria (e.g., *Pseudomonas* spp).
- b. Do not use nutrient-rich media (e.g., blood agar or chocolate agar).

2. In conjunction with microbiologic testing, perform endotoxin testing on product water used to reprocess dialyzers for multiple use (229,230,239--242). Category IA, IC (AAMI: ANSI/AAMI RD5:1992, ANSI/AAMI RD47:1993)

3. Ensure that water does not exceed the limits for microbial counts and endotoxin concentrations ([Table 2](#)) (229--231). Category IA, IC (AAMI: ANSI/AAMI RD5:1992, ANSI/AAMI RD47:1993)

D. Disinfect water distribution systems in dialysis settings at least weekly (226--228,231,236). Category IA, IC (AAMI: ANSI/AAMI RD62:2001)

E. Wherever practical, design and engineer water systems in dialysis settings to avoid incorporating joints, dead-end pipes, and unused branches and taps that can harbor bacteria (226-- 228,231,236). Category IA, IC (AAMI: ANSI/AAMI RD62:2001)

F. When storage tanks are used in dialysis systems, they should be routinely drained, disinfected with an EPA-registered product, and fitted with an ultrafilter or pyrogenic filter (membrane filter with a pore size sufficient to remove particles and molecules ≥ 1 kilodalton) installed in the water line distal to the storage tank (236). Category IC (AAMI: ANSI/AAMI RD62:2001)

IX. Ice Machines and Ice

A. Do not handle ice directly by hand, and wash hands before obtaining ice. Category II

B. Use a smooth-surface ice scoop to dispense ice (243,244). Category II

1. Keep the ice scoop on a chain short enough that the scoop cannot touch the floor or keep the scoop on a clean, hard surface when not in use (243,244). Category II

2. Do not store the ice scoop in the ice bin. Category II

C. Do not store pharmaceuticals or medical solutions on ice intended for consumption; use sterile ice to keep medical solutions cold, or use equipment specifically manufactured for this purpose (244,245). Category IB

D. Machines that dispense ice are preferred to those that require ice to be removed from bins or chests with a scoop (246,247). Category II

E. Limit access to ice-storage chests, and keep container doors closed except when removing ice (244). Category II

F. Clean, disinfect, and maintain ice-storage chests on a regular basis. Category II

1. Follow the manufacturer's instructions for cleaning. Category II

2. Use an EPA-registered disinfectant suitable for use on ice machines, dispensers, or storage chests in accordance with label instructions. Category II

3. If instructions and EPA-registered disinfectants suitable for use on ice machines are not available, use a general cleaning/disinfecting regimen ([Box 3](#)) (244). Category II

4. Flush and clean ice machines and dispensers if they have not been disconnected before anticipated lengthy water disruptions. Category II

G. Install proper air gaps where the condensate lines meet the waste lines. Category II.

H. Conduct microbiologic sampling of ice, ice chests, and ice-making machines and dispensers where indicated during an epidemiologic investigation (244,248,249). Category IB

X. Hydrotherapy Tanks and Pools

A. Drain and clean hydrotherapy equipment (e.g., Hubbard tanks, tubs, whirlpools, whirlpool spas, or birthing tanks) after each patient's use, and disinfect equipment surfaces and components by using an EPA-registered product in accordance with the manufacturer's instructions. Category II

B. In the absence of an EPA-registered product for water treatment, add sodium hypochlorite to the water:

1. Maintain a 15-ppm chlorine residual in the water of small hydrotherapy tanks, Hubbard tanks, and tubs (250). Category II
2. Maintain a 2--5-ppm chlorine residual in the water of whirlpools and whirlpool spas (251). Category II
3. If the pH of the municipal water is in the basic range (e.g., when chloramine is used as the primary drinking water disinfectant in the community), consult the facility engineer regarding the possible need to adjust the pH of the water to a more acidic level before disinfection, to enhance the biocidal activity of the chlorine (252). Category II

- C. Clean and disinfect hydrotherapy equipment after using tub liners. Category II
- D. Clean and disinfect inflatable tubs unless they are single-use equipment. Category II
- E. No recommendation is offered regarding the use of antiseptic chemicals (e.g., chloramine-T) in the water during hydrotherapy sessions. Unresolved issue
- F. Conduct a risk assessment of patients before their use of large hydrotherapy pools, deferring patients with draining wounds or fecal incontinence from pool use until their condition resolves. Category II
- G. For large hydrotherapy pools, use pH and chlorine residual levels appropriate for an indoor pool as provided by local and state health agencies. Category IC (States)
- H. No recommendation is offered regarding the use in health-care settings of whirlpool or spa equipment manufactured for home or recreational use. Unresolved issue

XI. Miscellaneous Medical Equipment Connected to Water Systems

- A. Clean, disinfect, and maintain AER equipment according to the manufacturer's instructions and relevant scientific literature to prevent inadvertent contamination of endoscopes and bronchoscopes with waterborne microorganisms (253--257). Category IB
 1. To rinse disinfected endoscopes and bronchoscopes, use water of the highest quality practical for the system's engineering and design (e.g., sterile water or bacteriologically filtered water [water filtered through 0.1--0.2- μ m filters]) (254,256--258). Category IB
 2. Dry the internal channels of the reprocessed endoscope or bronchoscope by using a proven method (e.g., 70% alcohol followed by forced-air treatment) to lessen the potential for proliferation of waterborne microorganisms and to help prevent biofilm formation (259--263). Category IB
- B. Use water that meets nationally recognized standards set by the EPA for drinking water (<500 CFU/mL for heterotrophic plate count) for routine dental treatment output water (264--267). Category IC (EPA: 40 CFR 1 Part 141, Subpart G)
- C. Take precautions to prevent waterborne contamination of dental unit water lines and instruments.
 1. After each patient, discharge water and air for a minimum of 20--30 seconds from any dental device connected to the dental water system that enters a patient's mouth (e.g., handpieces, ultrasonic scalers, or air/water syringes) (265,268). Category II
 2. Consult with dental water-line manufacturers to 1) determine suitable methods and equipment to obtain the recommended water quality; and 2) determine appropriate methods for monitoring the water to ensure quality is maintained (265,269). Category II
 3. Consult with the dental unit manufacturer regarding the need for periodic maintenance of antiretraction mechanisms (268,269). Category IB

Recommendations ---Environmental Services

I. Cleaning and Disinfecting Strategies for Environmental Surfaces in Patient-Care Areas

- A. Select EPA-registered disinfectants, if available, and use them in accordance with the manufacturer's instructions (270--272). Category IC (EPA: 7 United States Code [USC] § 136 et seq.)
- B. Do not use high-level disinfectants/liquid chemical sterilants for disinfection of either noncritical instruments and devices or any environmental surfaces; such use is counter to label instructions for these toxic chemicals (273--278). Category IC (Food and Drug Administration [FDA]: 21 CFR 801.5, 807.87.e)

C. Follow manufacturers' instructions for cleaning and maintaining noncritical medical equipment. Category II

D. In the absence of a manufacturer's cleaning instructions, follow certain procedures.

1. Clean noncritical medical equipment surfaces with a detergent/disinfectant. This may be followed by an application of an EPA-registered hospital disinfectant with or without a tuberculocidal claim (depending on the nature of the surface and the degree of contamination), in accordance with germicide label instructions (274). Category II
2. Do not use alcohol to disinfect large environmental surfaces (273). Category II
3. Use barrier protective coverings as appropriate for noncritical surfaces that are 1) touched frequently with gloved hands during the delivery of patient care; 2) likely to become contaminated with blood or body substances; or 3) difficult to clean (e.g., computer keyboards) (265). Category II

E. Keep housekeeping surfaces (e.g., floors, walls, tabletops) visibly clean on a regular basis and clean up spills promptly (279). Category II

1. Use a one-step process and an EPA-registered hospital detergent/disinfectant designed for general housekeeping purposes in patient-care areas where 1) uncertainty exists as to the nature of the soil on the surfaces (e.g., blood or body fluid contamination versus routine dust or dirt); or 2) uncertainty exists regarding the presence of multidrug resistant organisms on such surfaces (272,274,280,281). Category II
2. Detergent and water are adequate for cleaning surfaces in nonpatient-care areas (e.g., administrative offices). Category II
3. Clean and disinfect high-touch surfaces (e.g., doorknobs, bed rails, light switches, and surfaces in and around toilets in patients' rooms) on a more frequent schedule than minimal-touch housekeeping surfaces. Category II
4. Clean walls, blinds, and window curtains in patient-care areas when they are visibly dusty or soiled (270,282--284). Category II

F. Do not perform disinfectant fogging in patient-care areas (270,285). Category IB

G. Avoid large-surface cleaning methods that produce mists or aerosols, or disperse dust in patient-care areas (37,48,51,73). Category IB

H. Follow proper procedures for effective uses of mops, cloths, and solutions. Category II

1. Prepare cleaning solutions daily or as needed, and replace with fresh solution frequently according to facility policies and procedures (280,281). Category II
2. Change the mop head at the beginning of each day and also as required by facility policy, or after cleaning up large spills of blood or other body substances. Category II
3. Clean mops and cloths after use and allow to dry before reuse; or use single-use, disposable mop heads and cloths (282,286--288). Category II

I. After the last surgical procedure of the day or night, wet vacuum or mop operating room floors with a single-use mop and an EPA-registered hospital disinfectant (114). Category IB

J. Do not use mats with tacky surfaces at the entrances to operating rooms or infection-control suites (114). Category IB

K. Use appropriate dusting methods for patient-care areas designated for immunocompromised patients (e.g., HSCT patients) (37,40,280). Category IB

1. Wet-dust horizontal surfaces daily by moistening a cloth with a small amount of an EPA-registered hospital detergent/disinfectant (37,40,280). Category IB
2. Avoid dusting methods that disperse dust (e.g., feather-dusting) (40). Category IB

L. Keep vacuums in good repair and equip vacuums with HEPA filters for use areas with patients at risk (37,40,280,289). Category IB

M. Close the doors of immunocompromised patients' rooms when vacuuming, waxing, or buffing corridor floors to minimize exposure to airborne dust (37,40,289). Category IB

- N. When performing low- or intermediate-level disinfection of environmental surfaces in nurseries and neonatal units, avoid unnecessary exposure of neonates to disinfectant residues on these surfaces by using EPA-registered germicides in accordance with manufacturers' instructions and safety advisories (271,290--292). Category IB, IC (EPA: 7 USC § 136 et seq.)
1. Do not use phenolics or any other chemical germicide to disinfect bassinets or incubators during an infant's stay (271,290--292). Category IB
 2. Rinse disinfectant-treated surfaces, especially those treated with phenolics, with water (290--292). Category IB
- O. When using phenolic disinfectants in neonatal units, prepare solutions to correct concentrations in accordance with manufacturers' instructions, or use premixed formulations (271,290--292). Category IB, IC (EPA: 7 USC § 136 et seq.)

II. Cleaning Spills of Blood and Body Substances

- A. Promptly clean and decontaminate spills of blood or other potentially infectious materials (293--300). Category IB, IC (OSHA: 29 CFR 1910.1030 § d.4.ii.A)
- B. Follow proper procedures for site decontamination of spills of blood or blood-containing body fluids (293--300). Category IC (OSHA: 29 CFR 1910.1030 § d.4.ii.A)
1. Use protective gloves and other PPE appropriate for this task (293). Category IC (OSHA: 29 CFR 1910.1030 § d.3.i, ii)
 2. If the spill contains large amounts of blood or body fluids, clean the visible matter with disposable absorbent material, and discard the used cleaning materials in appropriate, labeled containers (293,298,299,301,302). Category IC (OSHA: 29 CFR 1910.1030 § d.4.iii.B)
 3. Swab the area with a cloth or paper towels moderately wetted with disinfectant, and allow the surface to dry (293,301). Category IC (OSHA: 29 CFR 1910.1030 § d.4.ii.A)
- C. Use germicides registered by the EPA for use as hospital disinfectants and labeled tuberculocidal or registered germicides on the EPA Lists D and E (i.e., products with specific label claims for HIV or hepatitis B virus [HBV]) in accordance with label instructions to decontaminate spills of blood and other body fluids (293,301,303). Category IC (OSHA 29 CFR 1910.1030 § d.4.ii. A memorandum 2/28/97; compliance document [CPL] 2-2.44D [11/99])
- D. An EPA-registered sodium hypochlorite product is preferred, but if such products are not available, generic sodium hypochlorite solutions (e.g., household chlorine bleach) may be used.
1. Use a 1:100 dilution (500--615 ppm available chlorine) to decontaminate nonporous surfaces after cleaning a spill of either blood or body fluids in patient-care settings (301,304). Category IB
 2. If a spill involves large amounts of blood or body fluids, or if a blood or culture spill occurs in the laboratory, use a 1:10 dilution (5,000--6,150 ppm available chlorine) for the first application of germicide before cleaning (279,301). Category IB

III. Carpeting and Cloth Furnishings

- A. Vacuum carpeting in public areas of health-care facilities and in general patient-care areas regularly with well-maintained equipment designed to minimize dust dispersion (280). Category II
- B. Periodically perform a thorough, deep cleaning of carpeting as determined by facility policy by using a method that minimizes the production of aerosols and leaves little or no residue (44). Category II
- C. Avoid use of carpeting in high-traffic zones in patient-care areas or where spills are likely (e.g., burn therapy units, operating rooms, laboratories, or intensive care units) (44,305,306). Category IB
- D. Follow appropriate procedures for managing spills on carpeting.
1. Spot-clean blood or body substance spills promptly (293,301,304,307). Category IC (OSHA: 29 CFR 1910.1030 § d.4.ii.A, interpretation)
 2. If a spill occurs on carpet tiles, replace any tiles contaminated by blood and body fluids or body

- E. Thoroughly dry wet carpeting to prevent the growth of fungi; replace carpeting that remains wet after 72 hours ([37,160](#)). Category IB
 - F. No recommendation is offered regarding the routine use of fungicidal or bactericidal treatments for carpeting in public areas of a health-care facility or in general patient-care areas. Unresolved issue
 - G. Do not use carpeting in hallways and patient rooms in areas housing immunosuppressed patients (e.g., PE areas) ([37,44](#)). Category IB
 - H. Avoid using upholstered furniture and furnishings in high-risk patient-care areas and in areas with increased potential for body substance contamination (e.g., pediatrics units) ([37](#)). Category II
 - I. No recommendation is offered regarding whether upholstered furniture and furnishings should be avoided in general patient-care areas. Unresolved issue
1. Maintain upholstered furniture in good repair. Category II
 2. Maintain the surface integrity of the upholstery by repairing tears and holes. Category II
 3. If upholstered furniture in a patient's room requires cleaning to remove visible soil or body substance contamination, move that item to a maintenance area where it can be adequately cleaned with a process appropriate for the type of upholstery and nature of the soil. Category II

IV. Flowers and Plants in Patient-Care Areas

- A. Flowers and potted plants need not be restricted from areas for immunocompetent patients (308-311). Category II
- B. Designate care and maintenance of flowers and potted plants to staff not directly involved with patient care (309). Category II
- C. If plant or flower care by patient-care staff is unavoidable, instruct the staff to wear gloves when handling plants and flowers and perform hand hygiene after glove removal (309). Category II
- D. Do not allow fresh or dried flowers, or potted plants, in patient-care areas for immunosuppressed patients ([37,51,308,312](#)). Category II

V. Pest Control

- A. Develop pest-control strategies, with emphasis on kitchens, cafeterias, laundries, central sterile supply areas, operating rooms, loading docks, construction activities, and other areas prone to infestations (313--315). Category II
- B. Install screens on all windows that open to the outside; keep screens in good repair (314). Category IB
- C. Contract for routine pest control service by a credentialed pest-control specialist who will tailor the application to the needs of a health-care facility (315). Category II
- D. Place laboratory specimens (e.g., fixed sputum smears) in covered containers for overnight storage (316,317). Category II

VI. Special Pathogens

- A. Use appropriate hand hygiene, PPE (e.g., gloves), and isolation precautions during cleaning and disinfecting procedures (146,274,[318,319](#)). Category IB
 - B. Use standard cleaning and disinfection protocols to control environmental contamination with antibiotic-resistant, gram-positive cocci (e.g., methicillin-resistant *Staphylococcus aureus*, vancomycin intermediate sensitive *Staphylococcus aureus*, or vancomycin-resistant *Enterococcus* [VRE]) ([318,320--322](#)). Category IB
1. Pay close attention to cleaning and disinfection of high-touch surfaces in patient-care areas (e.g., bed rails, carts, charts, bedside commodes, bed rails, doorknobs, or faucet handles) ([318,320--322](#)). Category IB
 2. Ensure compliance by housekeeping staff with cleaning and disinfection procedures ([318,320--322](#)). Category IB
 3. Use EPA-registered chemical germicides appropriate for the surface to be disinfected (e.g., either low- or intermediate-level disinfection) as specified by the manufacturer's

instructions (271,322--327). Category IB, IC (EPA: 7 USC § 136 et seq.)

4. When contact precautions are indicated for patient care, use disposable patient-care items (e.g., blood pressure cuffs) wherever possible to minimize cross-contamination with multiple-resistant microorganisms (328). Category IB

5. Follow these same surface-cleaning and disinfecting measures for managing the environment of VRSA patients (320--322,327). Category II

C. Environmental-surface culturing can be used to verify the efficacy of hospital policies and procedures before and after cleaning and disinfecting rooms that house patients with VRE (318,329--333). Category II

1. Obtain prior approval from infection-control staff and the clinical laboratory before performing environmental-surface culturing. Category II

2. Infection-control staff, with clinical laboratory staff consultation, must supervise all environmental culturing. Category II

D. Thoroughly clean and disinfect environmental and medical equipment surfaces on a regular basis by using EPA-registered disinfectants in accordance with manufacturers' instructions (271,274,319,334). Category IB, IC (EPA: 7 USC § 136 et seq.)

E. Advise families, visitors, and patients regarding the importance of hand hygiene to minimize the spread of body substance contamination (e.g., respiratory secretions or fecal matter) to surfaces (274). Category II

F. Do not use high-level disinfectants (i.e., liquid chemical sterilants) on environmental surfaces; such use is inconsistent with label instructions because of the toxicity of the chemicals (270,273,274,278). Category IC (FDA: 21 CFR 801.5, 807.87.e)

G. Because no EPA-registered products are specific for inactivating *Clostridium difficile* spores, use hypochlorite-based products for disinfection of environmental surfaces in accordance with guidance from the scientific literature in those patient-care areas where surveillance and epidemiology indicate ongoing transmission of *C. difficile* (274,319,334). Category II

H. No recommendation is offered regarding the use of specific EPA-registered hospital disinfectants with respect to environmental control of *C. difficile*. Unresolved issue

I. Apply standard cleaning and disinfection procedures to control environmental contamination with respiratory and enteric viruses in pediatric-care units and care areas for immunocompromised patients (280,335). Category IC (EPA: 7 USC § 136 et seq.)

J. Clean surfaces that have been contaminated with body substances; perform low- to intermediate-level disinfection on cleaned surfaces with an EPA-registered disinfectant in accordance with the manufacturer's instructions (271,293,335). Category IC (OSHA: 29 CFR 1910.1030 § d.4.ii.A; EPA: 7 USC § 136 et seq.)

K. Use disposable barrier coverings as appropriate to minimize surface contamination. Category II

L. Develop and maintain cleaning and disinfection procedures in patient-care areas to control environmental contamination with agents of Creutzfeldt-Jakob disease (CJD), for which no EPA-registered product exists. Category II

1. In the absence of contamination with central nervous system tissue, extraordinary measures (e.g., use of 2N sodium hydroxide [NaOH] or applying full-strength sodium hypochlorite) are not needed for routine cleaning or terminal disinfection of a room housing a confirmed or suspected CJD patient (273,336). Category II

2. After removing gross tissue from the surface, use either 1N NaOH or a sodium hypochlorite solution containing approximately 10,000--20,000 ppm available chlorine (dilutions of 1:5 to 1:3 v/v, respectively, of U.S. household chlorine bleach; contact the manufacturers of commercially available sodium hypochlorite products for advice) to decontaminate operating room or autopsy surfaces with central nervous system or cerebral spinal fluid contamination from a diagnosed or suspected CJD patient (273,337--342). Category II

a. The contact time for the chemical used during this process should be 30 min--1 hour (339,340,342).

b. Blot up the chemical with absorbent material and rinse the treated surface thoroughly with water.

c. Discard the used, absorbent material into appropriate waste containers.

3. Use disposable, impervious covers to minimize body substance contamination to autopsy tables and surfaces (340,342). Category II

M. Use standard procedures for containment, cleaning, and decontamination of blood spills on surfaces as previously described (Environmental Services: II) (293). Category IC (OSHA: 29 CFR 1910.1030 § d.4.ii.A)

1. Wear PPE appropriate for a surface decontamination and cleaning task (293,336). Category IC (OSHA 29 CFR 1910.1030 § d.3.i, ii)

2. Discard used PPE by using routine disposal procedures or decontaminate reusable PPE as appropriate (293,336). Category IC (OSHA 29 CFR 1910.1030 § d.3.viii)

Recommendations ---Environmental Sampling

I. General Information

- A. Do not conduct random, undirected, microbiologic sampling of air, water, and environmental surfaces in health-care facilities (270,343). Category IB
- B. When indicated, conduct microbiologic sampling as part of an epidemiologic investigation or during assessment of hazardous environmental conditions to detect contamination or verify abatement of a hazard (270,343). Category IB
- C. Limit microbiologic sampling for quality assurance purposes to 1) biologic monitoring of sterilization processes; 2) monthly cultures of water and dialysate in hemodialysis units; and 3) short-term evaluation of the impact of infection-control measures or changes in infection-control protocols (270,343). Category IB

II. Air, Water, and Environmental Surface Sampling

- A. When conducting any form of environmental sampling, identify existing comparative standards and fully document departures from standard methods (343--347). Category II
- B. Select a high-volume air sampling device if anticipated levels of microbial airborne contamination are expected to be low (345,346,348,349). Category II
- C. Do not use settle plates to quantify the concentration of airborne fungal spores (348). Category II
- D. When sampling water, choose growth media and incubation conditions that will facilitate recovery of waterborne organisms (344). Category II
- E. When using a sample/rinse method for sampling an environmental surface, develop and document a procedure for manipulating the swab, gauze, or sponge in a reproducible manner so that results are comparable (347). Category II
- F. When environmental samples and patient specimens are available for comparison, perform the laboratory analysis on the recovered microorganisms down to the species level at a minimum, and beyond the species level if possible (343). Category II

Recommendations ---Laundry and Bedding

I. Employer Responsibilities

- A. Employers must launder workers' personal protective garments or uniforms that are contaminated with blood or other potentially infectious materials (293). Category IC (OSHA: 29 CFR 1910.1030 § d.3.iv)

II. Laundry Facilities and Equipment

- A. Maintain the receiving area for contaminated textiles at negative pressure compared with the clean areas of the laundry in accordance with AIA construction standards in effect during the time of facility construction (1,350--352). Category IC (AIA: 7.23.B1, B2)

- B. Ensure that laundry areas have handwashing facilities and products and appropriate PPE available for workers (1,293). Category IC (AIA: 7.23.D4; OSHA: 29 CFR 1910.1030 § d.2.iii)
- C. Use and maintain laundry equipment according to manufacturers' instructions (353,354). Category II
- D. Do not leave damp textiles or fabrics in machines overnight (353). Category II
- E. Disinfection of washing and drying machines in residential care is not needed as long as gross soil is removed from items before washing and proper washing and drying procedures are used. Category II

III. Routine Handling of Contaminated Laundry

- A. Handle contaminated textiles and fabrics with minimum agitation to avoid contamination of air, surfaces, and persons (36,293,355,356). Category IC (OSHA: 29 CFR 1910.1030 § d.4.iv)
- B. Bag or otherwise contain contaminated textiles and fabrics at the point of use (293). Category IC (OSHA: 29 CFR 1910.1030 § d.4.iv)
 - 1. Do not sort or prerinse contaminated textiles or fabrics in patient-care areas (293). Category IC (OSHA: 29 CFR 1910.1030 § d.4.iv)
 - 2. Use leak-resistant containment for textiles and fabrics contaminated with blood or body substances (293,355). Category IC (OSHA: 29 CFR 1910.1030 § d.4.iv)
 - 3. Identify bags or containers for contaminated textiles with labels, color coding, or other alternative means of communication as appropriate (293). Category IC (OSHA: 29 CFR 1910.1030 § d.4.iv)
- C. Covers are not needed on contaminated textile hampers in patient-care areas. Category II
- D. If laundry chutes are used, ensure that they are properly designed, maintained, and used in a manner to minimize dispersion of aerosols from contaminated laundry (357--361). Category IC (AAMI: ANSI/AAMI ST65:2000)
 - 1. Ensure that laundry bags are closed before tossing the filled bag into the chute. Category II
 - 2. Do not place loose items in the laundry chute. Category II
- E. Establish a facility policy to determine when textiles or fabrics should be sorted in the laundry facility (i.e., before or after washing) (362,363). Category II

IV. Laundry Process

- A. If hot-water laundry cycles are used, wash with detergent in water $\geq 160^{\circ}\text{F}$ ($\geq 71^{\circ}\text{C}$) for ≥ 25 minutes (1,270). Category IC (AIA: 7.31.E3)
- B. No recommendation is offered regarding a hot-water temperature setting and cycle duration for items laundered in residence-style health-care facilities. Unresolved issue
- C. Follow fabric-care instructions and special laundering requirements for items used in the facility (364). Category II
- D. Choose chemicals suitable for low-temperature washing at proper use concentration if low-temperature ($< 160^{\circ}\text{F}$ [$< 70^{\circ}\text{C}$]) laundry cycles are used (365--370). Category II
- E. Package, transport, and store clean textiles and fabrics by methods that will ensure their cleanliness and protect them from dust and soil during interfacility loading, transport, and unloading (270). Category II

V. Microbiologic Sampling of Textiles

- A. Do not conduct routine microbiologic sampling of clean textiles (270,371). Category IB
- B. Use microbiologic sampling during outbreak investigations if epidemiologic evidence indicates a role for health-care textiles and clothing in disease transmission (371). Category IB

VI. Special Laundry Situations

- A. Use sterilized textiles, surgical drapes, and gowns for situations requiring sterility in patient care (114). Category IB

- B. Use hygienically clean textiles (i.e., laundered, but not sterilized) in neonatal intensive care units (292,372). Category IB
- C. Follow manufacturers' recommendations for cleaning fabric products, including those with coated or laminated surfaces. Category II
- D. Do not use dry cleaning for routine laundering in health-care facilities (373--375). Category II
- E. Use caution when considering use of antimicrobial mattresses, textiles, and clothing as replacements for standard bedding and other fabric items; EPA has not approved public health claims asserting protection against human pathogens for such treated items (376). Category II
- F. No recommendation is offered regarding using disposable fabrics and textiles versus durable goods. Unresolved issue

VII. Mattresses and Pillows

- A. Keep mattresses dry; discard them if they remain wet or stained, particularly in burn units (377--382). Category IB
- B. Clean and disinfect mattress covers by using EPA-registered disinfectants that are compatible with the materials to prevent the development of tears, cracks, or holes in the covers (377--382). Category IB
- C. Maintain the integrity of mattress and pillow covers. Category II
 - 1. Replace mattress and pillow covers if they become torn or otherwise in need of repair. Category II
 - 2. Do not stick needles into a mattress through the cover. Category II
- D. Clean and disinfect moisture-resistant mattress covers between patient use by using an EPA-registered product (377--382). Category IB
- E. If using a mattress cover completely made of fabric, change these covers and launder between patient use (377--382). Category IB
- F. Launder pillow covers and washable pillows in the hot-water cycle between patients or when they become contaminated with body substances (382). Category IB

VIII. Air-Fluidized Beds

- A. Follow manufacturers' instructions for air-fluidized bed maintenance and decontamination. Category II
- B. Change the polyester filter sheet at least weekly or as indicated by the manufacturer (383--386). Category II
- C. Clean and disinfect the polyester filter sheet thoroughly, especially between patients, using an EPA-registered product (383--386). Category IB
- D. Consult the facility engineer to determine the proper placement of air-fluidized beds in negative-pressure rooms (387). Category II

Recommendations --- Animals in Health-Care Facilities

I. General Infection-Control Measures for Animal Encounters

- A. Minimize contact with animal saliva, dander, urine, and feces (388--390). Category II
- B. Practice hand hygiene after any animal contact (146,270). Category II
 - 1. Wash hands with soap and water, especially if hands are visibly soiled or contaminated with proteinaceous material (146). Category II
 - 2. Use either soap and water or alcohol-based hand rubs when hands are not visibly soiled or contaminated (146). Category II

II. Animal-Assisted Activities and Resident Animal Programs

- A. Avoid selection of nonhuman primates and reptiles in animal-assisted activities, animal-assisted therapy, or resident animal programs (391--393). Category IB

- B. Enroll animals that are fully vaccinated for zoonotic diseases and that are healthy, clean, well-groomed, and negative for enteric parasites or otherwise have completed recent anthelmintic treatment under the regular care of a veterinarian (391,394). Category II
- C. Enroll animals that are trained with the assistance or under the direction of persons who are experienced in this field (391). Category II
- D. Ensure that animals are controlled by persons trained in providing activities or therapies safely, and who know the animal's health status and behavior traits (391,394). Category II
- E. Take prompt action when an incident of biting or scratching by an animal occurs during an animal-assisted activity or therapy.
 - 1. Remove the animal permanently from these programs (391). Category II
 - 2. Report the incident promptly to appropriate authorities (e.g., infection-control staff, animal program coordinator, or local animal control personnel) (391). Category II
 - 3. Promptly clean and treat scratches, bites, or other breaks in the skin. Category II
- F. Perform an ICRA and work actively with the animal handler before conducting an animal-assisted activity or therapy to determine whether the session should be held in a public area of the facility or in individual patient rooms (391,394). Category II
- G. Take precautions to mitigate allergic responses to animals. Category II
 - 1. Minimize shedding of animal dander by bathing animals <24 hours before a visit (391). Category II
 - 2. Groom animals to remove loose hair before a visit, or use a therapy animal cape (395). Category II
- H. Use routine cleaning protocols for housekeeping surfaces after therapy sessions. Category II
- I. Restrict resident animals, including fish in tanks, from access to patient-care areas, food-preparation areas, dining areas, laundry, central sterile supply areas, sterile and clean supply storage areas, medication preparation areas, operating rooms, isolation areas, and PE areas. Category II
- J. Establish a facility policy for regular cleaning of fish tanks, rodent cages, and bird cages, and any other animal dwellings and assign this cleaning task to a nonpatient-care staff member; avoid splashing tank water or contaminating environmental surfaces with animal bedding. Category II

III. Protective Measures for Immunocompromised Patients

- A. Advise patients to avoid contact with animal feces, saliva, urine, or solid litter box material (396). Category II
- B. Promptly clean and treat scratches, bites, or other wounds that break the skin (396). Category II
- C. Advise patients to avoid direct or indirect contact with reptiles (397). Category IB
- D. Conduct a case-by-case assessment to determine if animal-assisted activities or animal-assisted therapy programs are appropriate for immunocompromised patients (394). Category II
- E. No recommendation is offered regarding permitting pet visits to terminally ill immunocompromised patients outside their PE units. Unresolved issue.

IV. Service Animals

- A. Avoid providing facility access to nonhuman primates and reptiles as service animals (393,397). Category IB
- B. Allow service animals access to the facility in accordance with the Americans with Disabilities Act of 1990, unless the presence of the animal creates a direct threat to other persons or a fundamental alteration in the nature of services (389,398). Category IC (U.S. Department of Justice: 28 CFR § 36.302)
- C. When a decision must be made regarding a service animal's access to any particular area of the health-care facility, evaluate the service animal, patient, and health-care situation on a case-by-case basis to determine whether significant risk of harm exists and whether reasonable modifications in policies and procedures will mitigate this risk (398). Category IC (U.S. Department of Justice: 28 CFR § 36.208)
- D. If a patient must be separated from his or her service animal while in the health-care facility 1) ascertain from the person what arrangements have been made for supervision or care of the animal

during this period of separation; and 2) make appropriate arrangements to address the patient's needs in the absence of the service animal. Category II

V. Animals as Patients in Human Health-Care Facilities

- A. Develop health-care facility policies to address the treatment of animals in human health-care facilities.
 - 1. Use the multidisciplinary team approach to policy development, including public media relations efforts to disclose and discuss these activities. Category II
 - 2. Exhaust all veterinary facility, equipment, and instrument options before undertaking the procedure. Category II
 - 3. Ensure that the care of the animal is supervised by a licensed veterinarian. Category II
- B. When animals are treated in human health-care facilities, avoid treating animals in operating rooms or other patient-care areas where invasive procedures are performed (e.g., cardiac catheterization laboratories or invasive nuclear medicine areas). Category II
- C. Schedule the animal procedure for the last procedure of the day in the area, at a time when human patients are not scheduled to be in the vicinity. Category II
- D. Adhere strictly to standard precautions. Category II
- E. Clean and disinfect environmental surfaces thoroughly by using an EPA-registered product in the room after the animal has been removed. Category II
- F. Allow sufficient ACH to clean the air and help remove airborne dander, microorganisms, and allergens ([Table 1](#)). Category II
- G. Clean and disinfect using EPA-registered products or sterilize equipment that has been in contact with the animal; or use disposable equipment. Category II
- H. If reusable medical or surgical instruments are used in an animal procedure, restrict future use of these instruments to animals only. Category II

VI. Research Animals in Health-Care Facilities

- A. Use animals obtained from quality stock, or quarantine incoming animals to detect zoonotic diseases. Category II
- B. Treat sick animals or remove them from the facility. Category II
- C. Provide prophylactic vaccinations, as available, to animal handlers and contacts at high risk. Category II
- D. Ensure proper ventilation through appropriate facility design and location (399). Category IC (U.S. Department of Agriculture [USDA]: 7 USC 2131)
 - 1. Keep animal rooms at negative pressure relative to corridors (399). Category IC (USDA: 7 USC 2131)
 - 2. Prevent air in animal rooms from recirculating elsewhere in the health-care facility (399). Category IC (USDA: 7 USC 2131)
- E. Keep doors to animal research rooms closed. Category II
- F. Restrict access to animal facilities to essential personnel. Category II
- G. Establish employee occupational health programs specific to the animal research facility, and coordinate management of postexposure procedures specific to zoonoses with occupational health clinics in the health-care facility (400,401). Category IC (U.S. Department of Health and Human Services [DHHS]: Biosafety in Microbiological and Biomedical Laboratories [BMBL]; OSHA: 29 CFR 1910.1030.132-139)
- H. Document standard operating procedures for the unit (400). Category IC (DHHS: BMBL)
- I. Conduct routine employee training on worker safety concerns relevant to the animal research facility (e.g., working safely with animals, animal handling) (400,401). Category IC (DHHS: BMBL; OSHA: 29 CFR 1910.1030.132--139)
- J. Use precautions to prevent development of animal-induced asthma in animal workers (400). Category IC (DHHS: BMBL)

I. Categories of Regulated Medical Waste

- A. Designate the following as major categories of medical waste that require special handling and disposal precautions: 1) microbiology laboratory wastes [e.g., cultures and stocks of microorganisms]; 2) bulk blood, blood products, blood, and bloody body fluid specimens; 3) pathology and anatomy waste; and 4) sharps [e.g., needles and scalpels] (270). Category II
- B. Consult federal, state, and local regulations to determine if other waste items are considered regulated medical wastes (293,402,403). Category IC (States; OSHA: 29 CFR 1910.1030 § g.2.1; Department of Transportation [DOT]: 49 CFR 171-180; U.S. Postal Service: CO23.8)

II. Disposal Plan for Regulated Medical Wastes

- A. Develop a plan for the collection, handling, predisposal treatment, and terminal disposal of regulated medical wastes (293,404). Category IC (States; OSHA: 29 CFR 1910.1030 § g.2.i)
- B. Designate a person or persons as responsible for establishing, monitoring, reviewing, and administering the plan. Category II

III. Handling, Transporting, and Storing Regulated Medical Wastes

- A. Inform personnel involved in handling and disposal of potentially infective waste of possible health and safety hazards; ensure that they are trained in appropriate handling and disposal methods (293). Category IC (OSHA: 29 CFR 1910.1030 § g.2.i)
- B. Manage the handling and disposal of regulated medical wastes generated in isolation areas by using the same methods used for regulated medical wastes from other patient-care areas (270). Category II
- C. Use proper sharps disposal strategies (293). Category IC (OSHA: 29 CFR 1910.1030 § d.4.iii.A)
 - 1. Use a sharps container capable of maintaining its impermeability after waste treatment to avoid subsequent physical injuries during final disposal (293). Category IC (OSHA: 29 CFR 1910.1030 § d.4.iii.A)
 - 2. Place disposable syringes with needles, including sterile sharps that are being discarded, scalpel blades, and other sharp items into puncture-resistant containers located as close as practical to the point of use (293). Category IC (OSHA: 29 CFR 1910.1030 § d.4.iii.A)
 - 3. Do not bend, recap, or break used syringe needles before discarding them into a container (36,293,405). Category IC (OSHA: 29 CFR 1910.1030 § d.2.vii and § d.2.vii.A)
- D. Store regulated medical wastes awaiting treatment in a properly ventilated area inaccessible to vertebrate pests; use waste containers that prevent development of noxious odors. Category IC (States)
- E. If treatment options are not available at the site where the medical waste is generated, transport regulated medical wastes in closed, impervious containers to the on-site treatment location or to another facility for treatment as appropriate. Category IC (States)

IV. Treatment and Disposal of Regulated Medical Wastes

- A. Treat regulated medical wastes by using a method (e.g., steam sterilization, incineration, interment, or an alternative treatment technology) approved by the appropriate authority having jurisdiction (AHJ) (e.g., state, Indian Health Service, or Veterans Administration) before disposal in a sanitary landfill. Category IC (States, AHJ)
- B. Follow precautions for treating microbiologic wastes (e.g., amplified cultures and stocks of microorganisms) (400). Category IC (DHHS: BMBL)
 - 1. Biosafety level 4 laboratories must inactivate microbiologic wastes in the laboratory by using an approved inactivation method (e.g., autoclaving) before transport to and disposal in a sanitary landfill (400). Category IC (DHHS: BMBL)
 - 2. Biosafety level 3 laboratories must inactivate microbiologic wastes in the laboratory by using an approved inactivation method (e.g., autoclaving) or incinerate them at the facility

before transport to and disposal in a sanitary landfill (400). Category IC (DHHS: BMBL)

- C. Biosafety levels 1 and 2 laboratories should develop strategies to inactivate amplified microbial cultures and stocks onsite by using an approved inactivation method (e.g., autoclaving) instead of packaging and shipping untreated wastes to an offsite facility for treatment and disposal (400,406-408). Category II
- D. Laboratories that isolate select agents from clinical specimens must comply with federal regulations for receipt, transfer, management, and appropriate disposal of these agents (409). Category IC (DHHS: 42 CFR 72 § 72.6.i.1.iii)
- E. Sanitary sewers may be used for safe disposal of blood, suctioned fluids, ground tissues, excretions, and secretions, provided that local sewage discharge requirements are met and that the state has declared this to be an acceptable method of disposal (410). Category II

V. Special Precautions for Wastes Generated During Care of Patients with Rare Diseases

- A. When discarding items contaminated with blood and body fluids from VHF patients, contain these regulated medical wastes with minimal agitation during handling (36,109). Category II
- B. Manage properly contained wastes from areas providing care to VHF patients in accordance with recommendations for other isolation areas (Regulated Medical Waste: III B) (36,109,270). Category II
- C. Decontaminate bulk blood and body fluids from VHF patients by using approved inactivation methods (e.g., autoclaving or chemical treatment) before disposal (36,109). Category IC, II (States)
- D. When discarding regulated medical waste generated during the routine (i.e., nonsurgical) care of CJD patients, contain these wastes and decontaminate them by using approved inactivation methods (e.g., autoclaving or incineration) appropriate for the medical waste category (e.g., blood, sharps, or pathological waste) (36,270,273,336). Category IC, II (States)
- E. Incinerate medical wastes (e.g., central nervous system tissues or contaminated disposable materials) from brain autopsy or biopsy procedures of diagnosed or suspected CJD patients (340,342). Category IB

Mutchler JE. Principles of ventilation. In: NIOSH. The industrial environment — its evaluation and control. Washington, DC: US Department of Health, Education, and Welfare, Public Health Service, 1973. DHHS publication no. (NIOSH) 74-117. Available at: <http://www.cdc.gov/niosh/74-117.html>.

Note: Bold entries denote frequently cited ACH for patient-care areas.

*Values were derived from the formula

$$t_2 - t_1 = -[\ln(C_2 / C_1) / (Q / V)] \times 60, \text{ with } t_1 = 0$$

where

t_1 = initial timepoint (min)

t_2 = final timepoint (min)

C_1 = initial concentration of contaminant

C_2 = final concentration of contaminant

$C_2 / C_1 = 1 - (\text{removal efficiency}/100)$

Q = air flow rate in cubic feet/hour

V = room volume in cubic feet

Q / V = ACH

[†]Values apply to an empty room with no aerosol-generating source. With a person present and generating aerosol, this table would not apply. Other equations are available that include a constant generating source. However, certain diseases (e.g., infectious tuberculosis) are not likely to be aerosolized at a constant rate. The times given assume perfect mixing of the air within the space (i.e., mixing factor = 1). However, perfect mixing usually does not occur. Removal times will be longer in rooms or areas with imperfect mixing or air stagnation. Caution should be exercised in using this table in such situations. For booths or other local ventilation enclosures, manufacturers' instructions should be consulted.

Note: Stacked black boxes represent patient's bed. Long open box with cross-hatch represents supply air. Open boxes with single, diagonal slashes represent air exhaust registers. Arrows indicate directions of airflow.

*Possible uses include immunocompromised patient rooms (e.g., hematopoietic stem cell transplant or solid organ transplant procedure rooms) and orthopedic operating rooms.

†Positive-pressure room engineering features include

- positive pressure (greater supply than exhaust air volume);
- pressure differential range of 2.5–8 Pa (0.01–0.03-in. water gauge), ideal at 8 Pa;
- airflow differential >125-cfm supply versus exhaust;
- sealed room, approximately 0.5-sq. ft. leakage;
- clean to dirty airflow;
- monitoring;
- ≥ 12 air changes/hr (ACH); and
- return air if refiltered.

Box 3

BOX 3 . General steps for cleaning and maintaining ice machines, dispensers, and storage chests*

1. Disconnect unit from power supply.
2. Remove and discard ice from bin or storage chest.
3. Allow unit to warm to room temperature.
4. Disassemble removable parts of machine that make contact with water to make ice.
5. Thoroughly clean machine and parts with water and detergent.
6. Dry external surfaces of removable parts before reassembling.
7. Check for any needed repair.
8. Replace feeder lines as appropriate (e.g., when damaged, old, or difficult to clean).
9. Ensure presence of an air space in tubing leading from water inlet into water distribution system of machine.
10. Inspect for rodent or insect infestations under the unit and treat as needed.
11. Check door gaskets (open compartment models) for evidence of leakage or dripping into the storage chest.
12. Clean the ice-storage chest or bin with fresh water and detergent; rinse with fresh tap water.
13. Sanitize machine by circulating a 50–100 parts per million (ppm) solution of sodium hypochlorite (i.e., 4–8 mL sodium hypochlorite/gallon of water) through the ice-making and storage systems for 2 hours (100 ppm solution), or 4 hours (50 ppm solution).
14. Drain sodium hypochlorite solution and flush with fresh tap water.
15. Allow all surfaces of equipment to dry before returning to service.

Summary

In 1994, CDC published the Guidelines for Preventing the Transmission of Mycobacterium tuberculosis in Health-Care Facilities, 1994. The guidelines were issued in response to 1) a resurgence of tuberculosis (TB) disease that occurred in the United States in the mid-1980s and early 1990s, 2) the documentation of several high-profile health-care-associated (previously termed "nosocomial") outbreaks related to an increase in the prevalence of TB disease and human immunodeficiency virus (HIV) coinfection, 3) lapses in infection-control practices, 4) delays in the diagnosis and treatment of persons with infectious TB disease, and 5) the appearance and transmission of multidrug-resistant (MDR) TB strains. The 1994 guidelines, which followed statements issued in 1982 and 1990, presented recommendations for TB-infection control based on a risk assessment process that classified health-care facilities according to categories of TB risk, with a corresponding series of administrative, environmental, and respiratory-protection control measures.

The TB infection-control measures recommended by CDC in 1994 were implemented widely in health-care facilities in the United States. The result has been a decrease in the number of TB outbreaks in health-care settings reported to CDC and a reduction in health-care-associated transmission of Mycobacterium tuberculosis to patients and health-care workers (HCWs). Concurrent with this success, mobilization of the nation's TB-control programs succeeded in reversing the upsurge in reported cases of TB disease, and case rates have declined in the subsequent 10 years. Findings indicate that although the 2004 TB rate was the lowest recorded in the United States since national reporting began in 1953, the declines in rates for 2003 (2.3%) and 2004 (3.2%) were the smallest since 1993. In addition, TB infection rates greater than the U.S.

A48946859

average continue to be reported in certain racial/ethnic populations. The threat of MDR TB is decreasing, and the transmission of *M. tuberculosis* in health-care settings continues to decrease because of implementation of infection-control measures and reductions in community rates of TB.

Given the changes in epidemiology and a request by the Advisory Council for the Elimination of Tuberculosis (ACET) for review and update of the 1994 TB infection-control document, CDC has reassessed the TB infection-control guidelines for health-care settings. This report updates TB control recommendations reflecting shifts in the epidemiology of TB, advances in scientific understanding, and changes in health-care practice that have occurred in the United States during the preceding decade. In the context of diminished risk for health-care–associated transmission of *M. tuberculosis*, this document places emphasis on actions to maintain momentum and expertise needed to avert another TB resurgence and to eliminate the lingering threat to HCWs, which is mainly from patients or others with unsuspected and undiagnosed infectious TB disease. CDC prepared the current guidelines in consultation with experts in TB, infection control, environmental control, respiratory protection, and occupational health. The new guidelines have been expanded to address a broader concept; health-care–associated settings go beyond the previously defined facilities. The term "health-care setting" includes many types, such as inpatient settings, outpatient settings, TB clinics, settings in correctional facilities in which health care is delivered, settings in which home-based health-care and emergency medical services are provided, and laboratories handling clinical specimens that might contain *M. tuberculosis*. The term "setting" has been chosen over the term "facility," used in the previous guidelines, to broaden the potential places for which these guidelines apply.

Introduction

Overview

In 1994, CDC published the Guidelines for Preventing the Transmission of Mycobacterium tuberculosis in Health Care Facilities, 1994 (1). The guidelines were issued in response to 1) a resurgence of tuberculosis (TB) disease that occurred in the United States in the mid-1980s and early 1990s, 2) the documentation of multiple high-profile health-care–associated (previously "nosocomial") outbreaks related to an increase in the prevalence of TB disease and human immunodeficiency virus (HIV) coinfection, 3) lapses in infection-control practices, 4) delays in the diagnosis and treatment of persons with infectious TB disease (2,3), and 5) the appearance and transmission of multidrug-resistant (MDR) TB strains (4,5).

The 1994 guidelines, which followed CDC statements issued in 1982 and 1990 (1,6,7), presented recommendations for TB infection control based on a risk assessment process. In this process, health-care facilities were classified according to categories of TB risk, with a corresponding series of environmental and respiratory-protection control measures.

The TB infection-control measures recommended by CDC in 1994 were implemented widely in health-care facilities nationwide (8–15). As a result, a decrease has occurred in 1) the number of TB outbreaks in health-care settings reported to CDC and 2) health-care–associated transmission of *M. tuberculosis* to patients and health-care workers (HCWs) (9,16–23). Concurrent with this success, mobilization of the nation's TB-control programs succeeded in reversing the upsurge in reported cases of TB disease, and case rates have declined in the subsequent 10 years (4,5). Findings indicate that although the 2004 TB rate was the lowest recorded in the United States since national reporting began in 1953, the declines in rates for 2003 (2.3%) and 2004 (3.2%) were the lowest since 1993. In addition, TB rates higher than the U.S. average continue to be reported in certain racial/ethnic populations (24). The threat of MDR TB is decreasing, and the transmission of *M. tuberculosis* in health-care settings continues to decrease because of implementation of infection-control measures and reductions in community rates of TB (4,5,25).

Despite the general decline in TB rates in recent years, a marked geographic variation in TB case rates persists, which means that HCWs in different areas face different risks (10). In 2004, case rates varied per 100,000 population: 1.0 in Wyoming, 7.1 in New York, 8.3 in California, and 14.6 in the District of Columbia (26). In addition, despite the progress in the United States, the 2004 rate of 4.9

per 100,000 population remained higher than the 2000 goal of 3.5. This goal was established as part of the national strategic plan for TB elimination; the final goal is <1 case per 1,000,000 population by 2010 (4,5,26).

Given the changes in epidemiology and a request by the Advisory Council for the Elimination of Tuberculosis (ACET) for review and updating of the 1994 TB infection-control document, CDC has reassessed the TB infection-control guidelines for health-care settings. This report updates TB-control recommendations, reflecting shifts in the epidemiology of TB (27), advances in scientific understanding, and changes in health-care practice that have occurred in the United States in the previous decade (28). In the context of diminished risk for health-care–associated transmission of *M. tuberculosis*, this report emphasizes actions to maintain momentum and expertise needed to avert another TB resurgence and eliminate the lingering threat to HCWs, which is primarily from patients or other persons with unsuspected and undiagnosed infectious TB disease.

CDC prepared the guidelines in this report in consultation with experts in TB, infection control, environmental control, respiratory protection, and occupational health. This report replaces all previous CDC guidelines for TB infection control in health-care settings (1,6,7). Primary references citing evidence-based science are used in this report to support explanatory material and recommendations. Review articles, which include primary references, are used for editorial style and brevity.

The following changes differentiate this report from previous guidelines:

- The risk assessment process includes the assessment of additional aspects of infection control.
- The term "tuberculin skin tests" (TSTs) is used instead of purified protein derivative (PPD).
- The whole-blood interferon gamma release assay (IGRA), QuantiFERON(r)-TB Gold test (QFT-G) (Cellestis Limited, Carnegie, Victoria, Australia), is a Food and Drug Administration (FDA)–approved in vitro cytokine-based assay for cell-mediated immune reactivity to *M. tuberculosis* and might be used instead of TST in TB screening programs for HCWs. This IGRA is an example of a blood assay for *M. tuberculosis* (BAMT).
- The frequency of TB screening for HCWs has been decreased in various settings, and the criteria for determination of screening frequency have been changed.
- The scope of settings in which the guidelines apply has been broadened to include laboratories and additional outpatient and nontraditional facility-based settings.
- Criteria for serial testing for *M. tuberculosis* infection of HCWs are more clearly defined. In certain settings, this change will decrease the number of HCWs who need serial TB screening.
- These recommendations usually apply to an entire health-care setting rather than areas within a setting.
- New terms, airborne infection precautions (airborne precautions) and airborne infection isolation room (AII room), are introduced.
- Recommendations for annual respirator training, initial respirator fit testing, and periodic respirator fit testing have been added.
- The evidence of the need for respirator fit testing is summarized.
- Information on ultraviolet germicidal irradiation (UVGI) and room-air recirculation units has been expanded.
- Additional information regarding MDR TB and HIV infection has been included.

In accordance with relevant local, state, and federal laws, implementation of all recommendations must safeguard the confidentiality and civil rights of all HCWs and patients who have been infected with *M. tuberculosis* and who develop TB disease.

The 1994 CDC guidelines were aimed primarily at hospital-based facilities, which frequently refer to a physical building or set of buildings. The 2005 guidelines have been expanded to address a broader concept. Setting has been chosen instead of "facility" to expand the scope of potential places for which these guidelines apply ([Appendix A](#)). "Setting" is used to describe any relationship (physical or organizational) in which HCWs might share air space with persons with TB disease or in which HCWs might be in contact with clinical specimens. Various setting types might be present in a single facility. Health-care settings include inpatient settings, outpatient settings, and nontraditional facility-based settings.

- Inpatient settings include patient rooms, emergency departments (EDs), intensive care units (ICUs), surgical suites, laboratories, laboratory procedure areas, bronchoscopy suites, sputum induction or inhalation therapy rooms, autopsy suites, and embalming rooms.
- Outpatient settings include TB treatment facilities, medical offices, ambulatory-care settings, dialysis units, and dental-care settings.
- Nontraditional facility-based settings include emergency medical service (EMS), medical settings in correctional facilities (e.g., prisons, jails, and detention centers), home-based health-care and outreach settings, long-term-care settings (e.g., hospices, skilled nursing facilities), and homeless shelters. Other settings in which suspected and confirmed TB patients might be encountered might include cafeterias, general stores, kitchens, laundry areas, maintenance shops, pharmacies, and law enforcement settings.

HCWs Who Should Be Included in a TB Surveillance Program

HCWs refer to all paid and unpaid persons working in health-care settings who have the potential for exposure to *M. tuberculosis* through air space shared with persons with infectious TB disease. Part time, temporary, contract, and full-time HCWs should be included in TB screening programs. All HCWs who have duties that involve face-to-face contact with patients with suspected or confirmed TB disease (including transport staff) should be included in a TB screening program.

The following are HCWs who might be included in a TB screening program:

- Administrators or managers
- Bronchoscopy staff
- Chaplains
- Clerical staff
- Computer programmers
- Construction staff
- Correctional officers
- Craft or repair staff
- Dental staff
- Dietician or dietary staff
- ED staff
- Engineers
- Food service staff
- Health aides
- Health and safety staff
- Housekeeping or custodial staff
- Homeless shelter staff
- Infection-control staff
- ICU staff
- Janitorial staff
- Laboratory staff
- Maintenance staff
- Morgue staff
- Nurses
- Outreach staff
- Pathology laboratory staff
- Patient transport staff, including EMS
- Pediatric staff
- Pharmacists
- Phlebotomists
- Physical and occupational therapists
- Physicians (assistant, attending, fellow, resident, or intern), including
 - anesthesiologists
 - pathologists
 - psychiatrists
 - psychologists
- Public health educators or teachers
- Public safety staff

- Radiology staff
- Respiratory therapists
- Scientists
- Social workers
- Students (e.g., medical, nursing, technicians, and allied health)
- Technicians (e.g., health, laboratory, radiology, and animal)
- Veterinarians
- Volunteers

In addition, HCWs who perform any of the following activities should also be included in the TB screening program.

- entering patient rooms or treatment rooms whether or not a patient is present;
- participating in aerosol-generating or aerosol-producing procedures (e.g., bronchoscopy, sputum induction, and administration of aerosolized medications) (29);
- participating in suspected or confirmed *M. tuberculosis* specimen processing; or
- installing, maintaining, or replacing environmental controls in areas in which persons with TB disease are encountered.

Pathogenesis, Epidemiology, and Transmission of *M. tuberculosis*

M. tuberculosis is carried in airborne particles called droplet nuclei that can be generated when persons who have pulmonary or laryngeal TB disease cough, sneeze, shout, or sing (30,31). The particles are approximately 1–5 µm; normal air currents can keep them airborne for prolonged periods and spread them throughout a room or building (32). *M. tuberculosis* is usually transmitted only through air, not by surface contact. After the droplet nuclei are in the alveoli, local infection might be established, followed by dissemination to draining lymphatics and hematogenous spread throughout the body (33). Infection occurs when a susceptible person inhales droplet nuclei containing *M. tuberculosis*, and the droplet nuclei traverse the mouth or nasal passages, upper respiratory tract, and bronchi to reach the alveoli. Persons with TB pleural effusions might also have concurrent unsuspected pulmonary or laryngeal TB disease.

Usually within 2–12 weeks after initial infection with *M. tuberculosis*, the immune response limits additional multiplication of the tubercle bacilli, and immunologic test results for *M. tuberculosis* infection become positive. However, certain bacilli remain in the body and are viable for multiple years. This condition is referred to as latent tuberculosis infection (LTBI). Persons with LTBI are asymptomatic (they have no symptoms of TB disease) and are not infectious.

In the United States, LTBI has been diagnosed traditionally based on a PPD-based TST result after TB disease has been excluded. In vitro cytokine-based immunoassays for the detection of *M. tuberculosis* infection have been the focus of intense research and development. One such blood assay for *M. tuberculosis* (or BAMT) is an IGRA, the QuantiFERON(r)-TB test (QFT), and the subsequently developed version, QFT-G. The QFT-G measures cell-mediated immune responses to peptides from two *M. tuberculosis* proteins that are not present in any Bacille Calmette-Guérin (BCG) vaccine strain and that are absent from the majority of nontuberculous mycobacteria (NTM), also known as mycobacteria other than TB (MOTT). QFT-G was approved by FDA in 2005 and is an available option for detecting *M. tuberculosis* infection. CDC recommendations for the United States regarding QFT and QFT-G have been published (34,35). Because this field is rapidly evolving, in this report, BAMT will be used generically to refer to the test currently available in the United States.

Additional cytokine-based immunoassays are under development and might be useful in the diagnosis of *M. tuberculosis* infection. Future FDA-licensed products in combination with CDC-issued recommendations might provide additional diagnostic alternatives. The latest CDC recommendations for guidance on diagnostic use of these and related technologies are available at http://www.cdc.gov/nchstp/tb/pubs/mmwr/html/Maj_guide/Diagnosis.htm.

Typically, approximately 5%–10% of persons who become infected with *M. tuberculosis* and who are not treated for LTBI will develop TB disease during their lifetimes (1). The risk for progression of

Persons at Highest Risk for Exposure to and Infection with *M. tuberculosis*

Characteristics of persons exposed to *M. tuberculosis* that might affect the risk for infection are not as well defined. The probability that a person who is exposed to *M. tuberculosis* will become infected depends primarily on the concentration of infectious droplet nuclei in the air and the duration of exposure to a person with infectious TB disease. The closer the proximity and the longer the duration of exposure, the higher the risk is for being infected.

Close contacts are persons who share the same air space in a household or other enclosed environment for a prolonged period (days or weeks, not minutes or hours) with a person with pulmonary TB disease (39). A suspect TB patient is a person in whom a diagnosis of TB disease is being considered, whether or not antituberculosis treatment has been started. Persons generally should not remain a suspect TB patient for >3 months (30,39).

In addition to close contacts, the following persons are also at higher risk for exposure to and infection with *M. tuberculosis*. Persons listed who are also close contacts should be top priority.

- Foreign-born persons, including children, especially those who have arrived to the United States within 5 years after moving from geographic areas with a high incidence of TB disease (e.g., Africa, Asia, Eastern Europe, Latin America, and Russia) or who frequently travel to countries with a high prevalence of TB disease.
- Residents and employees of congregate settings that are high risk (e.g., correctional facilities, long-term-care facilities [LTCFs], and homeless shelters).
- HCWs who serve patients who are at high risk.
- HCWs with unprotected exposure to a patient with TB disease before the identification and correct airborne precautions of the patient.
- Certain populations who are medically underserved and who have low income, as defined locally.
- Populations at high risk who are defined locally as having an increased incidence of TB disease.
- Infants, children, and adolescents exposed to adults in high-risk categories.

Persons Whose Condition is at High Risk for Progression From LTBI to TB Disease

The following persons are at high risk for progressing from LTBI to TB disease:

- persons infected with HIV;
- persons infected with *M. tuberculosis* within the previous 2 years;
- infants and children aged <4 years;
- persons with any of the following clinical conditions or other immunocompromising conditions
 - silicosis,
 - diabetes mellitus,
 - chronic renal failure,
 - certain hematologic disorders (leukemias and lymphomas),
 - other specific malignancies (e.g., carcinoma of the head, neck, or lung),
 - body weight $\geq 10\%$ below ideal body weight,
 - prolonged corticosteroid use,
 - other immunosuppressive treatments (including tumor necrosis factor-alpha [TNF- α] antagonists),
 - organ transplant,
 - end-stage renal disease (ESRD), and
 - intestinal bypass or gastrectomy; and
- persons with a history of untreated or inadequately treated TB disease, including persons with chest radiograph findings consistent with previous TB disease.

Persons who use tobacco or alcohol (40,41), illegal drugs, including injection drugs and crack cocaine (42–47), might also be at increased risk for infection and disease. However, because of multiple other potential risk factors that commonly occur among such persons, use of these substances has been difficult to identify as separate risk factors.

HIV infection is the greatest risk factor for progression from LTBI to TB disease (22,39,48,49). Therefore, voluntary HIV counseling, testing, and referral should be routinely offered to all persons at risk for LTBI (1,50,51). Health-care settings should be particularly aware of the need for preventing transmission of *M. tuberculosis* in settings in which persons infected with HIV might be encountered or might work (52).

All HCWs should be informed regarding the risk for developing TB disease after being infected with *M. tuberculosis* (1). However, the rate of TB disease among persons who are HIV-infected and untreated for LTBI in the United States is substantially higher, ranging from 1.7–7.9 TB cases per 100 person-years (53). Persons infected with HIV who are already severely immunocompromised and who become newly infected with *M. tuberculosis* have a greater risk for developing TB disease, compared with newly infected persons without HIV infection (39,53–57).

The percentage of patients with TB disease who are HIV-infected is decreasing in the United States because of improved infection-control practices and better diagnosis and treatment of both HIV infection and TB. With increased voluntary HIV counseling and testing and the increasing use of treatment for LTBI, TB disease will probably continue to decrease among HIV-infected persons in the United States (58). Because the risk for disease is particularly high among HIV-infected persons with *M. tuberculosis* infection, HIV-infected contacts of persons with infectious pulmonary or laryngeal TB disease must be evaluated for *M. tuberculosis* infection, including the exclusion of TB disease, as soon as possible after learning of exposure (39,49,53).

Vaccination with BCG probably does not affect the risk for infection after exposure, but it might decrease the risk for progression from infection with *M. tuberculosis* to TB disease, preventing the development of miliary and meningeal disease in infants and young children (59,60). Although HIV infection increases the likelihood of progression from LTBI to TB disease (39,49), whether HIV infection increases the risk for becoming infected if exposed to *M. tuberculosis* is not known.

Characteristics of a Patient with TB Disease That Increase the Risk for Infectiousness

The following characteristics exist in a patient with TB disease that increases the risk for infectiousness:

- presence of cough;
- cavitation on chest radiograph;
- positive acid-fast bacilli (AFB) sputum smear result;
- respiratory tract disease with involvement of the larynx (substantially infectious);
- respiratory tract disease with involvement of the lung or pleura (exclusively pleural involvement is less infectious);
- failure to cover the mouth and nose when coughing;
- incorrect, lack of, or short duration of antituberculosis treatment; and
- undergoing cough-inducing or aerosol-generating procedures (e.g., bronchoscopy, sputum induction, and administration of aerosolized medications) (29).

Environmental Factors That Increase the Risk for Probability of Transmission of *M. tuberculosis*

The probability of the risk for transmission of *M. tuberculosis* is increased as a result of various environmental factors.

- Exposure to TB in small, enclosed spaces.
- Inadequate local or general ventilation that results in insufficient dilution or removal of infectious droplet nuclei.
- Recirculation of air containing infectious droplet nuclei.
- Inadequate cleaning and disinfection of medical equipment.
- Improper procedures for handling specimens.

Risk for Health-Care–Associated Transmission of *M. tuberculosis*

Transmission of *M. tuberculosis* is a risk in health-care settings (57,61–79). The magnitude of the risk varies by setting, occupational group, prevalence of TB in the community, patient population, and effectiveness of TB infection-control measures. Health-care–associated transmission of *M. tuberculosis* has been linked to close contact with persons with TB disease during aerosol-generating or aerosol-producing procedures, including bronchoscopy (29,63,80–82), endotracheal intubation, suctioning (66), other respiratory procedures (8,9,83–86), open abscess irrigation (69,83), autopsy (71,72,77), sputum induction, and aerosol treatments that induce coughing (87–90).

Of the reported TB outbreaks in health-care settings, multiple outbreaks involved transmission of MDR TB strains to both patients and HCWs (56,57,70,87,91–94). The majority of the patients and certain HCWs were HIV-infected, and progression to TB and MDR TB disease was rapid. Factors contributing to these outbreaks included delayed diagnosis of TB disease, delayed initiation and inadequate airborne precautions, lapses in AII practices and precautions for cough-inducing and aerosol-generating procedures, and lack of adequate respiratory protection. Multiple studies suggest that the decline in health-care–associated transmission observed in specific institutions is associated with the rigorous implementation of infection-control measures (11,12,18–20,23,95–97). Because various interventions were implemented simultaneously, the effectiveness of each intervention could not be determined.

After the release of the 1994 CDC infection-control guidelines, increased implementation of recommended infection-control measures occurred and was documented in multiple national surveys (13,15,98,99). In a survey of approximately 1,000 hospitals, a TST program was present in nearly all sites, and 70% reported having an AII room (13). Other surveys have documented improvement in the proportion of AII rooms meeting CDC criteria and proportion of HCWs using CDC-recommended respiratory protection and receiving serial TST (15,98). A survey of New York City hospitals with high caseloads of TB disease indicated 1) a decrease in the time that patients with TB disease spent in EDs before being transferred to a hospital room, 2) an increase in the proportion of patients initially placed in AII rooms, 3) an increase in the proportion of patients started on recommended antituberculosis treatment and reported to the local or state health department, and 4) an increase in the use of recommended respiratory protection and environmental controls (99). Reports of increased implementation of recommended TB infection controls combined with decreased reports of outbreaks of TB disease in health-care settings suggest that the recommended controls are effective in reducing and preventing health-care–associated transmission of *M. tuberculosis* (28).

Less information is available regarding the implementation of CDC-recommended TB infection-control measures in settings other than hospitals. One study identified major barriers to implementation that contribute to the costs of a TST program in health departments and hospitals, including personnel costs, HCWs' time off from work for TST administration and reading, and training and education of HCWs (100). Outbreaks have occurred in outpatient settings (i.e., private physicians' offices and pediatric settings) where the guidelines were not followed (101–103). CDC-recommended TB infection-control measures are implemented in correctional facilities, and certain variations might relate to resources, expertise, and oversight (104–106).

Fundamentals of TB Infection Control

One of the most critical risks for health-care–associated transmission of *M. tuberculosis* in health-care settings is from patients with unrecognized TB disease who are not promptly handled with appropriate airborne precautions (56,57,93,104) or who are moved from an AII room too soon (e.g., patients with unrecognized TB and MDR TB) (94). In the United States, the problem of MDR TB, which was amplified by health-care–associated transmission, has been substantially reduced by the use of standardized antituberculosis treatment regimens in the initial phase of therapy, rapid drug-susceptibility testing, directly observed therapy (DOT), and improved infection-control practices (1). DOT is an adherence-enhancing strategy in which an HCW or other specially trained health professional watches a patient swallow each dose of medication and records the dates that the administration was observed. DOT is the standard of care for all patients with TB disease and should be used for all doses during the course of therapy for TB disease and for LTBI whenever feasible.

All health-care settings need a TB infection-control program designed to ensure prompt detection, airborne precautions, and treatment of persons who have suspected or confirmed TB disease (or prompt referral of persons who have suspected TB disease for settings in which persons with TB disease are not expected to be encountered). Such a program is based on a three-level hierarchy of controls, including administrative, environmental, and respiratory protection (86,107,108).

Administrative Controls

The first and most important level of TB controls is the use of administrative measures to reduce the risk for exposure to persons who might have TB disease. Administrative controls consist of the following activities:

- assigning responsibility for TB infection control in the setting;
- conducting a TB risk assessment of the setting;
- developing and instituting a written TB infection-control plan to ensure prompt detection, airborne precautions, and treatment of persons who have suspected or confirmed TB disease;
- ensuring the timely availability of recommended laboratory processing, testing, and reporting of results to the ordering physician and infection-control team;
- implementing effective work practices for the management of patients with suspected or confirmed TB disease;
- ensuring proper cleaning and sterilization or disinfection of potentially contaminated equipment (usually endoscopes);
- training and educating HCWs regarding TB, with specific focus on prevention, transmission, and symptoms;
- screening and evaluating HCWs who are at risk for TB disease or who might be exposed to *M. tuberculosis* (i.e., TB screening program);
- applying epidemiologic-based prevention principles, including the use of setting-related infection-control data;
- using appropriate signage advising respiratory hygiene and cough etiquette; and
- coordinating efforts with the local or state health department.

HCWs with TB disease should be allowed to return to work when they 1) have had three negative AFB sputum smear results (109–112) collected 8–24 hours apart, with at least one being an early morning specimen because respiratory secretions pool overnight; and 2) have responded to antituberculosis treatment that will probably be effective based on susceptibility results. In addition, HCWs with TB disease should be allowed to return to work when a physician knowledgeable and experienced in managing TB disease determines that HCWs are noninfectious (see Treatment Procedures for LTBI and TB Disease). Consideration should also be given to the type of setting and the potential risk to patients (e.g., general medical office versus HIV clinic) (see Supplements, Estimating the Infectiousness of a TB Patient; Diagnostic Procedures for LTBI and TB Disease; and Treatment Procedures for LTBI and TB Disease).

Environmental Controls

The second level of the hierarchy is the use of environmental controls to prevent the spread and reduce the concentration of infectious droplet nuclei in ambient air.

Primary environmental controls consist of controlling the source of infection by using local exhaust ventilation (e.g., hoods, tents, or booths) and diluting and removing contaminated air by using general ventilation.

Secondary environmental controls consist of controlling the airflow to prevent contamination of air in areas adjacent to the source (AII rooms) and cleaning the air by using high efficiency particulate air (HEPA) filtration or UVGI.

Respiratory-Protection Controls

The first two control levels minimize the number of areas in which exposure to *M. tuberculosis* might occur and, therefore, minimize the number of persons exposed. These control levels also reduce, but do not eliminate, the risk for exposure in the limited areas in which exposure can still occur. Because

persons entering these areas might be exposed to *M. tuberculosis*, the third level of the hierarchy is the use of respiratory protective equipment in situations that pose a high risk for exposure. Use of respiratory protection can further reduce risk for exposure of HCWs to infectious droplet nuclei that have been expelled into the air from a patient with infectious TB disease (see Respiratory Protection). The following measures can be taken to reduce the risk for exposure:

- implementing a respiratory-protection program,
- training HCWs on respiratory protection, and
- training patients on respiratory hygiene and cough etiquette procedures.

Relevance to Biologic Terrorism Preparedness

MDR *M. tuberculosis* is classified as a category C agent of biologic terrorism (113). Implementation of the TB infection-control guidelines described in this document is essential for preventing and controlling transmission of *M. tuberculosis* in health-care settings. Additional information is at <http://www.bt.cdc.gov> and <http://www.idsociety.org/bt/toc.htm> (114).

Recommendations for Preventing Transmission of *M. tuberculosis* in Health-Care Settings

TB Infection-Control Program

Every health-care setting should have a TB infection-control plan that is part of an overall infection-control program. The specific details of the TB infection-control program will differ, depending on whether patients with suspected or confirmed TB disease might be encountered in the setting or whether patients with suspected or confirmed TB disease will be transferred to another health-care setting. Administrators making this distinction should obtain medical and epidemiologic consultation from state and local health departments.

TB Infection-Control Program for Settings in Which Patients with Suspected or Confirmed TB Disease Are Expected To Be Encountered

The TB infection-control program should consist of administrative controls, environmental controls, and a respiratory-protection program. Every setting in which services are provided to persons who have suspected or confirmed infectious TB disease, including laboratories and nontraditional facility-based settings, should have a TB infection-control plan. The following steps should be taken to establish a TB infection-control program in these settings:

1. Assign supervisory responsibility for the TB infection-control program to a designated person or group with expertise in LTBI and TB disease, infection control, occupational health, environmental controls, and respiratory protection. Give the supervisor or supervisory body the support and authority to conduct a TB risk assessment, implement and enforce TB infection-control policies, and ensure recommended training and education of HCWs.
 - Train the persons responsible for implementing and enforcing the TB infection-control program.
 - Designate one person with a back-up as the TB resource person to whom questions and problems should be addressed, if supervisory responsibility is assigned to a committee.
2. Develop a written TB infection-control plan that outlines a protocol for the prompt recognition and initiation of airborne precautions of persons with suspected or confirmed TB disease, and update it annually.
3. Conduct a problem evaluation (see Problem Evaluation) if a case of suspected or confirmed TB disease is not promptly recognized and appropriate airborne precautions not initiated, or if administrative, environmental, or respiratory-protection controls fail.
4. Perform a contact investigation in collaboration with the local or state health department if health-care-associated transmission of *M. tuberculosis* is suspected (115). Implement and monitor corrective action.
5. Collaborate with the local or state health department to develop administrative controls consisting of the risk assessment, the written TB infection-control plan, management of patients with suspected or confirmed TB disease, training and education of HCWs, screening and evaluation of HCWs, problem evaluation, and coordination.

6. Implement and maintain environmental controls, including AII room(s) (see Environmental Controls).
7. Implement a respiratory-protection program.
8. Perform ongoing training and education of HCWs (see Suggested Components of an Initial TB Training and Education Program for HCWs).
9. Create a plan for accepting patients who have suspected or confirmed TB disease if they are transferred from another setting.

TB Infection-Control Program for Settings in Which Patients with Suspected or Confirmed TB Disease Are Not Expected To Be Encountered

Settings in which TB patients might stay before transfer should still have a TB infection-control program in place consisting of administrative, environmental, and respiratory-protection controls. The following steps should be taken to establish a TB infection-control program in these settings:

1. Assign responsibility for the TB infection-control program to appropriate personnel.
2. Develop a written TB infection-control plan that outlines a protocol for the prompt recognition and transfer of persons who have suspected or confirmed TB disease to another health-care setting. The plan should indicate procedures to follow to separate persons with suspected or confirmed infectious TB disease from other persons in the setting until the time of transfer. Evaluate the plan annually, if possible, to ensure that the setting remains one in which persons who have suspected or confirmed TB disease are not encountered and that they are promptly transferred.
3. Conduct a problem evaluation (see Problem Evaluation) if a case of suspected or confirmed TB disease is not promptly recognized, separated from others, and transferred.
4. Perform an investigation in collaboration with the local or state health department if health-care–associated transmission of *M. tuberculosis* is suspected.
5. Collaborate with the local or state health department to develop administrative controls consisting of the risk assessment and the written TB infection-control plan.

TB Risk Assessment

Every health-care setting should conduct initial and ongoing evaluations of the risk for transmission of *M. tuberculosis*, regardless of whether or not patients with suspected or confirmed TB disease are expected to be encountered in the setting. The TB risk assessment determines the types of administrative, environmental, and respiratory-protection controls needed for a setting and serves as an ongoing evaluation tool of the quality of TB infection control and for the identification of needed improvements in infection-control measures. Part of the risk assessment is similar to a program review that is conducted by the local TB-control program (42). The TB Risk Assessment Worksheet ([Appendix B](#)) can be used as a guide for conducting a risk assessment. This worksheet frequently does not specify values for acceptable performance indicators because of the lack of scientific data.

TB Risk Assessment for Settings in Which Patients with Suspected or Confirmed TB Disease Are Expected To Be Encountered

The initial and ongoing risk assessment for these settings should consist of the following steps:

1. Review the community profile of TB disease in collaboration with the state or local health department.
2. Consult the local or state TB-control program to obtain epidemiologic surveillance data necessary to conduct a TB risk assessment for the health-care setting.
3. Review the number of patients with suspected or confirmed TB disease who have been encountered in the setting during at least the previous 5 years.
4. Determine if persons with unrecognized TB disease have been admitted to or were encountered in the setting during the previous 5 years.
5. Determine which HCWs need to be included in a TB screening program and the frequency of screening (based on risk classification) ([Appendix C](#)).
6. Ensure the prompt recognition and evaluation of suspected episodes of health-care–associated transmission of *M. tuberculosis*.
7. Identify areas in the setting with an increased risk for health-care–associated transmission of *M. tuberculosis*, and target them for improved TB infection controls.

8. Assess the number of AII rooms needed for the setting. The risk classification for the setting should help to make this determination, depending on the number of TB patients examined. At least one AII room is needed for settings in which TB patients stay while they are being treated, and additional AII rooms might be needed, depending on the magnitude of patient-days of cases of suspected or confirmed TB disease. Additional AII rooms might be considered if options are limited for transferring patients with suspected or confirmed TB disease to other settings with AII rooms.
9. Determine the types of environmental controls needed other than AII rooms (see TB Airborne Precautions).
10. Determine which HCWs need to be included in the respiratory-protection program.
11. Conduct periodic reassessments (annually, if possible) to ensure
 - proper implementation of the TB infection-control plan,
 - prompt detection and evaluation of suspected TB cases,
 - prompt initiation of airborne precautions of suspected infectious TB cases,
 - recommended medical management of patients with suspected or confirmed TB disease (31),
 - functional environmental controls,
 - implementation of the respiratory-protection program, and
 - ongoing HCW training and education regarding TB.
12. Recognize and correct lapses in infection control.

TB Risk Assessment for Settings in Which Patients with Suspected or Confirmed TB Disease Are Not Expected To Be Encountered

The initial and ongoing risk assessment for these settings should consist of the following steps:

1. Review the community profile of TB disease in collaboration with the local or state health department.
2. Consult the local or state TB-control program to obtain epidemiologic surveillance data necessary to conduct a TB risk assessment for the health-care setting.
3. Determine if persons with unrecognized TB disease were encountered in the setting during the previous 5 years.
4. Determine if any HCWs need to be included in the TB screening program.
5. Determine the types of environmental controls that are currently in place, and determine if any are needed in the setting (Appendices A and D).
6. Document procedures that ensure the prompt recognition and evaluation of suspected episodes of health-care–associated transmission of *M. tuberculosis*.
7. Conduct periodic reassessments (annually, if possible) to ensure 1) proper implementation of the TB infection-control plan; 2) prompt detection and evaluation of suspected TB cases; 3) prompt initiation of airborne precautions of suspected infectious TB cases before transfer; 4) prompt transfer of suspected infectious TB cases; 5) proper functioning of environmental controls, as applicable; and 6) ongoing TB training and education for HCWs.
8. Recognize and correct lapses in infection control.

Use of Risk Classification to Determine Need for TB Screening and Frequency of Screening HCWs

Risk classification should be used as part of the risk assessment to determine the need for a TB screening program for HCWs and the frequency of screening ([Appendix C](#)). A risk classification usually should be determined for the entire setting. However, in certain settings (e.g., health-care organizations that encompass multiple sites or types of services), specific areas defined by geography, functional units, patient population, job type, or location within the setting might have separate risk classifications. Examples of assigning risk classifications have been provided (see Risk Classification Examples).

TB Screening Risk Classifications

The three TB screening risk classifications are low risk, medium risk, and potential ongoing transmission. The classification of low risk should be applied to settings in which persons with TB disease are not expected to be encountered, and, therefore, exposure to *M. tuberculosis* is unlikely. This classification should also be applied to HCWs who will never be exposed to persons with TB disease or to clinical specimens that might contain *M. tuberculosis*.

The classification of medium risk should be applied to settings in which the risk assessment has determined that HCWs will or will possibly be exposed to persons with TB disease or to clinical specimens that might contain *M. tuberculosis*.

The classification of potential ongoing transmission should be temporarily applied to any setting (or group of HCWs) if evidence suggestive of person-to-person (e.g., patient-to-patient, patient-to-HCW, HCW-to-patient, or HCW-to-HCW) transmission of *M. tuberculosis* has occurred in the setting during the preceding year. Evidence of person-to-person transmission of *M. tuberculosis* includes 1) clusters of TST or BAMT conversions, 2) HCW with confirmed TB disease, 3) increased rates of TST or BAMT conversions, 4) unrecognized TB disease in patients or HCWs, or 5) recognition of an identical strain of *M. tuberculosis* in patients or HCWs with TB disease identified by deoxyribonucleic acid (DNA) fingerprinting.

If uncertainty exists regarding whether to classify a setting as low risk or medium risk, the setting typically should be classified as medium risk.

TB Screening Procedures for Settings (or HCWs) Classified as Low Risk

- All HCWs should receive baseline TB screening upon hire, using two-step TST or a single BAMT to test for infection with *M. tuberculosis*.
- After baseline testing for infection with *M. tuberculosis*, additional TB screening is not necessary unless an exposure to *M. tuberculosis* occurs.
- HCWs with a baseline positive or newly positive test result for *M. tuberculosis* infection (i.e., TST or BAMT) or documentation of treatment for LTBI or TB disease should receive one chest radiograph result to exclude TB disease (or an interpretable copy within a reasonable time frame, such as 6 months). Repeat radiographs are not needed unless symptoms or signs of TB disease develop or unless recommended by a clinician (39,116).

TB Screening Procedures for Settings (or HCWs) Classified as Medium Risk

- All HCWs should receive baseline TB screening upon hire, using two-step TST or a single BAMT to test for infection with *M. tuberculosis*.
- After baseline testing for infection with *M. tuberculosis*, HCWs should receive TB screening annually (i.e., symptom screen for all HCWs and testing for infection with *M. tuberculosis* for HCWs with baseline negative test results).
- HCWs with a baseline positive or newly positive test result for *M. tuberculosis* infection or documentation of previous treatment for LTBI or TB disease should receive one chest radiograph result to exclude TB disease. Instead of participating in serial testing, HCWs should receive a symptom screen annually. This screen should be accomplished by educating the HCW about symptoms of TB disease and instructing the HCW to report any such symptoms immediately to the occupational health unit. Treatment for LTBI should be considered in accordance with CDC guidelines (39).

TB Screening Procedures for Settings (or HCWs) Classified as Potential Ongoing Transmission

- Testing for infection with *M. tuberculosis* might need to be performed every 8–10 weeks until lapses in infection control have been corrected, and no additional evidence of ongoing transmission is apparent.
- The classification of potential ongoing transmission should be used as a temporary classification only. It warrants immediate investigation and corrective steps. After a determination that ongoing transmission has ceased, the setting should be reclassified as medium risk. Maintaining the classification of medium risk for at least 1 year is recommended.

Settings Adopting BAMT for Use in TB Screening

Settings that use TST as part of TB screening and want to adopt BAMT can do so directly (without any overlapping TST) or in conjunction with a period of evaluation (e.g., 1 or 2 years) during which time both TST and BAMT are used. Baseline testing for BAMT would be established as a single step test. As with the TST, BAMT results should be recorded in detail. The details should include date of blood

draw, result in specific units, and the laboratory interpretation (positive, negative, or indeterminate—and the concentration of cytokine measured, for example, interferon-gamma [IFN- γ]).

Risk Classification Examples

Inpatient Settings with More Than 200 Beds

If less than six TB patients for the preceding year, classify as low risk. If greater than or equal to six TB patients for the preceding year, classify as medium risk.

Inpatient Settings with Less Than 200 Beds

If less than three TB patients for the preceding year, classify as low risk. If greater than or equal to three TB patients for the preceding year, classify as medium risk.

Outpatient, Outreach, and Home-Based Health-Care Settings

If less than three TB patients for the preceding year, classify as low risk. If greater than or equal to three TB patients for the preceding year, classify as medium risk.

Hypothetical Risk Classification Examples

The following hypothetical situations illustrate how assessment data are used to assign a risk classification. The risk classifications are for settings in which patients with suspected or confirmed infectious TB disease are expected to be encountered.

Example A. The setting is a 150-bed hospital located in a small city. During the preceding year, the hospital admitted two patients with a diagnosis of TB disease. One was admitted directly to an AII room, and one stayed on a medical ward for 2 days before being placed in an AII room. A contact investigation of exposed HCWs by hospital infection-control personnel in consultation with the state or local health department did not identify any health-care–associated transmission. Risk classification: low risk.

Example B. The setting is an ambulatory-care site in which a TB clinic is held 2 days per week. During the preceding year, care was delivered to six patients with TB disease and approximately 50 persons with LTBI. No instances of transmission of *M. tuberculosis* were noted. Risk classification: medium risk (because it is a TB clinic).

Example C. The setting is a large publicly funded hospital in a major metropolitan area. The hospital admits an average of 150 patients with TB disease each year, comprising 35% of the city burden. The setting has a strong TB infection-control program (i.e., annually updates infection-control plan, fully implements infection-control plan, and has enough AII rooms [see Environmental Controls]) and an annual conversion rate (for tests for *M. tuberculosis* infection) among HCWs of 0.5%. No evidence of health-care–associated transmission is apparent. The hospital has strong collaborative linkages with the state or local health department. Risk classification: medium risk (with close ongoing surveillance for episodes of transmission from unrecognized cases of TB disease, test conversions for *M. tuberculosis* infection in HCWs as a result of health-care–associated transmission, and specific groups or areas in which a higher risk for health-care–associated transmission exists).

Example D. The setting is an inpatient area of a correctional facility. A proportion of the inmates were born in countries where TB disease is endemic. Two cases of TB disease were diagnosed in inmates during the preceding year. Risk classification: medium risk (Correctional facilities should be classified as at least medium risk).

Example E. A hospital located in a large city admits 35 patients with TB disease per year, uses QFT-G to measure *M. tuberculosis* infection, and has an overall HCW *M. tuberculosis* infection test conversion rate of 1.0%. However, on annual testing, three of the 20 respiratory therapists tested had QFT-G conversions, for a rate of 15%. All of the respiratory therapists who tested positive received medical evaluations, had TB disease excluded, were diagnosed with LTBI, and were offered and completed a course of treatment for LTBI. None of the respiratory therapists had known exposures to

M. tuberculosis outside the hospital. The problem evaluation revealed that 1) the respiratory therapists who converted had spent part of their time in the pulmonary function laboratory where induced sputum specimens were collected, and 2) the ventilation in the laboratory was inadequate. Risk classification: potential ongoing transmission for the respiratory therapists (because of evidence of health-care–associated transmission). The rest of the setting was classified as medium risk. To address the problem, booths were installed for sputum induction. On subsequent testing for *M. tuberculosis* infection, no conversions were noted at the repeat testing 3 months later, and the respiratory therapists were then reclassified back to medium risk.

Example F. The setting is an ambulatory-care center associated with a large health maintenance organization (HMO). The patient volume is high, and the HMO is located in the inner city where TB rates are the highest in the state. During the preceding year, one patient who was known to have TB disease was evaluated at the center. The person was recognized as a TB patient on his first visit and was promptly triaged to an ED with an AII room capacity. While in the ambulatory-care center, the patient was held in an area separate from HCWs and other patients and instructed to wear a surgical or procedure mask, if possible. QFT-G was used for infection-control surveillance purposes, and a contact investigation was conducted among exposed staff, and no QFT-G conversions were noted. Risk classification: low risk.

Example G. The setting is a clinic for the care of persons infected with HIV. The clinic serves a large metropolitan area and a patient population of 2,000. The clinic has an AII room and a TB infection-control program. All patients are screened for TB disease upon enrollment, and airborne precautions are promptly initiated for anyone with respiratory complaints while the patient is being evaluated. During the preceding year, seven patients who were encountered in the clinic were subsequently determined to have TB disease. All patients were promptly put into an AII room, and no contact investigations were performed. The local health department was promptly notified in all cases. Annual TST has determined a conversion rate of 0.3%, which is low compared with the rate of the hospital with which the clinic is associated. Risk classification: medium risk (because persons infected with HIV might be encountered).

Example H. A home health-care agency employs 125 workers, many of whom perform duties, including nursing, physical therapy, and basic home care. The agency did not care for any patients with suspected or confirmed TB disease during the preceding year. Approximately 30% of the agency's workers are foreign-born, many of whom have immigrated within the previous 5 years. At baseline two-step testing, four had a positive initial TST result, and two had a positive second-step TST result. All except one of these workers was foreign-born. Upon further screening, none were determined to have TB disease. The home health-care agency is based in a major metropolitan area and delivers care to a community where the majority of persons are poor and medically underserved and TB case rates are higher than the community as a whole. Risk classification: low risk (because HCWs might be from populations at higher risk for LTBI and subsequent progression to TB disease because of foreign birth and recent immigration or HIV-infected clients might be overrepresented, medium risk could be considered).

Screening HCWs Who Transfer to Other Health-Care Settings

All HCWs should receive baseline TB screening, even in settings considered to be low risk. Infection-control plans should address HCWs who transfer from one health-care setting to another and consider that the transferring HCWs might be at an equivalent or higher risk for exposure in different settings. Infection-control plans might need to be customized to balance the assessed risks and the efficacy of the plan based on consideration of various logistical factors. Guidance is provided based on different scenarios.

Because some institutions might adopt BAMT for the purposes of testing for *M. tuberculosis* infection, infection-control programs might be confronted with interpreting historic and current TST and BAMT results when HCWs transfer to a different setting. On a case-by-case basis, expert medical opinion might be needed to interpret results and refer patients with discordant BAMT and TST baseline results. Therefore, infection-control programs should keep all records when documenting

previous test results. For example, an infection-control program using a BAMT strategy should request and keep historic TST results of a HCW transferring from a previous setting. Even if the HCW is transferring from a setting that used BAMT to a setting that uses BAMT, historic TST results might be needed when in the future the HCW transfers to a setting that uses TST. Similarly, historic BAMT results might be needed when the HCW transfers from a setting that used TST to a setting that uses BAMT.

HCWs transferring from low-risk to low-risk settings. After a baseline result for infection with *M. tuberculosis* is established and documented, serial testing for *M. tuberculosis* infection is not necessary.

HCWs transferring from low-risk to medium-risk settings. After a baseline result for infection with *M. tuberculosis* is established and documented, annual TB screening (including a symptom screen and TST or BAMT for persons with previously negative test results) should be performed.

HCWs transferring from low- or medium-risk settings to settings with a temporary classification of potential ongoing transmission. After a baseline result for infection with *M. tuberculosis* is established, a decision should be made regarding follow-up screening on an individual basis. If transmission seems to be ongoing, consider including the HCW in the screenings every 8–10 weeks until a determination has been made that ongoing transmission has ceased. When the setting is reclassified back to medium-risk, annual TB screening should be resumed.

Calculation and Use of Conversion Rates for *M. tuberculosis* Infection

The *M. tuberculosis* infection conversion rate is the percentage of HCWs whose test result for *M. tuberculosis* infection has converted within a specified period. Timely detection of *M. tuberculosis* infection in HCWs not only facilitates treatment for LTBI, but also can indicate the need for a source case investigation and a revision of the risk assessment for the setting. Conversion in test results for *M. tuberculosis*, regardless of the testing method used, is usually interpreted as presumptive evidence of new *M. tuberculosis* infection, and recent infections are associated with an increased risk for progression to TB disease.

For administrative purposes, a TST conversion is ≥ 10 mm increase in the size of the TST induration during a 2-year period in 1) an HCW with a documented negative (< 10 mm) baseline two-step TST result or 2) a person who is not an HCW with a negative (< 10 mm) TST result within 2 years.

In settings conducting serial testing for *M. tuberculosis* infection (medium-risk settings), use the following steps to estimate the risk for test conversion in HCWs.

- Calculate a conversion rate by dividing the number of conversions among HCWs in the setting in a specified period (numerator) by the number of HCWs who received tests in the setting over the same period (denominator) multiplied by 100 (see Use of Conversion Test Data for *M. tuberculosis* Infection To Identify Lapses in Infection Control).
- Identify areas or groups in the setting with a potentially high risk for *M. tuberculosis* transmission by comparing conversion rates in HCWs with potential exposure to patients with TB disease to conversion rates in HCWs for whom health-care–associated exposure to *M. tuberculosis* is not probable.

Use of Conversion Test Data for *M. tuberculosis* Infection To Identify Lapses in Infection Control

- Conversion rates above the baseline level (which will be different in each setting) should instigate an investigation to evaluate the likelihood of health-care–associated transmission. When testing for *M. tuberculosis* infection, if conversions are determined to be the result of well-documented community exposure or probable false-positive test results, then the risk classification of the setting does not need to be adjusted.
- For settings that no longer perform serial testing for *M. tuberculosis* infection among HCWs, reassessment of the risk for the setting is essential to ensure that the infection-control program is effective. The setting should have ongoing communication with the local or state health department regarding incidence and epidemiology of TB in the population served and should

ensure that timely contact investigations are performed for HCWs or patients with unprotected exposure to a person with TB disease.

Example Calculation of Conversion Rates

Medical Center A is classified as medium risk and uses TST for annual screening. At the end of 2004, a total of 10,051 persons were designated as HCWs. Of these, 9,246 had negative baseline test results for *M. tuberculosis* infection. Of the HCWs tested, 10 experienced an increase in TST result by ≥ 10 mm. The overall setting conversion rate for 2004 is 0.11%. If five of the 10 HCWs whose test results converted were among the 100 HCWs employed in the ICU of Hospital X (in Medical Center A), then the ICU setting-specific conversion rate for 2004 is 5%.

Evaluation of HCWs for LTBI should include information from a serial testing program, but this information must be interpreted as only one part of a full assessment. TST or BAMT conversion criteria for administrative (surveillance) purposes are not applicable for medical evaluation of HCWs for the diagnosis of LTBI (see Supplement, Surveillance and Detection of *M. tuberculosis* Infections in Health-Care Workers [HCWs]).

Evaluation of TB Infection-Control Procedures and Identification of Problems

Annual evaluations of the TB infection-control plan are needed to ensure the proper implementation of the plan and to recognize and correct lapses in infection control. Previous hospital admissions and outpatient visits of patients with TB disease should be noted before the onset of TB symptoms.

Medical records of a sample of patients with suspected and confirmed TB disease who were treated or examined at the setting should be reviewed to identify possible problems in TB infection control. The review should be based on the factors listed on the TB Risk Assessment Worksheet ([Appendix B](#)).

- Time interval from suspicion of TB until initiation of airborne precautions and antituberculosis treatment to:
 - suspicion of TB disease and patient triage to proper AII room or referral center for settings that do not provide care for patients with suspected or confirmed TB disease;
 - admission until TB disease was suspected;
 - admission until medical evaluation for TB disease was performed;
 - admission until specimens for AFB smears and polymerase chain reaction (PCR)–based nucleic acid amplification (NAA) tests for *M. tuberculosis* were ordered;
 - admission until specimens for mycobacterial culture were ordered;
 - ordering of AFB smears, NAA tests, and mycobacterial culture until specimens were collected;
 - collection of specimens until performance and AFB smear results were reported;
 - collection of specimens until performance and culture results were reported;
 - collection of specimens until species identification was reported;
 - collection of specimens until drug-susceptibility test results were reported;
 - admission until airborne precautions were initiated; and
 - admission until antituberculosis treatment was initiated.
- Duration of airborne precautions.
- Measurement of meeting criteria for discontinuing airborne precautions. Certain patients might be correctly discharged from an AII room to home.
- Patient history of previous admission.
- Adequacy of antituberculosis treatment regimens.
- Adequacy of procedures for collection of follow-up sputum specimens.
- Adequacy of discharge planning.
- Number of visits to outpatient setting from the start of symptoms until TB disease was suspected (for outpatient settings).

Work practices related to airborne precautions should be observed to determine if employers are enforcing all practices, if HCWs are adhering to infection-control policies, and if patient adherence to airborne precautions is being enforced. Data from the case reviews and observations in the annual risk assessment should be used to determine the need to modify 1) protocols for identifying and initiating prompt airborne precautions for patients with suspected or confirmed infectious TB disease, 2) protocols for patient management, 3) laboratory procedures, or 4) TB training and education programs for HCWs.

- Data from the most recent environmental evaluation should be reviewed to determine if recommended environmental controls are in place (see Suggested Components of an Initial TB Training and Education Program for HCWs).
- Environmental control maintenance procedures and logs should be reviewed to determine if maintenance is conducted properly and regularly.
- Environmental control design specifications should be compared with guidelines from the American Institute of Architects (AIA) and other ventilation guidelines (117,118) (see Risk Classification Examples) and the installed system performance.
- Environmental data should be used to assist building managers and engineers in evaluating the performance of the installed system.
- The number and types of aerosol-generating or aerosol-producing procedures (e.g., specimen processing and manipulation, bronchoscopy, sputum induction, and administration of aerosolized medications) performed in the setting should be assessed.
- The number of AII rooms should be suitable for the setting based on AIA Guidelines and the setting risk assessment. The Joint Commission on Accreditation of Healthcare Organizations (JCAHO) has adapted the AIA guidelines when accrediting facilities (118).

Suggested Components of an Initial TB Training and Education Program for HCWs

The following are suggested components of an initial TB training and education program:

1. Clinical Information

Basic concepts of *M. tuberculosis* transmission, pathogenesis, and diagnosis, including the difference between LTBI and TB disease and the possibility of reinfection after previous infection with *M. tuberculosis* or TB disease.

- Symptoms and signs of TB disease and the importance of a high index of suspicion for patients or HCWs with these symptoms.
- Indications for initiation of airborne precautions of inpatients with suspected or confirmed TB disease.
- Policies and indications for discontinuing airborne precautions.
- Principles of treatment for LTBI and for TB disease (indications, use, effectiveness, and potential adverse effects).

2. Epidemiology of TB

- Epidemiology of TB in the local community, the United States, and worldwide.
- Risk factors for TB disease.

3. Infection-Control Practices to Prevent and Detect *M. tuberculosis* Transmission in Health-Care Settings

- Overview of the TB infection-control program.
- Potential for occupational exposure to infectious TB disease in health-care settings.
- Principles and practices of infection control to reduce the risk for transmission of *M. tuberculosis*, including the hierarchy of TB infection-control measures, written policies and procedures, monitoring, and control measures for HCWs at increased risk for exposure to *M. tuberculosis*.
- Rationale for infection-control measures and documentation evaluating the effect of these measures in reducing occupational TB risk exposure and *M. tuberculosis* transmission.
- Reasons for testing for *M. tuberculosis* infection, importance of a positive test result for *M. tuberculosis* infection, importance of participation in a TB screening program, and importance of retaining documentation of previous test result for *M. tuberculosis* infection, chest radiograph results, and treatment for LTBI and TB disease.
- Efficacy and safety of BCG vaccination and principles of screening for *M. tuberculosis* infection and interpretation in BCG recipients.

- Procedures for investigating an *M. tuberculosis* infection test conversion or TB disease occurring in the workplace.
- Joint responsibility of HCWs and employers to ensure prompt medical evaluation after *M. tuberculosis* test conversion or development of symptoms or signs of TB disease in HCWs.
- Role of HCW in preventing transmission of *M. tuberculosis*.
- Responsibility of HCWs to promptly report a diagnosis of TB disease to the setting's administration and infection-control program.
- Responsibility of clinicians and the infection-control program to report to the state or local health department a suspected case of TB disease in a patient (including autopsy findings) or HCW.
- Responsibilities and policies of the setting, the local health department, and the state health department to ensure confidentiality for HCWs with TB disease or LTBI.
- Responsibility of the setting to inform EMS staff who transported a patient with suspected or confirmed TB disease.
- Responsibilities and policies of the setting to ensure that an HCW with TB disease is noninfectious before returning to duty.
- Importance of completing therapy for LTBI or TB disease to protect the HCW's health and to reduce the risk to others.
- Proper implementation and monitoring of environmental controls (see Environmental Controls).
- Training for safe collection, management, and disposal of clinical specimens.
- Required Occupational Safety and Health Administration (OSHA) record keeping on HCW test conversions for *M. tuberculosis* infection.
- Record-keeping and surveillance of TB cases among patients in the setting.
- Proper use of (see Respiratory Protection) and the need to inform the infection-control program of factors that might affect the efficacy of respiratory protection as required by OSHA.
- Success of adherence to infection-control practices in decreasing the risk for transmission of *M. tuberculosis* in health-care settings.

4. TB and Immunocompromising Conditions

- Relationship between infection with *M. tuberculosis* and medical conditions and treatments that can lead to impaired immunity.
- Available tests and counseling and referrals for persons with HIV infection, diabetes, and other immunocompromising conditions associated with an increased risk for progression to TB disease.
- Procedures for informing employee health or infection-control personnel of medical conditions associated with immunosuppression.
- Policies on voluntary work reassignment options for immunocompromised HCWs.
- Applicable confidentiality safeguards of the health-care setting, locality, and state.

5. TB and Public Health

- Role of the local and state health department's TB-control program in screening for LTBI and TB disease, providing treatment, conducting contact investigations and outbreak investigations, and providing education, counseling, and responses to public inquiries.
- Roles of CDC and of OSHA.
- Availability of information, advice, and counseling from community sources, including universities, local experts, and hotlines.
- Responsibility of the setting's clinicians and infection-control program to promptly report to the state or local health department a case of suspected TB disease or a cluster of TST or BAMT conversions.
- Responsibility of the setting's clinicians and infection-control program to promptly report to the state or local health department a person with suspected or confirmed TB disease who leaves the setting against medical advice.

Managing Patients Who Have Suspected or Confirmed TB Disease: General Recommendations

The primary TB risk to HCWs is the undiagnosed or unsuspected patient with infectious TB disease. A high index of suspicion for TB disease and rapid implementation of precautions are essential to

prevent and interrupt transmission. Specific precautions will vary depending on the setting.

Prompt Triage

Within health-care settings, protocols should be implemented and enforced to promptly identify, separate from others, and either transfer or manage persons who have suspected or confirmed infectious TB disease. When patients' medical histories are taken, all patients should be routinely asked about 1) a history of TB exposure, infection, or disease; 2) symptoms or signs of TB disease; and 3) medical conditions that increase their risk for TB disease (see Supplements, Diagnostic Procedures for LTBI and TB Disease; and Treatment Procedures for LTBI and TB Disease). The medical evaluation should include an interview conducted in the patient's primary language, with the assistance of a qualified medical interpreter, if necessary. HCWs who are the first point of contact should be trained to ask questions that will facilitate detection of persons who have suspected or confirmed infectious TB disease. For assistance with language interpretation, contact the local and state health department. Interpretation resources are also available (119) at <http://www.atanet.org> ; <http://www.languageine.com> ; and <http://www.ncihc.org> .

A diagnosis of respiratory TB disease should be considered for any patient with symptoms or signs of infection in the lung, pleura, or airways (including larynx), including coughing for ≥ 3 weeks, loss of appetite, unexplained weight loss, night sweats, bloody sputum or hemoptysis, hoarseness, fever, fatigue, or chest pain. The index of suspicion for TB disease will vary by geographic area and will depend on the population served by the setting. The index of suspicion should be substantially high for geographic areas and groups of patients characterized by high TB incidence (26).

Special steps should be taken in settings other than TB clinics. Patients with symptoms suggestive of undiagnosed or inadequately treated TB disease should be promptly referred so that they can receive a medical evaluation. These patients should not be kept in the setting any longer than required to arrange a referral or transfer to an AII room. While in the setting, symptomatic patients should wear a surgical or procedure mask, if possible, and should be instructed to observe strict respiratory hygiene and cough etiquette procedures (see Glossary) (120–122).

Immunocompromised persons, including those who are HIV-infected, with infectious TB disease should be physically separated from other persons to protect both themselves and others. To avoid exposing HIV-infected or otherwise severely immunocompromised persons to *M. tuberculosis*, consider location and scheduling issues to avoid exposure.

TB Airborne Precautions

Within health-care settings, TB airborne precautions should be initiated for any patient who has symptoms or signs of TB disease, or who has documented infectious TB disease and has not completed antituberculosis treatment. For patients placed in AII rooms because of suspected infectious TB disease of the lungs, airway, or larynx, airborne precautions may be discontinued when infectious TB disease is considered unlikely and either 1) another diagnosis is made that explains the clinical syndrome or 2) the patient has three consecutive, negative AFB sputum smear results (109–112,123). Each of the three sputum specimens should be collected in 8–24-hour intervals (124), and at least one specimen should be an early morning specimen because respiratory secretions pool overnight. Generally, this method will allow patients with negative sputum smear results to be released from airborne precautions in 2 days.

The classification of the risk assessment of the health-care setting is used to determine how many AII rooms each setting needs, depending on the number of TB patients examined. At least one AII room is needed for settings in which TB patients stay while they are being treated, and additional AII rooms might be needed depending on the magnitude of patient-days of persons with suspected or confirmed TB disease (118). Additional rooms might be considered if options are limited for transferring patients with suspected or confirmed TB disease to other settings with AII rooms. For example, for a hospital with 120 beds, a minimum of one AII room is needed, possibly more, depending on how many TB patients are examined in 1 year.

TB Airborne Precautions for Settings in Which Patients with Suspected or Confirmed TB Disease Are Expected To Be Encountered

Settings that plan to evaluate and manage patients with TB disease should have at least one AII room or enclosure that meets AII requirements (see Environmental Controls; and Supplement, Environmental Controls). These settings should develop written policies that specify 1) indications for airborne precautions, 2) persons authorized to initiate and discontinue airborne precautions, 3) specific airborne precautions, 4) AII room-monitoring procedures, 5) procedures for managing patients who do not adhere to airborne precautions, and 6) criteria for discontinuing airborne precautions.

A high index of suspicion should be maintained for TB disease. If a patient has suspected or confirmed TB disease, airborne precautions should be promptly initiated. Persons with suspected or confirmed TB disease who are inpatients should remain in AII rooms until they are determined to be noninfectious and have demonstrated a clinical response to a standard multidrug antituberculosis treatment regimen or until an alternative diagnosis is made. If the alternative diagnosis cannot be clearly established, even with three negative sputum smear results, empiric treatment of TB disease should strongly be considered (see Supplement, Estimating the Infectiousness of a TB Patient). Outpatients with suspected or confirmed infectious TB disease should remain in AII rooms until they are transferred or until their visit is complete.

TB Airborne Precautions for Settings in Which Patients with Suspected or Confirmed TB Disease Are Not Expected To Be Encountered

Settings in which patients with suspected or confirmed TB disease are not expected to be encountered do not need an AII room or a respiratory-protection program for the prevention of transmission of *M. tuberculosis*. However, follow these steps in these settings.

A written protocol should be developed for referring patients with suspected or confirmed TB disease to a collaborating referral setting in which the patient can be evaluated and managed properly. The referral setting should provide documentation of intent to collaborate. The protocol should be reviewed routinely and revised as needed.

Patients with suspected or confirmed TB disease should be placed in an AII room, if available, or in a room that meets the requirements for an AII room, or in a separate room with the door closed, apart from other patients and not in an open waiting area. Adequate time should elapse to ensure removal of *M. tuberculosis*–contaminated room air before allowing entry by staff or another patient ([Tables 1 and 2](#)).

If an AII room is not available, persons with suspected or confirmed infectious TB disease should wear a surgical or procedure mask, if possible. Patients should be instructed to keep the mask on and to change the mask if it becomes wet. If patients cannot tolerate a mask, they should observe strict respiratory hygiene and cough etiquette procedures.

AII Room Practices

AII rooms should be single-patient rooms in which environmental factors and entry of visitors and HCWs are controlled to minimize the transmission of *M. tuberculosis*. All HCWs who enter an AII room should wear at least N95 disposable respirators (see Respiratory Protection). Visitors may be offered respiratory protection (i.e., N95) and should be instructed by HCWs on the use of the respirator before entering an AII room. AII rooms have specific requirements for controlled ventilation, negative pressure, and air filtration (118) (see Environmental Controls). Each inpatient AII room should have a private bathroom.

Settings with AII Rooms

Health-care personnel settings with AII rooms should

- keep doors to AII rooms closed except when patients, HCWs, or others must enter or exit the room (118);

- maintain enough AII rooms to provide airborne precautions of all patients who have suspected or confirmed TB disease. Estimate the number of AII rooms needed based on the results of the risk assessment for the setting;
- monitor and record direction of airflow (i.e., negative pressure) in the room on a daily basis, while the room is being used for TB airborne precautions. Record results in an electronic or readily retrievable document;
- consider grouping AII rooms in one part of the health-care setting to limit costs, reduce the possibility of transmitting *M. tuberculosis* to other patients, facilitate the care of TB patients, and facilitate the installation and maintenance of optimal environmental controls (particularly ventilation). Depending on the architecture and the environmental control systems of a particular setting, AII rooms might be grouped either horizontally (e.g., a wing of a facility) or vertically (e.g., the last few rooms of separate floors of a facility);
- perform diagnostic and treatment procedures (e.g., sputum collection and inhalation therapy) in an AII room.
- ensure patient adherence to airborne precautions. In their primary language, with the assistance of a qualified medical interpreter, if necessary, educate patients (and family and visitors) who are placed in an AII room about *M. tuberculosis* transmission and the reasons for airborne precautions. For assistance with language interpretation, contact the local and state health department. Interpretation resources are available (119) at <http://www.atanet.org>; <http://www.languageine.com>; and <http://www.ncihc.org>. Facilitate patient adherence by using incentives (e.g., provide telephones, televisions, or radios in AII rooms; and grant special dietary requests) and other measures. Address problems that could interfere with adherence (e.g., management of withdrawal from addictive substances, including tobacco); and
- ensure that patients with suspected or confirmed infectious TB disease who must be transported to another area of the setting or to another setting for a medically essential procedure bypass the waiting area and wear a surgical or procedure mask, if possible. Drivers, HCWs, and other staff who are transporting persons with suspected or confirmed infectious TB disease might consider wearing an N95 respirator. Schedule procedures on patients with TB disease when a minimum number of HCWs and other patients are present and as the last procedure of the day to maximize the time available for removal of airborne contamination (Tables 1 and 2).

Diagnostic Procedures

Diagnostic procedures should be performed in settings with appropriate infection-control capabilities. The following recommendations should be applied for diagnosing TB disease and for evaluating patients for potential infectiousness.

Clinical Diagnosis

A complete medical history should be obtained, including symptoms of TB disease, previous TB disease and treatment, previous history of infection with *M. tuberculosis*, and previous treatment of LTBI or exposure to persons with TB disease. A physical examination should be performed, including chest radiograph, microscopic examination, culture, and, when indicated, NAA testing of sputum (39,53,125,126). If possible, sputum induction with aerosol inhalation is preferred, particularly when the patient cannot produce sputum. Gastric aspiration might be necessary for those patients, particularly children, who cannot produce sputum, even with aerosol inhalation (127–130). Bronchoscopy might be needed for specimen collection, especially if sputum specimens have been nondiagnostic and doubt exists as to the diagnosis (90,111,127,128,131–134).

All patients with suspected or confirmed infectious TB disease should be placed under airborne precautions until they have been determined to be noninfectious (see Supplement, Estimating the Infectiousness of a TB Patient). Adult and adolescent patients who might be infectious include persons who are coughing; have cavitation on chest radiograph; have positive AFB sputum smear results; have respiratory tract disease with involvement of the lung, pleura or airways, including larynx, who fail to cover the mouth and nose when coughing; are not on antituberculosis treatment or are on incorrect antituberculosis treatment; or are undergoing cough-inducing or aerosol-generating procedures (e.g., sputum induction, bronchoscopy, and airway suction) (30,135).

Persons diagnosed with extrapulmonary TB disease should be evaluated for the presence of concurrent pulmonary TB disease. An additional concern in infection control with children relates to adult household members and visitors who might be the source case (136). Pediatric patients,

including adolescents, who might be infectious include those who have extensive pulmonary or laryngeal involvement, prolonged cough, positive sputum AFB smears results, cavitary TB on chest radiograph (as is typically observed in immunocompetent adults with TB disease), or those for whom cough-inducing or aerosol-generating procedures are performed (136,137).

Although children are uncommonly infectious, pediatric patients should be evaluated for infectiousness by using the same criteria as for adults (i.e., on the basis of pulmonary or laryngeal involvement). Patients with suspected or confirmed TB disease should be immediately reported to the local public health authorities so that arrangements can be made for tracking their treatment to completion, preferably through a case management system, so that DOT can be arranged and standard procedures for identifying and evaluating TB contacts can be initiated. Coordinate efforts with the local or state health department to arrange treatment and long-term follow-up and evaluation of contacts.

Laboratory Diagnosis

To produce the highest quality laboratory results, laboratories performing mycobacteriologic tests should be skilled in both the laboratory and the administrative aspects of specimen processing. Laboratories should use or have prompt access to the most rapid methods available: 1) fluorescent microscopy and concentration for AFB smears; 2) rapid NAA testing for direct detection of *M. tuberculosis* in patient specimens (125); 3) solid and rapid broth culture methods for isolation of mycobacteria; 4) nucleic acid probes or high pressure liquid chromatography (HPLC) for species identification; and 5) rapid broth culture methods for drug susceptibility testing. Laboratories should incorporate other more rapid or sensitive tests as they become available, practical, and affordable (see Supplement, Diagnostic Procedures for LTBI and TB Disease) (138,139).

In accordance with local and state laws and regulations, a system should be in place to ensure that laboratories report any positive results from any specimens to clinicians within 24 hours of receipt of the specimen (139,140). Certain settings perform AFB smears on-site for rapid results (and results should be reported to clinicians within 24 hours) and then send specimens or cultures to a referral laboratory for identification and drug-susceptibility testing. This referral practice can speed the receipt of smear results but delay culture identification and drug-susceptibility results. Settings that cannot provide the full range of mycobacteriologic testing services should contract with their referral laboratories to ensure rapid results while maintaining proficiency for on-site testing. In addition, referral laboratories should be instructed to store isolates in case additional testing is necessary.

All drug susceptibility results on *M. tuberculosis* isolates should be reported to the local or state health department as soon as these results are available. Laboratories that rarely receive specimens for mycobacteriologic analysis should refer specimens to a laboratory that performs these tests routinely. The reference laboratory should provide rapid testing and reporting. Out-of-state reference laboratories should provide all results to the local or state health department from which the specimen originated.

Special Considerations for Persons Who Are at High Risk for TB Disease or in Whom TB Disease Might Be Difficult to Diagnose

The probability of TB disease is higher among patients who 1) previously had TB disease or were exposed to *M. tuberculosis*, 2) belong to a group at high risk for TB disease or, 3) have a positive TST or BAMT result. TB disease is strongly suggested if the diagnostic evaluation reveals symptoms or signs of TB disease, a chest radiograph consistent with TB disease, or AFB in sputum or from any other specimen. TB disease can occur simultaneously in immunocompromised persons who have pulmonary infections caused by other organisms (e.g., *Pneumocystis jirovecii* [formerly *P. carinii*] and *M. avium* complex) and should be considered in the diagnostic evaluation of all such patients with symptoms or signs of TB disease (53).

TB disease can be difficult to diagnose in persons who have HIV infection (49) (or other conditions associated with severe suppression of cell mediated immunity) because of nonclassical or normal radiographic presentation or the simultaneous occurrence of other pulmonary infections (e.g., *P.*

jaroveci or *M. avium* complex) (2). Patients who are HIV-infected are also at greater risk for having extrapulmonary TB (2). The difficulty in diagnosing TB disease in HIV-infected can be compounded by the possible lower sensitivity and specificity of sputum smear results for detecting AFB (53,141) and the overgrowth of cultures with *M. avium* complex in specimens from patients infected with both *M. tuberculosis* and *M. avium* complex. The TST in patients with advanced HIV infection is unreliable and cannot be used in clinical decision making (35,53,142).

For immunocompromised patients who have respiratory symptoms or signs that are attributed initially to infections or conditions other than TB disease, conduct an evaluation for coexisting TB disease. If the patient does not respond to recommended treatment for the presumed cause of the pulmonary abnormalities, repeat the evaluation (see Supplement, Diagnostic Procedures for LTBI and TB Disease). In certain settings in which immunocompromised patients and patients with TB disease are examined, implementing airborne precautions might be prudent for all persons at high risk. These persons include those infected with HIV who have an abnormal chest radiograph or respiratory symptoms, symptomatic foreign-born persons who have immigrated within the previous 5 years from TB-endemic countries, and persons with pulmonary infiltrates on chest radiograph, or symptoms or signs of TB disease.

Initiation of Treatment

For patients who have confirmed TB disease or who are considered highly probable to have TB disease, promptly start antituberculosis treatment in accordance with current guidelines (see Supplements, Diagnostic Procedures for LTBI and TB Disease; and Treatment Procedures for LTBI and TB Disease) (31). In accordance with local and state regulations, local health departments should be notified of all cases of suspected TB.

DOT is the standard of care for all patients with TB disease and should be used for all doses during the course of therapy for treatment of TB disease. All inpatient medication should be administered by DOT and reported to the state or local health department. Rates of relapse and development of drug-resistance are decreased when DOT is used (143–145). All patients on intermittent (i.e., once or twice per week) treatment for TB disease or LTBI should receive DOT. Settings should collaborate with the local or state health department on decisions concerning inpatient DOT and arrangements for outpatient DOT (31).

Managing Patients Who Have Suspected or Confirmed TB Disease: Considerations for Special Circumstances and Settings

The recommendations for preventing transmission of *M. tuberculosis* are applicable to all health-care settings, including those that have been described ([Appendix A](#)). These settings should each have independent risk assessments if they are stand-alone settings, or each setting should have a detailed section written as part of the risk assessment for the overall setting.

Minimum Requirements

The specific precautions for the settings included in this section vary, depending on the setting.

Inpatient Settings

Emergency Departments (EDs)

The symptoms of TB disease are usually symptoms for which patients might seek treatment in EDs. Because TB symptoms are common and nonspecific, infectious TB disease could be encountered in these settings. The use of ED-based TB screening has not been demonstrated to be consistently effective (146).

The amount of time patients with suspected or confirmed infectious TB disease spend in EDs and urgent-care settings should be minimized. Patients with suspected or confirmed infectious TB disease should be promptly identified, evaluated, and separated from other patients. Ideally, such patients should be placed in an AII room. When an AII room is not available, use a room with effective general ventilation, and use air cleaning technologies (e.g., a portable HEPA filtration system), if available, or

transfer the patient to a setting or area with recommended infection-control capacity. Facility engineering personnel with expertise in heating, ventilation, and air conditioning (HVAC) and air handlers have evaluated how this option is applied to ensure no over pressurization of return air or unwanted deviations exists in design of air flow in the zone.

EDs with a high volume of patients with suspected or confirmed TB disease should have at least one AII room (see TB Risk Assessment). Air-cleaning technologies (e.g., HEPA filtration and UVGI) can be used to increase equivalent air changes per hour (ACH) in waiting areas ([Table 1](#)). HCWs entering an AII room or any room with a patient with infectious TB disease should wear at least an N95 disposable respirator. After a patient with suspected or confirmed TB disease exits a room, allow adequate time to elapse to ensure removal of *M. tuberculosis*-contaminated room air before allowing entry by staff or another patient ([Tables 1](#) and [2](#)).

Before a patient leaves an AII room, perform an assessment of 1) the patient's need to discontinue airborne precautions, 2) the risk for transmission and the patient's ability to observe strict respiratory hygiene, and 3) cough etiquette procedures. Patients with suspected or confirmed infectious TB who are outside an AII room should wear a surgical or procedure mask, if possible. Patients who cannot tolerate masks because of medical conditions should observe strict respiratory hygiene and cough etiquette procedures.

Intensive Care Units (ICUs)

Patients with infectious TB disease might become sick enough to require admission to an ICU. Place ICU patients with suspected or confirmed infectious TB disease in an AII room, if possible. ICUs with a high volume of patients with suspected or confirmed TB disease should have at least one AII room ([Appendix B](#)). Air-cleaning technologies (e.g., HEPA filtration and UVGI) can be used to increase equivalent ACH in waiting areas (see Environmental Controls).

HCWs entering an AII room or any room with a patient with infectious TB disease should wear at least an N95 disposable respirator. To help reduce the risk for contaminating a ventilator or discharging *M. tuberculosis* into the ambient air when mechanically ventilating (i.e., with a ventilator or manual resuscitator) a patient with suspected or confirmed TB disease, place a bacterial filter on the patient's endotracheal tube (or at the expiratory side of the breathing circuit of a ventilator) (147–151). In selecting a bacterial filter, give preference to models specified by the manufacturer to filter particles 0.3 μm in size in both the unloaded and loaded states with a filter efficiency of $\geq 95\%$ (i.e., filter penetration of $< 5\%$) at the maximum design flow rates of the ventilator for the service life of the filter, as specified by the manufacturer.

Surgical Suites

Surgical suites require special infection-control considerations for preventing transmission of *M. tuberculosis*. Normally, the direction of airflow should be from the operating room (OR) to the hallway (positive pressure) to minimize contamination of the surgical field. Certain hospitals have procedure rooms with reversible airflow or pressure, whereas others have positive-pressure rooms with a negative pressure anteroom. Surgical staff, particularly those close to the surgical field, should use respiratory protection (e.g., a valveless N95 disposable respirator) to protect themselves and the patient undergoing surgery.

When possible, postpone non-urgent surgical procedures on patients with suspected or confirmed TB disease until the patient is determined to be noninfectious or determined to not have TB disease. When surgery cannot be postponed, procedures should be performed in a surgical suite with recommended ventilation controls. Procedures should be scheduled for patients with suspected or confirmed TB disease when a minimum number of HCWs and other patients are present in the surgical suite, and at the end of the day to maximize the time available for removal of airborne contamination ([Tables 1](#) and [2](#)).

If a surgical suite or an OR has an anteroom, the anteroom should be either 1) positive pressure compared with both the corridor and the suite or OR (with filtered supply air) or 2) negative pressure

compared with both the corridor and the suite or OR. In the usual design in which an OR has no anteroom, keep the doors to the OR closed, and minimize traffic into and out of the room and in the corridor. Using additional air-cleaning technologies (e.g., UVGI) should be considered to increase the equivalent ACH. Air-cleaning systems can be placed in the room or in surrounding areas to minimize contamination of the surroundings after the procedure (114) (see Environmental Controls).

Ventilation in the OR should be designed to provide a sterile environment in the surgical field while preventing contaminated air from flowing to other areas in the health-care setting. Personnel steps should be taken to reduce the risk for contaminating ventilator or anesthesia equipment or discharging tubercle bacilli into the ambient air when operating on a patient with suspected or confirmed TB disease (152). A bacterial filter should be placed on the patient's endotracheal tube (or at the expiratory side of the breathing circuit of a ventilator or anesthesia machine, if used) (147–151). When selecting a bacterial filter, give preference to models specified by the manufacturer to filter particles 0.3 μm in size in both the unloaded and loaded states with a filter efficiency of $\geq 95\%$ (i.e., filter penetration of $< 5\%$) at the maximum design flow rates of the ventilator for the service life of the filter, as specified by the manufacturer.

When surgical procedures (or other procedures that require a sterile field) are performed on patients with suspected or confirmed infectious TB, respiratory protection should be worn by HCWs to protect the sterile field from the respiratory secretions of HCWs and to protect HCWs from the infectious droplet nuclei generated from the patient. When selecting respiratory protection, do not use valved or positive-pressure respirators, because they do not protect the sterile field. A respirator with a valveless filtering facepiece (e.g., N95 disposable respirator) should be used.

Postoperative recovery of a patient with suspected or confirmed TB disease should be in an AII room in any location where the patient is recovering (118). If an AII or comparable room is not available for surgery or postoperative recovery, air-cleaning technologies (e.g., HEPA filtration and UVGI) can be used to increase the number of equivalent ACH (see Environmental Controls); however, the infection-control committee should be involved in the selection and placement of these supplemental controls.

Laboratories

Staff who work in laboratories that handle clinical specimens encounter risks not typically present in other areas of a health-care setting (153–155). Laboratories that handle TB specimens include 1) pass-through facilities that forward specimens to reference laboratories for analysis; 2) diagnostic laboratories that process specimens and perform acid-fast staining and primary culture for *M. tuberculosis*; and 3) facilities that perform extensive identification, subtyping, and susceptibility studies.

Procedures involving the manipulation of specimens or cultures containing *M. tuberculosis* introduce additional substantial risks that must be addressed in an effective TB infection-control program. Personnel who work with mycobacteriology specimens should be thoroughly trained in methods that minimize the production of aerosols and undergo periodic competency testing to include direct observation of their work practices. Risks for transmission of *M. tuberculosis* in laboratories include aerosol formation during any specimen or isolate manipulation and percutaneous inoculation from accidental exposures. Biosafety recommendations for laboratories performing diagnostic testing for TB have been published (74,75,138,156,157).

In laboratories affiliated with a health-care setting (e.g., a hospital) and in free-standing laboratories, the laboratory director, in collaboration with the infection-control staff for the setting, and in consultation with the state TB laboratory, should develop a risk-based infection-control plan for the laboratory that minimizes the risk for exposure to *M. tuberculosis*. Consider factors including 1) incidence of TB disease (including drug-resistant TB) in the community and in patients served by settings that submit specimens to the laboratory, 2) design of the laboratory, 3) level of TB diagnostic service offered, 4) number of specimens processed, and 5) whether or not aerosol-generating or aerosol-producing procedures are performed and the frequency at which they are performed. Referral laboratories should store isolates in case additional testing is necessary.

Biosafety level (BSL)-2 practices and procedures, containment equipment, and facilities are required for nonaerosol-producing manipulations of clinical specimens (e.g., preparing direct smears for acid-fast staining when done in conjunction with training and periodic checking of competency) (138). All specimens suspected of containing *M. tuberculosis* (including specimens processed for other microorganisms) should be handled in a Class I or II biological safety cabinet (BSC) (158,159). Conduct all aerosol-generating activities (e.g., inoculating culture media, setting up biochemical and antimicrobial susceptibility tests, opening centrifuge cups, and performing sonication) in a Class I or II BSC (158).

For laboratories that are considered at least medium risk ([Appendix C](#)), conduct testing for *M. tuberculosis* infection at least annually among laboratorians who perform TB diagnostics or manipulate specimens from which *M. tuberculosis* is commonly isolated (e.g., sputum, lower respiratory secretions, or tissues) ([Appendix D](#)). More frequent testing for *M. tuberculosis* is recommended in the event of a documented conversion among laboratory staff or a laboratory accident that poses a risk for exposure to *M. tuberculosis* (e.g., malfunction of a centrifuge leading to aerosolization of a sample).

Based on the risk assessment for the laboratory, employees should use personal protective equipment (including respiratory protection) recommended by local regulations for each activity. For activities that have a low risk for generating aerosols, standard personal protective equipment consists of protective laboratory coats, gowns, or smocks designed specifically for use in the laboratory. Protective garments should be left in the laboratory before going to nonlaboratory areas.

For all laboratory procedures, disposable gloves should be worn. Gloves should be disposed of when work is completed, the gloves are overtly contaminated, or the integrity of the glove is compromised. Local or state regulations should determine procedures for the disposal of gloves. Face protection (e.g., goggles, full-facepiece respirator, face shield, or other splatter guard) should also be used when manipulating specimens inside or outside a BSC. Use respiratory protection when performing procedures that can result in aerosolization outside a BSC. The minimum level of respiratory protection is an N95 filtering facepiece respirator. Laboratory workers who use respiratory protection should be provided with the same training on respirator use and care and the same fit testing as other HCWs.

After documented laboratory accidents, conduct an investigation of exposed laboratory workers. Laboratories in which specimens for mycobacteriologic studies (e.g., AFB smears and cultures) are processed should follow the AIA and CDC/National Institute of Health guidelines (118,159) (see Environmental Controls). BSL-3 practices, containment equipment, and facilities are recommended for the propagation and manipulation of cultures of *M. tuberculosis* complex (including *M. bovis*) and for animal studies in which primates that are experimentally or naturally infected with *M. tuberculosis* or *M. bovis* are used. Animal studies in which guinea pigs or mice are used can be conducted at animal BSL-2. Aerosol infection methods are recommended to be conducted at BSL-3 (159).

Bronchoscopy Suites

Because bronchoscopy is a cough-inducing procedure that might be performed on patients with suspected or confirmed TB disease, bronchoscopy suites require special attention (29,81,160,161). Bronchoscopy can result in the transmission of *M. tuberculosis* either through the airborne route (29,63,81,86,162) or a contaminated bronchoscope (80,82,163–170). Closed and effectively filtered ventilatory circuitry and minimizing opening of such circuitry in intubated and mechanically ventilated patients might minimize exposure (see Intensive Care Units) (149).

If possible, avoid bronchoscopy on patients with suspected or confirmed TB disease or postpone the procedure until the patient is determined to be noninfectious, by confirmation of the three negative AFB sputum smear results (109–112). When collection of spontaneous sputum specimen is not adequate or possible, sputum induction has been demonstrated to be equivalent to bronchoscopy for obtaining specimens for culture (110). Bronchoscopy might have the advantage of confirmation of the

diagnosis with histologic specimens, collection of additional specimens, including post bronchoscopy sputum that might increase the diagnostic yield, and the opportunity to confirm an alternate diagnosis. If the diagnosis of TB disease is suspected, consideration should be given to empiric antituberculosis treatment.

A physical examination should be performed, and a chest radiograph, microscopic examination, culture, and NAA testing of sputum or other relevant specimens should also be obtained, including gastric aspirates (125), as indicated (53,126,131,130). Because 15%–20% of patients with TB disease have negative TST results, a negative TST result is of limited value in the evaluation of the patient with suspected TB disease, particularly in patients from high TB incidence groups in whom TST positive rates exceed 30% (31).

Whenever feasible, perform bronchoscopy in a room that meets the ventilation requirements for an AII room (same as the AIA guidelines parameters for bronchoscopy rooms) (see Environmental Controls). Air-cleaning technologies (e.g., HEPA filtration and UVGI) can be used to increase equivalent ACH.

If sputum specimens must be obtained and the patient cannot produce sputum, consider sputum induction before bronchoscopy (111). In a patient who is intubated and mechanically ventilated, minimize the opening of circuitry. At least N95 respirators should be worn by HCWs while present during a bronchoscopy procedure on a patient with suspected or confirmed infectious TB disease. Because of the increased risk for *M. tuberculosis* transmission during the performance of bronchoscopy procedures on patients with TB disease, consider using a higher level of respiratory protection than an N95 disposable respirator (e.g., an elastomeric full-facepiece respirator or a powered air-purifying respirator [PAPR] [29]) (see Respiratory Protection).

After bronchoscopy is performed on a patient with suspected or confirmed infectious TB disease, allow adequate time to elapse to ensure removal of *M. tuberculosis*–contaminated room air before performing another procedure in the same room ([Tables 1](#) and [2](#)). During the period after bronchoscopy when the patient is still coughing, collect at least one sputum for AFB to increase the yield of the procedure. Patients with suspected or confirmed TB disease who are undergoing bronchoscopy should be kept in an AII room until coughing subsides.

Sputum Induction and Inhalation Therapy Rooms

Sputum induction and inhalation therapy induces coughing, which increases the potential for transmission of *M. tuberculosis* (87,88,90). Therefore, appropriate precautions should be taken when working with patients with suspected or confirmed TB disease. Sputum induction procedures for persons with suspected or confirmed TB disease should be considered after determination that self-produced sputum collection is inadequate and that the AFB smear result on other specimens collected is negative. HCWs who order or perform sputum induction or inhalation therapy in an environment without proper controls for the purpose of diagnosing conditions other than TB disease should assess the patient's risk for TB disease.

Cough-inducing or aerosol-generating procedures in patients with diagnosed TB should be conducted only after an assessment of infectiousness has been considered for each patient and should be conducted in an environment with proper controls. Sputum induction should be performed by using local exhaust ventilation (e.g., booths with special ventilation) or alternatively in a room that meets or exceeds the requirements of an AII room (see Environmental Controls) (90). At least an N95 disposable respirator should be worn by HCWs performing sputum inductions or inhalation therapy on a patient with suspected or confirmed infectious TB disease. Based on the risk assessment, consideration should be given to using a higher level of respiratory protection (e.g., an elastomeric full-facepiece respirator or a PAPR) (see Respiratory Protection) (90).

After sputum induction or inhalation therapy is performed on a patient with suspected or confirmed infectious TB disease, allow adequate time to elapse to ensure removal of *M. tuberculosis*–contaminated room air before performing another procedure in the same room ([Tables 1](#) and [2](#)).

Patients with suspected or confirmed TB disease who are undergoing sputum induction or inhalation therapy should be kept in an AII room until coughing subsides.

Autopsy Suites

Autopsies performed on bodies with suspected or confirmed TB disease can pose a high risk for transmission of *M. tuberculosis*, particularly during the performance of aerosol-generating procedures (e.g., median sternotomy). Persons who handle bodies might be at risk for transmission of *M. tuberculosis* (77,78,171–177). Because certain procedures performed as part of an autopsy might generate infectious aerosols, special airborne precautions are required.

Autopsies should not be performed on bodies with suspected or confirmed TB disease without adequate protection for those performing the autopsy procedures. Settings in which autopsies are performed should meet or exceed the requirements of an AII room, if possible (see Environmental Controls), and the drawing in the American Conference of Governmental Industrial Hygienists(r) (ACGIH) Industrial Ventilation Manual VS-99-07 (178). Air should be exhausted to the outside of the building. Air-cleaning technologies (e.g., HEPA filtration or UVGI) can be used to increase the number of equivalent ACH (see Environmental Controls).

As an added administrative measure, when performing autopsies on bodies with suspected or confirmed TB disease, coordination between attending physicians and pathologists is needed to ensure proper infection control and specimen collection. The use of local exhaust ventilation should be considered to reduce exposures to infectious aerosols (e.g., when using a saw, including Striker saw). For HCWs performing an autopsy on a body with suspected or confirmed TB disease, at least N95 disposable respirators should be worn (see Respiratory Protection). Based on the risk assessment, consider using a higher level of respiratory protection than an N95 disposable respirator (e.g., an elastomeric full-facepiece respirator or a PAPR) (see Respiratory Protection).

After an autopsy is performed on a body with suspected or confirmed TB disease, allow adequate time to elapse to ensure removal of *M. tuberculosis*–contaminated room air before performing another procedure in the same room (Tables 1 and 2). If time delay is not feasible, the autopsy staff should continue to wear respirators while they are in the room.

Embalming Rooms

Tissue or organ removal in an embalming room performed on bodies with suspected or confirmed TB disease can pose a high risk for transmission of *M. tuberculosis*, particularly during the performance of aerosol-generating procedures. Persons who handle corpses might be at risk for transmission of *M. tuberculosis* (77,78,171–176). Because certain procedures performed as part of embalming might generate infectious aerosols, special airborne precautions are required.

Embalming involving tissue or organ removal should not be performed on bodies with suspected or confirmed TB disease without adequate protection for the persons performing the procedures. Settings in which these procedures are performed should meet or exceed the requirements of an AII room, if possible (see Environmental Controls), and the drawing in the ACGIH Industrial Ventilation Manual VS-99-07 (178). Air should be exhausted to the outside of the building. Air-cleaning technologies (e.g., HEPA filtration or UVGI) can be used to increase the number of equivalent ACH (see Environmental Controls). The use of local exhaust ventilation should be considered to reduce exposures to infectious aerosols (e.g., when using a saw, including Striker saw) and vapors from embalming fluids.

When HCWs remove tissues or organs from a body with suspected or confirmed TB disease, at least N95 disposable respirators should be worn (see Respiratory Protection). Based on the risk assessment, consider using a higher level of respiratory protection than an N95 disposable respirator (e.g., an elastomeric full-facepiece respirator or a PAPR) (see Respiratory Protection).

After tissue or organ removal is performed on a body with suspected or confirmed TB disease, allow adequate time to elapse to ensure removal of *M. tuberculosis*–contaminated room air before

performing another procedure in the same room (see Environmental Controls). If time delay is not feasible, the staff should continue to wear respirators while in the room.

Outpatient Settings

Outpatient settings might include TB treatment facilities, dental-care settings, medical offices, ambulatory-care settings, and dialysis units. Environmental controls should be implemented based on the types of activities that are performed in the setting.

TB Treatment Facilities

TB treatment facilities might include TB clinics, infectious disease clinics, or pulmonary clinics. TB clinics and other settings in which patients with TB disease and LTBI are examined on a regular basis require special attention. The same principles of triage used in EDs and ambulatory-care settings (see Minimum Requirements) should be applied to TB treatment facilities. These principles include prompt identification, evaluation, and airborne precautions of patients with suspected or confirmed infectious TB disease.

All TB clinic staff, including outreach workers, should be screened for *M. tuberculosis* infection ([Appendix C](#)). Patients with suspected or confirmed infectious TB disease should be physically separated from all patients, but especially from those with HIV infection and other immunocompromising conditions that increase the likelihood of development of TB disease if infected. Immunosuppressed patients with suspected or confirmed infectious TB disease need to be physically separated from others to protect both the patient and others. Appointments should be scheduled to avoid exposing HIV-infected or otherwise severely immunocompromised persons to *M. tuberculosis*. Certain times of the day should be designated for appointments for patients with infectious TB disease or treat them in areas in which immunocompromised persons are not treated.

Persons with suspected or confirmed infectious TB disease should be promptly placed in an AII room to minimize exposure in the waiting room and other areas of the clinic, and they should be instructed to observe strict respiratory hygiene and cough etiquette procedures. Clinics that provide care for patients with suspected or confirmed infectious TB disease should have at least one AII room. The need for additional AII rooms should be based on the risk assessment for the setting.

All cough-inducing and aerosol-generating procedures should be performed using environmental controls (e.g., in a booth or an AII room) (see Environmental Controls). Patients should be left in the booth or AII room until coughing subsides. Another patient or HCW should not be allowed to enter the booth or AII room until sufficient time has elapsed for adequate removal of *M. tuberculosis*-contaminated air (see Environmental Controls). A respiratory-protection program should be implemented for all HCWs who work in the TB clinic and who enter AII rooms, visit areas in which persons with suspected or confirmed TB disease are located, or transport patients with suspected or confirmed TB disease in vehicles. When persons with suspected or confirmed infectious TB disease are in the TB clinic and not in an AII room, they should wear a surgical or procedure mask, if possible.

Medical Offices and Ambulatory-Care Settings

The symptoms of TB disease are usually symptoms for which patients might seek treatment in a medical office. Therefore, infectious TB disease could possibly be encountered in certain medical offices and ambulatory-care settings.

Because of the potential for *M. tuberculosis* transmission in medical offices and ambulatory-care settings, follow the general recommendations for management of patients with suspected or confirmed TB disease and the specific recommendations for EDs (see Intensive Care Units [ICUs]). The risk assessment may be used to determine the need for or selection of environmental controls and the frequency of testing HCWs for *M. tuberculosis* infection.

Dialysis Units

Certain patients with TB disease need chronic dialysis for treatment of ESRD (179–181). The incidence of TB disease and infection in patients with ESRD might be higher than in the general population (181–183) and might be compounded by the overlapping risks for ESRD and TB disease among patients with diabetes mellitus (39). In addition, certain dialysis patients or patients who are otherwise immunocompromised (e.g., patients with organ transplants) might be on immunosuppressive medications (162,183). Patients with ESRD who need chronic dialysis should have at least one test for *M. tuberculosis* infection to determine the need for treatment of LTBI. Annual re-screening is indicated if ongoing exposure of ESRD patients to *M. tuberculosis* is probable.

Hemodialysis procedures should be performed on hospitalized patients with suspected or confirmed TB disease in an AII room. Dialysis staff should use recommended respiratory protection, at least an N95 disposable respirator. Patients with suspected or confirmed TB disease who need chronic hemodialysis might need referral to a hospital or other setting with the ability to perform dialysis procedures in an AII room until the patient is no longer infectious or another diagnosis is made. Certain antituberculosis medications are prescribed differently for hemodialysis patients (31).

Dental-Care Settings

The generation of droplet nuclei containing *M. tuberculosis* as a result of dental procedures has not been demonstrated (184). Nonetheless, oral manipulations during dental procedures could stimulate coughing and dispersal of infectious particles. Patients and dental HCWs share the same air space for varying periods, which contributes to the potential for transmission of *M. tuberculosis* in dental settings (185). For example, during primarily routine dental procedures in a dental setting, MDR TB might have been transmitted between two dental workers (186).

To prevent the transmission of *M. tuberculosis* in dental-care settings, certain recommendations should be followed (187,188). Infection-control policies for each dental health-care setting should be developed, based on the community TB risk assessment ([Appendix B](#)), and should be reviewed annually, if possible. The policies should include appropriate screening for LTBI and TB disease for dental HCWs, education on the risk for transmission to the dental HCWs, and provisions for detection and management of patients who have suspected or confirmed TB disease.

When taking a patient's initial medical history and at periodic updates, dental HCWs should routinely document whether the patient has symptoms or signs of TB disease. If urgent dental care must be provided for a patient who has suspected or confirmed infectious TB disease, dental care should be provided in a setting that meets the requirements for an AII room (see Environmental Controls). Respiratory protection (at least N95 disposable respirator) should be used while performing procedures on such patients.

In dental health-care settings that routinely provide care to populations at high risk for TB disease, using engineering controls (e.g., portable HEPA units) similar to those used in waiting rooms or clinic areas of health-care settings with a comparable community-risk profile might be beneficial.

During clinical assessment and evaluation, a patient with suspected or confirmed TB disease should be instructed to observe strict respiratory hygiene and cough etiquette procedures (122). The patient should also wear a surgical or procedure mask, if possible. Non-urgent dental treatment should be postponed, and these patients should be promptly referred to an appropriate medical setting for evaluation of possible infectiousness. In addition, these patients should be kept in the dental health-care setting no longer than required to arrange a referral.

Nontraditional Facility-Based Settings

Nontraditional facility-based settings include EMS, medical settings in correctional facilities, home-based health-care and outreach settings, long-term-care settings (e.g., hospices and skilled nursing facilities), and homeless shelters. Environmental controls should be implemented based on the types of activities that are performed in the setting.

TB is more common in the homeless population than in the general population (189–192). Because persons who visit homeless shelters frequently share exposure and risk characteristics of TB patients

who are treated in outpatient clinics, homeless shelters with clinics should observe the same TB infection-control measures as outpatient clinics. ACET has developed recommendations to assist health-care providers, health departments, shelter operators and workers, social service agencies, and homeless persons to prevent and control TB in this population (189).

Emergency Medical Services (EMS)

Although the overall risk is low (193), documented transmission of *M. tuberculosis* has occurred in EMS occupational settings (194), and approaches to reduce this risk have been described (193,195). EMS personnel should be included in a comprehensive screening program to test for *M. tuberculosis* infection and provide baseline screening and follow-up testing as indicated by the risk classification of the setting. Persons with suspected or confirmed infectious TB disease who are transported in an ambulance should wear a surgical or procedure mask, if possible, and drivers, HCWs, and other staff who are transporting the patient might consider wearing an N95 respirator.

The ambulance ventilation system should be operated in the nonrecirculating mode, and the maximum amount of outdoor air should be provided to facilitate dilution. If the vehicle has a rear exhaust fan, use this fan during transport. If the vehicle is equipped with a supplemental recirculating ventilation unit that passes air through HEPA filters before returning it to the vehicle, use this unit to increase the number of ACH (188). Air should flow from the cab (front of vehicle), over the patient, and out the rear exhaust fan. If an ambulance is not used, the ventilation system for the vehicle should bring in as much outdoor air as possible, and the system should be set to nonrecirculating. If possible, physically isolate the cab from the rest of the vehicle, and place the patient in the rear seat (194).

EMS personnel should be included in the follow-up contact investigations of patients with infectious TB disease. The Ryan White Comprehensive AIDS Resource Emergency Act of 1990 (Public law 101–381) mandates notification of EMS personnel after they have been exposed to a patient with suspected or confirmed infectious TB disease (Title 42 U.S. Code 1994) (<http://hab.hrsa.gov/data2/adap/introduction.htm>).

Medical Settings in Correctional Facilities

TB is a substantial health concern in correctional facilities; employees and inmates are at high risk (105,196–205). TB outbreaks in correctional facilities can lead to transmission in surrounding communities (201,206,207). ACET recommends that all correctional facilities have a written TB infection-control plan (196), and multiple studies indicate that screening correctional employees and inmates is a vital TB control measure (204,208,209).

The higher risk for *M. tuberculosis* transmission in health-care settings in correctional facilities (including jails and prisons) is a result of the disproportionate number of inmates with risk factors for TB infection and TB disease (203,210). Compared with the general population, TB prevalence is higher among inmates and is associated with a higher prevalence of HIV infection (197), increased illicit substance use, lower socioeconomic status (201), and their presence in settings that are at high risk for transmission of *M. tuberculosis*.

A TB infection-control plan should be developed specifically for that setting, even if the institution is part of a multifacility system (196,211). Medical settings in correctional facilities should be classified as at least medium risk; therefore, all correctional facility health-care personnel and other staff, including correctional officers should be screened for TB at least annually (201,203,208).

Correctional facilities should collaborate with the local or state health department to decide on TB contact investigations and discharge planning (105,212) and to provide TB training and education to inmates and employees (196). Corrections staff should be educated regarding symptoms and signs of TB disease and encouraged to facilitate prompt evaluation of inmates with suspected infectious TB disease (206).

At least one AII room should be available in correctional facilities. Any inmate with suspected or confirmed infectious TB disease should be placed in an AII room immediately or transferred to a

setting with an AII room; base the number of additional AII rooms needed on the risk assessment for the setting. Sputum samples should be collected in sputum induction booths or AII rooms, not in inmates' cells. Sputum collection can also be performed safely outside, away from other persons, windows, and ventilation intakes.

Inmates with suspected or confirmed infectious TB disease who must be transported outside an AII room for medically essential procedures should wear a surgical or procedure mask during transport, if possible. If risk assessment indicates the need for respiratory protection, drivers, medical or security staff, and others who are transporting patients with suspected or confirmed infectious TB disease in an enclosed vehicle should consider wearing an N95 disposable respirator.

A respiratory-protection program, including training, education, and fit-testing in the correctional facility's TB infection-control program should be implemented. Correctional facilities should maintain a tracking system for inmate TB screening and treatment and establish a mechanism for sharing this information with state and local health departments and other correctional facilities (196,201). Confidentiality of inmates should be ensured during screening for symptoms or signs of TB disease and risk factors.

Home-Based Health-Care and Outreach Settings

Transmission of *M. tuberculosis* has been documented in staff who work in home-based health-care and outreach settings (213,214). The setting's infection-control plan should include training that reminds HCWs who provide medical services in the homes of patients or other outreach settings of the importance of early evaluation of symptoms or signs of TB disease for early detection and treatment of TB disease. Training should also include the role of the HCW in educating patients regarding the importance of reporting symptoms or signs of TB disease and the importance of reporting any adverse effects to treatment for LTBI or TB disease.

HCWs who provide medical services in the homes of patients with suspected or confirmed TB disease can help prevent transmission of *M. tuberculosis* by 1) educating patients and other household members regarding the importance of taking medications as prescribed, 2) facilitating medical evaluation of symptoms or signs of TB disease, and 3) administering DOT, including DOT for treatment of LTBI whenever feasible.

HCWs who provide medical services in the homes of patients should not perform cough-inducing or aerosol-generating procedures on patients with suspected or confirmed infectious TB disease, because recommended infection controls probably will not be in place. Sputum collection should be performed outdoors, away from other persons, windows, and ventilation intakes.

HCWs who provide medical services in the homes of patients with suspected or confirmed infectious TB disease should instruct TB patients to observe strict respiratory hygiene and cough etiquette procedures. HCWs who enter homes of persons with suspected or confirmed infectious TB disease or who transport such persons in an enclosed vehicle should consider wearing at least an N95 disposable respirator (see Respiratory Protection).

Long-Term–Care Facilities (LTCFs)

TB poses a health risk to patients, HCWs, visitors, and volunteers in LTCFs (e.g., hospices and skilled nursing facilities) (215,216). Transmission of *M. tuberculosis* has occurred in LTCF (217–220), and pulmonary TB disease has been documented in HIV-infected patients and other immunocompromised persons residing in hospices (218,221,222). New employees and residents to these settings should receive a symptom screen and possibly a test for *M. tuberculosis* infection (see TB Risk Assessment Worksheet).

LTCFs must have adequate administrative and environmental controls, including airborne precautions capabilities and a respiratory-protection program, if they accept patients with suspected or confirmed infectious TB disease. The setting should have 1) a written protocol for the early identification of patients with symptoms or signs of TB disease and 2) procedures for referring these patients to a setting where they can be evaluated and managed. Patients with suspected or confirmed

infectious TB disease should not stay in LTCFs unless adequate administrative and environmental controls and a respiratory-protection program are in place. Persons with TB disease who are determined to be noninfectious can remain in the LTCF and do not need to be in an AII room.

Training and Educating HCWs

HCW training and education regarding infection with *M. tuberculosis* and TB disease is an essential part of administrative controls in a TB surveillance or infection-control program. Training physicians and nurse managers is especially essential because of the leadership role they frequently fulfill in infection control. HCW training and education can increase adherence to TB infection-control measures. Training and education should emphasize the increased risks posed by an undiagnosed person with TB disease in a health-care setting and the specific measures to reduce this risk. HCWs receive various types of training; therefore, combining training for TB infection control with other related trainings might be preferable.

Initial TB Training and Education

The setting should document that all HCWs, including physicians, have received initial TB training relevant to their work setting and additional occupation-specific education. The level and detail of baseline training will vary according to the responsibilities of the HCW and the risk classification of the setting.

Educational materials on TB training are available from various sources at no cost in printed copy, on videotape (223), on compact discs, and the Internet. The local or state health department should have access to additional materials and resources and might be able to help develop a setting-specific TB education program. Suggested components of a baseline TB training program for HCWs have been described previously. CDC's TB website provides information regarding training and education materials (<http://www.cdc.gov/tb>). Additional training and education materials are available on CDC's TB Education and Training Resources website (<http://www.findtbresources.org>) and on other TB-related websites and resources ([Appendix E](#)).

Physicians, trainees, students, and other HCWs who work in a health-care setting but do not receive payment from that setting should receive baseline training in TB infection-control policies and practices, the TB screening program, and procedures for reporting an *M. tuberculosis* infection test conversion or diagnosis of TB disease. Initial TB training should be provided before the HCW starts working.

Follow-Up TB Training and Education

All settings should conduct an annual evaluation of the need for follow-up training and education for HCWs based on the number of untrained and new HCWs, changes in the organization and services of the setting, and availability of new TB infection-control information.

If a potential or known exposure to *M. tuberculosis* occurs in the setting, prevention and control measures should include retraining HCWs in the infection-control procedures established to prevent the recurrence of exposure. If a potential or known exposure results in a newly recognized positive TST or BAMT result, test conversion, or diagnosis of TB disease, education should include information on 1) transmission of *M. tuberculosis*, 2) noninfectiousness of HCWs with LTBI, and 3) potential infectiousness of HCWs with TB disease.

OSHA requires annual respiratory-protection training for HCWs who use respiratory devices (see Respiratory Protection). HCWs in settings with a classification of potential ongoing transmission should receive additional training and education on 1) symptoms and signs of TB disease, 2) *M. tuberculosis* transmission, 3) infection-control policies, 4) importance of TB screening for HCWs, and 5) responsibilities of employers and employees regarding *M. tuberculosis* infection test conversion and diagnosis of TB disease.

TB Infection-Control Surveillance

HCW Screening Programs for TB Support Surveillance and Clinical Care

TB screening programs provide critical information for caring for individual HCWs and information that facilitates detection of *M. tuberculosis* transmission. The screening program consists of four major components: 1) baseline testing for *M. tuberculosis* infection, 2) serial testing for *M. tuberculosis* infection, 3) serial screening for symptoms or signs of TB disease, and 4) TB training and education.

Surveillance data from HCWs can protect both HCWs and patients. Screening can prevent future transmission by identifying lapses in infection control and expediting treatment for persons with LTBI or TB disease. Tests to screen for *M. tuberculosis* infection should be administered, interpreted, and recorded according to procedures in this report (see Supplement, Diagnostic Procedures for LTBI and TB Disease). Protection of privacy and maintenance of confidentiality of HCW test results should be ensured. Methods to screen for infection with *M. tuberculosis* are available (30,31,39).

Baseline Testing for *M. tuberculosis* Infection

Baseline testing for *M. tuberculosis* infection is recommended for all newly hired HCWs, regardless of the risk classification of the setting and can be conducted with the TST or BAMT. Baseline testing is also recommended for persons who will receive serial TB screening (e.g., residents or staff of correctional facilities or LTCFs) (39,224). Certain settings, with the support of the infection-control committee, might choose not to perform baseline or serial TB screening for HCWs who will never be in contact with or have shared air space with patients who have TB disease (e.g., telephone operators who work in a separate building from patients) or who will never be in contact with clinical specimens that might contain *M. tuberculosis*.

Baseline test results 1) provide a basis for comparison in the event of a potential or known exposure to *M. tuberculosis* and 2) facilitate the detection and treatment of LTBI or TB disease in an HCW before employment begins and reduces the risk to patients and other HCWs. If TST is used for baseline testing, two-step testing is recommended for HCWs whose initial TST results are negative (39,224). If the first-step TST result is negative, the second-step TST should be administered 1–3 weeks after the first TST result was read. If either 1) the baseline first-step TST result is positive or 2) the first-step TST result is negative but the second-step TST result is positive, TB disease should be excluded, and if it is excluded, then the HCW should be evaluated for treatment of LTBI. If the first and second-step TST results are both negative, the person is classified as not infected with *M. tuberculosis*.

If the second test result of a two-step TST is not read within 48–72 hours, administer a TST as soon as possible (even if several months have elapsed) and ensure that the result is read within 48–72 hours (39). Certain studies indicate that positive TST reactions might still be measurable from 4–7 days after testing (225,226). However, if a patient fails to return within 72 hours and has a negative test result, the TST should be repeated (42).

A positive result to the second step of a baseline two-step TST is probably caused by boosting as opposed to recent infection with *M. tuberculosis*. These responses might result from remote infections with *M. tuberculosis*, infection with an NTM (also known as MOTT), or previous BCG vaccination. Two-step testing will minimize the possibility that boosting will lead to an unwarranted suspicion of transmission of *M. tuberculosis* with subsequent testing. A second TST is not needed if the HCW has a documented TST result from any time during the previous 12 months (see Baseline Testing for *M. tuberculosis* Infection After TST Within the Previous 12 Months).

A positive TST reaction as a result of BCG wanes after 5 years. Therefore, HCWs with previous BCG vaccination will frequently have a negative TST result (74,227–232). Because HCWs with a history of BCG are frequently from high TB-prevalence countries, positive test results for *M. tuberculosis* infection in HCWs with previous BCG vaccination should be interpreted as representing infection with *M. tuberculosis* (74,227–233). Although BCG reduces the occurrence of severe forms of TB disease in children and overall might reduce the risk for progression from LTBI to TB disease (234,235), BCG is not thought to prevent *M. tuberculosis* infection (236). Test results for *M. tuberculosis* infection for HCWs with a history of BCG should be interpreted by using the same diagnostic cut points used for HCWs without a history of BCG vaccination.

BAMT does not require two-step testing and is more specific than skin testing. BAMT that uses *M. tuberculosis*-specific antigens (e.g., QFT-G) are not expected to result in false-positive results in persons vaccinated with BCG. Baseline test results should be documented, preferably within 10 days of HCWs starting employment.

Baseline Testing for *M. tuberculosis* Infection After TST Within the Previous 12 Months

A second TST is not needed if the HCW has a documented TST result from any time during the previous 12 months. If a newly employed HCW has had a documented negative TST result within the previous 12 months, a single TST can be administered in the new setting ([Box 1](#)). This additional TST represents the second stage of two-step testing. The second test decreases the possibility that boosting on later testing will lead to incorrect suspicion of transmission of *M. tuberculosis* in the setting.

A recent TST (performed in ≤ 12 months) is not a contraindication to a subsequent TST unless the test was associated with severe ulceration or anaphylactic shock, which are substantially rare adverse events (30,237–239). Multiple TSTs are safe and do not increase the risk for a false-positive result or a TST conversion in persons without infection with mycobacteria (39).

Baseline Documentation of a History of TB Disease, a Previously Positive Test Result for *M. tuberculosis* Infection, or Completion of Treatment for LTBI or TB Disease

Additional tests for *M. tuberculosis* infection do not need to be performed for HCWs with a documented history of TB disease, documented previously positive test result for *M. tuberculosis* infection, or documented completion of treatment for LTBI or TB disease. Documentation of a previously positive test result for *M. tuberculosis* infection can be substituted for a baseline test result if the documentation includes a recorded TST result in millimeters (or BAMT result), including the concentration of cytokine measured (e.g., IFN- γ). All other HCWs should undergo baseline testing for *M. tuberculosis* infection to ensure that the test result on record in the setting has been performed and measured using the recommended diagnostic the recommended procedures (see Supplement, Diagnostic Procedures for LTBI and TB Disease).

A recent TST (performed in ≤ 12 months) is not a contraindication to the administration of an additional test unless the TST was associated with severe ulceration or anaphylactic shock, which are substantially rare adverse events (30,237,238). However, the recent test might complicate interpretation of subsequent test results because of the possibility of boosting.

Serial Follow-Up of TB Screening and Testing for *M. tuberculosis* Infection

The need for serial follow-up screening for groups of HCWs with negative test results for *M. tuberculosis* infection is an institutional decision that is based on the setting's risk classification. This decision and changes over time based on updated risk assessments should be official and documented. If a serial follow-up screening program is required, the risk assessment for the setting ([Appendix B](#)) will determine which HCWs should be included in the program and the frequency of screening. Two-step TST testing should not be performed for follow-up testing.

If possible, stagger follow-up screening (rather than testing all HCWs at the same time each year) so that all HCWs who work in the same area or profession are not tested in the same month. Staggered screening of HCWs (e.g., on the anniversary of their employment or on their birthdays) increases opportunities for early recognition of infection-control problems that can lead to conversions in test results for *M. tuberculosis* infection. Processing aggregate analysis of TB screening data on a periodic regular basis is important for detecting problems.

HCWs with a Newly Recognized Positive Test Result for *M. tuberculosis* Infection or Symptoms or Signs of TB Disease

Clinical Evaluation

Any HCW with a newly recognized positive test result for *M. tuberculosis* infection, test conversion, or symptoms or signs of TB disease should be promptly evaluated. The evaluation should be arranged with employee health, the local or state health department, or a personal physician. Any physicians who evaluate HCWs with suspected TB disease should be familiar with current diagnostic and therapeutic guidelines for LTBI and TB disease (31,39).

The definitions for positive test results for *M. tuberculosis* infection and test conversion in HCWs are included in this report (see Supplement, Diagnostic Procedures for LTBI and TB Disease). Symptoms of disease in the lung, pleura, or airways, and the larynx include coughing for ≥ 3 weeks, loss of appetite, unexplained weight loss, night sweats, bloody sputum or hemoptysis, hoarseness, fever, fatigue, or chest pain. The evaluation should include a clinical examination and symptom screen (a procedure used during a clinical evaluation in which patients are asked if they have experienced any symptoms or signs of TB disease), chest radiograph, and collection of sputum specimens.

If TB disease is diagnosed, begin antituberculosis treatment immediately, according to published guidelines (31). The diagnosing clinician (who might not be a physician with the institution's infection-control program) should notify the local or state health department in accordance with disease reporting laws, which generally specify a 24-hour time limit.

If TB disease is excluded, offer the HCW treatment for LTBI in accordance with published guidelines (see Supplements, Diagnostic Procedures for LTBI and TB Disease; and Treatment Procedures for LTBI and TB Disease [39,240]). If the HCW has already completed treatment for LTBI and is part of a TB screening program, instead of participating in serial skin testing, the HCW should be monitored for symptoms of TB disease and should receive any available training, which should include information on the symptoms of TB disease and instructing the HCW to report any such symptoms immediately to occupational health. In addition, annual symptom screens should be performed, which can be administered as part of other HCW screening and education efforts. Treatment for LTBI should be offered to HCWs who are eligible (39).

HCWs with a previously negative test result who have an increase of ≥ 10 mm induration when examined on follow-up testing probably have acquired *M. tuberculosis* infection and should be evaluated for TB disease. When disease is excluded, HCWs should be treated for LTBI unless medically contraindicated (39,240).

Chest Radiography

HCWs with a baseline positive or newly positive TST or BAMT result should receive one chest radiograph to exclude a diagnosis of TB disease (or an interpretable copy within a reasonable time frame, such as 6 months). After this baseline chest radiograph is performed and the result is documented, repeat radiographs are not needed unless symptoms or signs of TB disease develop or a clinician recommends a repeat chest radiograph (39,116). Instead of participating in serial testing for *M. tuberculosis* infection, HCWs with a positive test result for *M. tuberculosis* infection should receive a symptom screen. The frequency of this symptom screen should be determined by the risk classification for the setting.

Serial follow-up chest radiographs are not recommended for HCWs with documentation of a previously positive test result for *M. tuberculosis* infection, treatment for LTBI or TB disease, or for asymptomatic HCWs with negative test results for *M. tuberculosis* infection. HCWs who have a previously positive test result for *M. tuberculosis* infection and who change jobs should carry documentation of a baseline chest radiograph result (and the positive test result for *M. tuberculosis* infection) to their new employers.

Workplace Restrictions

HCWs with a baseline positive or newly positive test result for *M. tuberculosis* infection should receive one chest radiograph result to exclude TB disease (or an interpretable copy within a reasonable time frame, such as 6 months).

HCWs with confirmed infectious pulmonary, laryngeal, endobroncheal, or tracheal TB disease, or a draining TB skin lesion pose a risk to patients, HCWs, and others. Such HCWs should be excluded from the workplace and should be allowed to return to work when the following criteria have been met: 1) three consecutive sputum samples (109–112) collected in 8–24-hour intervals that are negative, with at least one sample from an early morning specimen (because respiratory secretions pool overnight); 2) the person has responded to antituberculosis treatment that will probably be effective (can be based on susceptibility results); and 3) the person is determined to be noninfectious by a physician knowledgeable and experienced in managing TB disease (see Supplements, Estimating the Infectiousness of a TB Patient; Diagnostic Procedures for LTBI and TB Disease; and Treatment Procedures for LTBI and TB Disease).

HCWs with extrapulmonary TB disease usually do not need to be excluded from the workplace as long as no involvement of the respiratory track has occurred. They can be confirmed as noninfectious and can continue to work if documented evidence is available that indicates that concurrent pulmonary TB disease has been excluded.

HCWs receiving treatment for LTBI can return to work immediately. HCWs with LTBI who cannot take or do not accept or complete a full course of treatment for LTBI should not be excluded from the workplace. They should be counseled regarding the risk for developing TB disease and instructed to report any TB symptoms immediately to the occupational health unit.

HCWs who have a documented positive TST or BAMT result and who leave employment should be counseled again, if possible, regarding the risk for developing TB disease and instructed to seek prompt evaluation with the local health department or their primary care physician if symptoms of TB disease develop. Consider mailing letters to former HCWs who have LTBI. This information should be recorded in the HCWs' employee health record when they leave employment.

Asymptomatic HCWs with a baseline positive or newly positive TST or BAMT result do not need to be excluded from the workplace. Treatment for LTBI should be considered in accordance with CDC guidelines (39).

Identification of Source Cases and Recording of Drug-Susceptibility Patterns

If an HCW experiences a conversion in a test result for *M. tuberculosis* infection, evaluate the HCW for a history of suspected or known exposure to *M. tuberculosis* to determine the potential source. When the source case is identified, also identify the drug susceptibility pattern of the *M. tuberculosis* isolate from the source. The drug-susceptibility pattern should be recorded in the HCW's medical or employee health record to guide the treatment of LTBI or TB disease, if indicated.

HCWs with Medical Conditions Associated with Increased Risk for Progression to TB Disease

In settings in which HCWs are severely immunocompromised, additional precautions must be taken. HIV infection is the highest risk factor for progression from LTBI to TB disease (22,39,42,49). Other immunocompromising conditions, including diabetes mellitus, certain cancers, and certain drug treatments, also increase the risk for rapid progression from LTBI to TB disease. TB disease can also adversely affect the clinical course of HIV infection and acquired immunodeficiency syndrome (AIDS) and can complicate HIV treatment (31,39,53).

Serial TB screening beyond that indicated by the risk classification for the setting is not indicated for persons with the majority of medical conditions that suppress the immune system or otherwise increase the risk for infection with *M. tuberculosis* progressing to TB disease (58). However, consideration should be given to repeating the TST for HIV-infected persons whose initial TST result was negative and whose immune function has improved in response to highly active antiretroviral therapy (HAART) (i.e., those whose CD4-T lymphocyte count has increased to >200 cells/mL).

All HCWs should, however, be encouraged during their initial TB training to determine if they have such a medical condition and should be aware that receiving medical treatment can improve cell-mediated immunity. HCWs should be informed concerning the availability of counseling, testing, and

referral for HIV (50,51). In addition, HCWs should know whether they are immunocompromised, and they should be aware of the risks from exposure to *M. tuberculosis* (1). In certain cases, reassignment to areas in which exposure is minimized or nonexistent might be medically advisable or desirable.

Immunocompromised HCWs should have the option of an assignment in an area or activity where the risk for exposure to *M. tuberculosis* is low. This choice is a personal decision for the immunocompromised HCW (241) (<http://www.eeoc.gov/laws/ada.html> ). Health-care settings should provide education and follow infection-control recommendations (70).

Information provided by HCWs regarding their immune status and request for voluntary work assignments should be treated confidentially, according to written procedures on the confidential handling of such information. All HCWs should be made aware of these procedures at the time of employment and during initial TB training and education.

Problem Evaluation

Contact investigations might be initiated in response to 1) conversions in test results in HCWs for *M. tuberculosis* infection, 2) diagnosis of TB disease in an HCW, 3) suspected person-to-person transmission of *M. tuberculosis*, 4) lapses in TB infection-control practices that expose HCWs and patients to *M. tuberculosis*, or 5) possible TB outbreaks identified using automated laboratory systems (242). In these situations, the objectives of a contact investigation might be to 1) determine the likelihood that transmission of *M. tuberculosis* has occurred; 2) determine the extent of *M. tuberculosis* transmission; 3) identify persons who were exposed, and, if possible, the sources of potential transmission; 4) identify factors that could have contributed to transmission, including failure of environmental infection-control measures, failure to follow infection-control procedures, or inadequacy of current measures or procedures; 5) implement recommended interventions; 6) evaluate the effectiveness of the interventions; and 7) ensure that exposure to *M. tuberculosis* has been terminated and that the conditions leading to exposure have been eliminated.

Earlier recognition of a setting in which *M. tuberculosis* transmission has occurred could be facilitated through innovative approaches to TB contact investigations (e.g., network analysis and genetic typing of isolates). Network analysis makes use of information (e.g., shared locations within a setting that might not be collected in traditional TB contact investigations) (45). This type of information might be useful during contact investigations involving hospitals or correctional settings to identify any shared wards, hospital rooms, or cells. Genotyping of isolates is universally available in the United States and is a useful adjunct in the investigation of *M. tuberculosis* transmission (44,89,243,244). Because the situations prompting an investigation are likely to vary, investigations should be tailored to the individual circumstances. Recommendations provide general guidance for conducting contact investigations (34,115).

General Recommendations for Investigating Conversions in Test Results for *M. tuberculosis* Infection in HCWs

A test conversion might need to be reported to the health department, depending on state and local regulations. Problem evaluation during contact investigations should be accomplished through cooperation between infection-control personnel, occupational health, and the local or state TB-control program. If a test conversion in an HCW is detected as a result of serial screening and the source is not apparent, conduct a source case investigation to determine the probable source and the likelihood that transmission occurred in the health-care setting (115).

Lapses in TB infection control that might have contributed to the transmission of *M. tuberculosis* should be corrected. Test conversions and TB disease among HCWs should be recorded and reported, according to OSHA requirements (<http://www.osha.gov/recordkeeping> ). Consult Recording and Reporting Occupational Injuries and Illness (OSHA standard 29 Code of Federal Regulations [CFR], 1904) to determine recording and reporting requirements (245).

Investigating Conversions in Test Results for *M. tuberculosis* Infection in HCWs: Probable Source Outside the Health-Care Setting

If a test conversion in an HCW is detected and exposure outside the health-care setting has been documented by the corresponding local or state health department, terminate the investigation within the health-care setting.

Investigating Conversions in Test Results for *M. tuberculosis* Infection in HCWs: Known Source in the Health-Care Setting

An investigation of a test conversion should be performed in collaboration with the local or state health department. If a conversion in an HCW is detected and the HCW's history does not document exposure outside the health-care setting but does identify a probable source in the setting, the following steps should be taken: 1) identify and evaluate close contacts of the suspected source case, including other patients and visitors; 2) determine possible reasons for the exposure; 3) implement interventions to correct the lapse(s) in infection control; and 4) immediately screen HCWs and patients if they were close contacts to the source case. For exposed HCWs and patients in a setting that has chosen to screen for infection with *M. tuberculosis* by using the TST, the following steps should be taken:

- administer a symptom screen;
- administer a TST to those who had previously negative TST results; baseline two-step TST should not be performed in contact investigations;
- repeat the TST and symptom screen 8–10 weeks after the end of exposure, if the initial TST result is negative (33);
- administer a symptom screen, if the baseline TST result is positive;
- promptly evaluate (including a chest radiograph) the exposed person for TB disease, if the symptom screen or the initial or 8–10-week follow-up TST result is positive; and
- conduct additional medical and diagnostic evaluation (which includes a judgment about the extent of exposure) for LTBI, if TB disease is excluded.

If no additional conversions in the test results for *M. tuberculosis* infection are detected in the follow-up testing, terminate the investigation. If additional conversions in the tests for *M. tuberculosis* infection are detected in the follow-up testing, transmission might still be occurring, and additional actions are needed: 1) implement a classification of potential ongoing transmission for the specific setting or group of HCWs; 2) the initial cluster of test conversions should be reported promptly to the local or state health department; 3) possible reasons for exposure and transmission should be reassessed and 4) the degree of adherence to the interventions implemented should be evaluated.

Testing for *M. tuberculosis* infection should be repeated 8–10 weeks after the end of exposure for HCW contacts who previously had negative test results, and the circle of contacts should be expanded to include other persons who might have been exposed. If no additional TST conversions are detected on the second round of follow-up testing, terminate the investigation. If additional TST conversions are detected on the second round of follow-up testing, maintain a classification of potential ongoing transmission and consult the local or state health department or other persons with expertise in TB infection control for assistance.

The classification of potential ongoing transmission should be used as a temporary classification only. This classification warrants immediate investigation and corrective steps. After determination has been made that ongoing transmission has ceased, the setting should be reclassified as medium risk. Maintaining the classification of medium risk for at least 1 year is recommended.

Investigating a Conversion of a Test Result for *M. tuberculosis* Infection in an HCW with an Unknown Exposure

If a test conversion in an HCW is detected and the HCW's history does not document exposure outside the health-care setting and does not identify a probable source of exposure in the setting, additional investigation to identify a probable source in the health-care setting is warranted.

If no source case is identified, estimate the interval during which the HCW might have been infected. The interval is usually 8–10 weeks before the most recent negative test result through 2 weeks before the first positive test result. Laboratory and infection-control records should be reviewed to identify

all patients (and any HCWs) who have had suspected or confirmed infectious TB disease and who might have transmitted *M. tuberculosis* to the HCW. If the investigation identifies a probable source, identify and evaluate contacts of the suspected source. Close contacts should be the highest priority for screening.

The following steps should be taken in a setting that uses TST or BAMT to screen for *M. tuberculosis*: 1) administer a symptom screen and the test routinely used in the setting (i.e., TST or BAMT) to persons who previously had negative results; 2) if the initial result is negative, the test and symptom screen should be repeated 8–10 weeks after the end of exposure; 3) if the symptom screen, the first test result, or the 8–10-week follow-up test result is positive, the presumed exposed person should be promptly evaluated for TB disease, including the use of a chest radiograph; and 4) if TB disease is excluded, additional medical and diagnostic evaluation for LTBI is needed, which includes a judgment regarding the extent of exposure (see Investigating Conversions in Test Results for *M. tuberculosis* Infection in HCWs: Known Source in the Health-Care Setting).

Investigations That Do Not Identify a Probable Source

If serial TB screening is performed in the setting, review the results of screening of other HCWs in the same area of the health-care setting or same occupational group. If serial TB screening is not performed in the setting or if insufficient numbers of recent results are available, conduct additional TB screening of other HCWs in the same area or occupational group. If the review and screening yield no additional test conversions, and no evidence to indicate health-care–associated transmission exists, then the investigation should be terminated.

Whether HCW test conversions resulted from exposure in the setting or elsewhere or whether true infection with *M. tuberculosis* has even occurred is uncertain. However, the absence of other data implicating health-care–associated transmission suggests that the conversion could have resulted from 1) unrecognized exposure to *M. tuberculosis* outside the health-care setting; 2) cross reactivity with another antigen (e.g., BCG or nontuberculous mycobacteria); or 3) errors in applying, reading, or interpreting the test result for *M. tuberculosis* infection. If the review and screening identify additional test conversions, health-care–associated transmission is more probable.

Evaluation of the patient identification process, TB infection-control policies and practices, and environmental controls to identify lapses that could have led to exposure and transmission should be conducted. If no problems are identified, a classification of potential ongoing transmission should be applied, and the local or state health department or other persons with expertise in TB infection control should be consulted for assistance. If problems are identified, implement recommended interventions and repeat testing for *M. tuberculosis* infection 8–10 weeks after the end of exposure for HCWs with negative test results. If no additional test conversions are detected in the follow-up testing, terminate the investigation.

Conversions in Test Results for *M. tuberculosis* Infection Detected in Follow-Up Testing

In follow-up testing, a classification of potential ongoing transmission should be maintained. Possible reasons for exposure and transmission should be reassessed, and the appropriateness of and degree of adherence to the interventions implemented should be evaluated. For HCWs with negative test results, repeat testing for *M. tuberculosis* infection 8–10 weeks after the end of exposure. The local or state health department or other persons with expertise in TB infection control should be consulted.

If no additional conversions are detected during the second round of follow-up testing, terminate the investigation. If additional conversions are detected, continue a classification of potential ongoing transmission and consult the local or state health department or other persons with expertise in TB infection control.

The classification of potential ongoing transmission should be used as a temporary classification only. This classification warrants immediate investigation and corrective steps. After a determination that

ongoing transmission has ceased, the setting should be reclassified as medium risk. Maintaining the classification of medium risk for at least 1 year is recommended.

Investigating a Case of TB Disease in an HCW

Occupational health services and other physicians in the setting should have procedures for immediately notifying the local administrators or infection-control personnel if an HCW is diagnosed with TB disease so that a problem evaluation can be initiated. If an HCW is diagnosed with TB disease and does not have a previously documented positive test result for *M. tuberculosis* infection, conduct an investigation to identify the probable sources and circumstances for transmission (see General Recommendations for Investigating Conversions in Test Results for *M. tuberculosis* Infection in HCWs). If an HCW is diagnosed with TB disease, regardless of previous test result status, an additional investigation must be conducted to ascertain whether the disease was transmitted from this HCW to others, including other HCWs, patients, and visitors.

The potential infectiousness of the HCW, if potentially infectious, and the probable period of infectiousness (see Contact Investigations) should be determined. For HCWs with suspected or confirmed infectious TB disease, conduct an investigation that includes 1) identification of contacts (e.g., other HCWs, patients, and visitors), 2) evaluation of contacts for LTBI and TB disease, and 3) notification of the local or state health department for consultation and investigation of community contacts who were exposed outside the health-care setting.

M. tuberculosis genotyping should be performed so that the results are promptly available. Genotyping results are useful adjuncts to epidemiologically based public health investigations of contacts and possible source cases (especially in determining the role of laboratory contamination) (89,166,243,246–261). When confidentiality laws prevent the local or state health department from communicating information regarding a patient's identity, health department staff should work with hospital staff and legal counsel, and the HCW to determine how the hospital can be notified without breaching confidentiality.

Investigating Possible Patient-to-Patient Transmission of *M. tuberculosis*

Information concerning TB cases among patients in the setting should be routinely recorded for risk classification and risk assessment purposes. Documented information by location and date should include results of sputum smear and culture, chest radiograph, drug-susceptibility testing, and adequacy of infection-control measures.

Each time a patient with suspected or confirmed TB disease is encountered in a health-care setting, an assessment of the situation should be made and the focus should be on 1) a determination of infectiousness of the patient, 2) confirmation of compliance with local public health reporting requirements (including the prompt reporting of a person with suspected TB disease as required), and 3) assessment of the adequacy of infection control.

A contact investigation should be initiated in situations where infection control is inadequate and the patient is infectious. Patients with positive AFB sputum smear results are more infectious than patients with negative AFB sputum smear results, but the possibility exists that patients with negative sputum smear results might be infectious (262). Patients with negative AFB sputum smear results but who undergo aerosol-generating or aerosol-producing procedures (including bronchoscopy) without adequate infection-control measures create a potential for exposure. All investigations should be conducted in consultation with the local public health department.

If serial surveillance of these cases reveals one of the following conditions, patient-to-patient transmission might have occurred, and a contact investigation should be initiated:

- A high proportion of patients with TB disease were admitted to or examined in the setting during the year preceding onset of their TB disease, especially when TB disease is identified in patients who were otherwise unlikely to be exposed to *M. tuberculosis*.
- An increase occurred in the number of TB patients diagnosed with drug-resistant TB, compared with the previous year.

- Isolates from multiple patients had identical and characteristic drug susceptibility or DNA fingerprint patterns.

Surveillance of TB Cases in Patients Indicates Possible Patient-to-Patient Transmission of *M. tuberculosis*

Health-care settings should collaborate with the local or state health department to conduct an investigation. For settings in which HCWs are serially tested for *M. tuberculosis* infection, review HCW records to determine whether an increase in the number of conversions in test results for *M. tuberculosis* infection has occurred. Patient surveillance data and medical records should be reviewed for additional cases of TB disease. Settings should look for possible exposures from previous or current admissions that might have exposed patients with newly diagnosed TB disease to other patients with TB disease, determining if the patients were admitted to the same room or area, or if they received the same procedure or went to the same treatment area on the same day.

If the investigation suggests that transmission has occurred, possible causes of transmission of *M. tuberculosis* (e.g., delayed diagnosis of TB disease, institutional barriers to implementing timely and correct airborne precautions, and inadequate environmental controls) should be evaluated. Possible exposure to other patients or HCWs should be determined, and if exposure has occurred, these persons should be evaluated for LTBI and TB disease (i.e., test for *M. tuberculosis* infection and administer a symptom screen).

If the local or state health department was not previously contacted, settings should notify the health department so that a community contact investigation can be initiated, if necessary. The possibility of laboratory errors in diagnosis or the contamination of bronchoscopes (82,169) or other equipment should be considered (136).

Contact Investigations

The primary goal of contact investigations is to identify secondary cases of TB disease and LTBI among contacts so that therapy can be initiated as needed (263–265). Contact investigations should be collaboratively conducted by both infection-control personnel and local TB-control program personnel.

Initiating a Contact Investigation

A contact investigation should be initiated when 1) a person with TB disease has been examined at a health-care setting, and TB disease was not diagnosed and reported quickly, resulting in failure to apply recommended TB infection controls; 2) environmental controls or other infection-control measures have malfunctioned while a person with TB disease was in the setting; or 3) an HCW develops TB disease and exposes other persons in the setting.

As soon as TB disease is diagnosed or a problem is recognized, standard public health practice should be implemented to prioritize the identification of other patients, HCWs, and visitors who might have been exposed to the index case before TB infection-control measures were correctly applied (52). Visitors of these patients might also be contacts or the source case.

The following activities should be implemented in collaboration with or by the local or state health department (34,266): 1) interview the index case and all persons who might have been exposed; 2) review the medical records of the index case; 3) determine the exposure sites (i.e., where the index case lived, worked, visited, or was hospitalized before being placed under airborne precautions); and 4) determine the infectious period of the index case, which is the period during which a person with TB disease is considered contagious and most capable of transmitting *M. tuberculosis* to others.

For programmatic purposes, for patients with positive AFB sputum smear results, the infectious period can be considered to begin 3 months before the collection date of the first positive AFB sputum smear result or the symptom onset date (whichever is earlier). The end of the infectious period is the date the patient is placed under airborne precautions or the date of collection of the first of consistently negative AFB sputum smear results (whichever is earlier). For patients with negative

AFB sputum smear results, the infectious period can begin 1 month before the symptom onset date and end when the patient is placed under airborne precautions.

The exposure period, the time during which a person shared the same air space with a person with TB disease for each contact, should be determined as well as whether transmission occurred from the index patient to persons with whom the index patient had intense contact. In addition, the following should be determined: 1) intensity of the exposure based on proximity, 2) overlap with the infectious period of the index case, 3) duration of exposure, 4) presence or absence of infection-control measures, 5) infectiousness of the index case, 6) performance of procedures that could increase the risk for transmission during contact (e.g., sputum induction, bronchoscopy, and airway suction), and 7) the exposed cohort of contacts for TB screening.

The most intensely exposed HCWs and patients should be screened as soon as possible after exposure to *M. tuberculosis* has occurred and 8–10 weeks after the end of exposure if the initial TST result is negative. Close contacts should be the highest priority for screening.

For HCWs and patients who are presumed to have been exposed in a setting that screens for infection with *M. tuberculosis* using the TST, the following activities should be implemented:

- performing a symptom screen;
- administering a TST to those who previously had negative TST results;
- repeating the TST and symptom screen 8–10 weeks after the end of exposure, if the initial TST result is negative;
- promptly evaluating the HCW for TB disease, including performing a chest radiograph, if the symptom screen or the initial or 8–10-week follow-up TST result is positive; and
- providing additional medical and diagnostic evaluation for LTBI, including determining the extent of exposure, if TB disease is excluded.

For HCWs and patients who are presumed to have been exposed in a setting that screens for infection with *M. tuberculosis* using the BAMT, the following activities should be implemented (see Supplement, Surveillance and Detection of *M. tuberculosis* Infections in Health-Care Settings). If the most intensely exposed persons have test conversions or positive test results for *M. tuberculosis* infection in the absence of a previous history of a positive test result or TB disease, expand the investigation to evaluate persons with whom the index patient had less contact. If the evaluation of the most intensely exposed contacts yields no evidence of transmission, expanding testing to others is not necessary.

Exposed persons with documented previously positive test results for *M. tuberculosis* infection do not require either repeat testing for *M. tuberculosis* infection or a chest radiograph (unless they are immunocompromised or otherwise at high risk for TB disease), but they should receive a symptom screen. If the person has symptoms of TB disease, 1) record the symptoms in the HCW's medical chart or employee health record, 2) perform a chest radiograph, 3) perform a full medical evaluation, and 4) obtain sputum samples for smear and culture, if indicated.

The setting should determine the reason(s) that a TB diagnosis or initiation of airborne precautions was delayed or procedures failed, which led to transmission of *M. tuberculosis* in the setting. Reasons and corrective actions taken should be recorded, including changes in policies, procedures, and TB training and education practices.

Collaboration with the Local or State Health Department

For assistance with the planning and implementation of TB-control activities in the health-care setting and for names of experts to help with policies, procedures, and program evaluation, settings should coordinate with the local or state TB-control program. By law, the local or state health department must be notified when TB disease is suspected or confirmed in a patient or HCW so that follow up can be arranged and a community contact investigation can be conducted. The local or state health department should be notified as early as possible before the patient is discharged to facilitate followup and continuation of therapy by DOT (31). For inpatient settings, coordinate a discharge plan

with the patient (including a patient who is an HCW with TB disease) and the TB-control program of the local or state health department.

Environmental Controls

Environmental controls are the second line of defense in the TB infection-control program, after administrative controls. Environmental controls include technologies for the removal or inactivation of airborne *M. tuberculosis*. These technologies include local exhaust ventilation, general ventilation, HEPA filtration, and UVGI. These controls help to prevent the spread and reduce the concentration of infectious droplet nuclei in the air. A summary of environmental controls and their use in prevention of transmission of *M. tuberculosis* is provided in this report (see Supplement, Environmental Controls), including detailed information concerning the application of environmental controls.

Local Exhaust Ventilation

Local exhaust ventilation is a source-control technique used for capturing airborne contaminants (e.g., infectious droplet nuclei or other infectious particles) before they are dispersed into the general environment. In local exhaust ventilation methods, external hoods, enclosing booths, and tents are used. Local exhaust ventilation (e.g., enclosed, ventilated booth) should be used for cough-inducing and aerosol-generating procedures. When local exhaust is not feasible, perform cough-inducing and aerosol-generating procedures in a room that meets the requirements for an AII room.

General Ventilation

General ventilation systems dilute and remove contaminated air and control airflow patterns in a room or setting. An engineer or other professional with expertise in ventilation should be included as part of the staff of the health-care setting or hire a consultant with expertise in ventilation engineering specific to health-care settings. Ventilation systems should be designed to meet all applicable federal, state, and local requirements.

A single-pass ventilation system is the preferred choice in areas in which infectious airborne droplet nuclei might be present (e.g., AII rooms). Use HEPA filtration if recirculation of air is necessary.

AII rooms in health-care settings pre-existing 1994 guidelines should have an airflow of ≥ 6 ACH. When feasible, the airflow should be increased to ≥ 12 ACH by 1) adjusting or modifying the ventilation system or 2) using air-cleaning methods (e.g., room-air recirculation units containing HEPA filters or UVGI systems that increase the equivalent ACH). New construction or renovation of health-care settings should be designed so that AII rooms achieve an airflow of ≥ 12 ACH. Ventilation rates for other areas in health-care settings should meet certain specifications (see Risk Classification Examples). If a variable air volume (VAV) ventilation system is used in an AII room, design the system to maintain the room under negative pressure at all times. The VAV system minimum set point must be adequate to maintain the recommended mechanical and outdoor ACH and a negative pressure ≥ 0.01 inch of water gauge compared with adjacent areas.

Based on the risk assessment for the setting, the required number of AII rooms, other negative-pressure rooms, and local exhaust devices should be determined. The location of these rooms and devices will depend partially on where recommended ventilation conditions can be achieved. Grouping AII rooms in one area might facilitate the care of patients with TB disease and the installation and maintenance of optimal environmental controls.

AII rooms should be checked for negative pressure by using smoke tubes or other visual checks before occupancy, and these rooms should be checked daily when occupied by a patient with suspected or confirmed TB disease. Design, construct, and maintain general ventilation systems so that air flows from clean to less clean (more contaminated) areas. In addition, design general ventilation systems to provide optimal airflow patterns within rooms and to prevent air stagnation or short-circuiting of air from the supply area to the exhaust area.

Health-care settings serving populations with a high prevalence of TB disease might need to improve the existing general ventilation system or use air-cleaning technologies in general-use areas (e.g., waiting rooms, EMS areas, and radiology suites). Applicable approaches include 1) single-pass,

nonrecirculating systems that exhaust air to the outside, 2) recirculation systems that pass air through HEPA filters before recirculating it to the general ventilation system, and 3) room-air recirculation units with HEPA filters and/or UVGI systems.

Air-Cleaning Methods

High-Efficiency Particulate Air (HEPA) Filters

HEPA filters can be used to filter infectious droplet nuclei from the air and must be used 1) when discharging air from local exhaust ventilation booths or enclosures directly into the surrounding room or area and 2) when discharging air from an AII room (or other negative-pressure room) into the general ventilation system (e.g., in settings in which the ventilation system or building configuration makes venting the exhaust to the outside impossible).

HEPA filters can be used to remove infectious droplet nuclei from air that is recirculated in a setting or exhausted directly to the outside. HEPA filters can also be used as a safety measure in exhaust ducts to remove droplet nuclei from air being discharged to the outside. Air can be recirculated through HEPA filters in areas in which 1) no general ventilation system is present, 2) an existing system is incapable of providing sufficient ACH, or 3) air-cleaning (particulate removal) without affecting the fresh-air supply or negative-pressure system is desired. Such uses can increase the number of equivalent ACH in the room or area.

Recirculation of HEPA filtered air can be achieved by exhausting air from the room into a duct, passing it through a HEPA filter installed in the duct, and returning it to the room or the general ventilation system. In addition, recirculation can be achieved by filtering air through HEPA recirculation systems installed on the wall or ceiling of the room or filtering air through portable room-air recirculation units.

To ensure adequate functioning, install HEPA filters carefully and maintain the filters according to the instructions of the manufacturer. Maintain written records of all prefilter and HEPA maintenance and monitoring (114). Manufacturers of room-air recirculation units should provide installation instructions and documentation of the filtration efficiency and of the overall efficiency of the unit (clean air delivery rate) in removing airborne particles from a space of a given size.

UVGI

UVGI is an air-cleaning technology that can be used in a room or corridor to irradiate the air in the upper portion of the room (upper-air irradiation) and is installed in a duct to irradiate air passing through the duct (duct irradiation) or incorporated into room air-recirculation units. UVGI can be used in ducts that recirculate air back into the same room or in ducts that exhaust air directly to the outside. However, UVGI should not be used in place of HEPA filters when discharging air from isolation booths or enclosures directly into the surrounding room or area or when discharging air from an AII room into the general ventilation system. Effective use of UVGI ensures that *M. tuberculosis*, as contained in an infectious droplet nucleus is exposed to a sufficient dose of ultraviolet-C (UV-C) radiation at 253.7 nanometers (nm) to result in inactivation. Because dose is a function of irradiance and time, the effectiveness of any application is determined by its ability to deliver sufficient irradiance for enough time to result in inactivation of the organism within the infectious droplet. Achieving a sufficient dose can be difficult for airborne inactivation because the exposure time can be substantially limited; therefore, attaining sufficient irradiance is essential.

For each system, follow design guidelines to maximize UVGI effectiveness in equivalent ACH. Because air velocity, air mixing, relative humidity, UVGI intensity, and lamp position all affect the efficacy of UVGI systems, consult a UVGI system designer before purchasing and installing a UVGI system. Experts who might be consulted include industrial hygienists, engineers, and health physicists.

To function properly and minimize potential hazards to HCWs and other room occupants, upper-air UVGI systems should be properly installed, maintained, and labeled. A person knowledgeable in the use of ultraviolet (UV) radiometers or actinometers should monitor UV irradiance levels to ensure

that exposures in the work area are within safe exposure levels. UV irradiance levels in the upper-air, where the air disinfection is occurring, should also be monitored to determine that irradiance levels are within the desired effectiveness range.

UVGI tubes should be changed and cleaned according to the instructions of the manufacturer or when irradiance measurements indicate that output is reduced below effective levels. In settings that use UVGI systems, education of HCWs should include 1) basic principles of UVGI systems (mechanism and limitations), 2) potential hazardous effects of UVGI if overexposure occurs, 3) potential for photosensitivity associated with certain medical conditions or use of certain medications, and 4) the importance of maintenance procedures and record-keeping. In settings that use UVGI systems, patients and visitors should be informed of the purpose of UVGI systems and be warned about the potential hazards and safety precautions.

Program Issues

Personnel from engineering, maintenance, safety and infection control, and environmental health should collaborate to ensure the optimal selection, installation, operation, and maintenance of environmental controls. A written maintenance plan should be developed that outlines the responsibility and authority for maintenance of the environmental controls and addresses HCW training needs. Standard operating procedures should include the notification of infection-control personnel before performing maintenance on ventilation systems servicing TB patient-care areas.

Personnel should schedule routine preventive maintenance for all components of the ventilation systems (e.g., fans, filters, ducts, supply diffusers, and exhaust grills) and air-cleaning devices. Quality control (QC) checks should be conducted to verify that environmental controls are operating as designed and that records are current. Provisions for emergency electrical power should be made so that the performance of essential environmental controls is not interrupted during a power failure.

Respiratory Protection

The first two levels of the infection-control hierarchy, administrative and environmental controls, minimize the number of areas in which exposure to *M. tuberculosis* might occur. In addition, these administrative and environmental controls also reduce, but do not eliminate, the risk in the few areas in which exposures can still occur (e.g., AII rooms and rooms where cough-inducing or aerosol-generating procedures are performed). Because persons entering these areas might be exposed to airborne *M. tuberculosis*, the third level of the hierarchy is the use of respiratory protective equipment in situations that pose a high risk for exposure (see Supplement, Respiratory Protection).

On October 17, 1997, OSHA published a proposed standard for occupational exposure to *M. tuberculosis* (267). On December 31, 2003, OSHA announced the termination of rulemaking for a TB standard (268). Previous OSHA policy permitted the use of any Part 84 particulate filter respirator for protection against TB disease (269). Respirator use for TB had been regulated by OSHA under CFR Title 29, Part 1910.139 (29CFR1910.139) (270) and compliance policy directive (CPL) 2.106 (Enforcement Procedures and Scheduling for Occupational Exposure to Tuberculosis). Respirator use for TB is regulated under the general industry standard for respiratory protection (29 CFR 1910.134, <http://www.osha.gov/SLTC/respiratoryprotection/index.html> ) (271). General information concerning respiratory protection for aerosols, including *M. tuberculosis*, has been published (272–274).

Indications for Use

Respiratory protection should be used by the following persons:

- all persons, including HCWs and visitors, entering rooms in which patients with suspected or confirmed infectious TB disease are being isolated;
- persons present during cough-inducing or aerosol-generating procedures performed on patients with suspected or confirmed infectious TB disease; and
- persons in other settings in which administrative and environmental controls probably will not protect them from inhaling infectious airborne droplet nuclei. These persons might also include persons who transport patients with suspected or confirmed infectious TB disease in vehicles

(e.g., EMS vehicles or, ideally, ambulances) and persons who provide urgent surgical or dental care to patients with suspected or confirmed infectious TB disease (see Supplement, Estimating the Infectiousness of a TB Patient).

Laboratorians conducting aerosol-producing procedures might require respiratory protection. A decision concerning use of respiratory protection in laboratories should be made on an individual basis, depending on the type of ventilation in use for the laboratory procedure and the likelihood of aerosolization of viable mycobacteria that might result from the laboratory procedure.

Respiratory-Protection Program

OSHA requires health-care settings in which HCWs use respiratory protection to develop, implement, and maintain a respiratory-protection program. All HCWs who use respiratory protection should be included in the program (see Supplement, Respiratory Protection).

Training HCWs

Annual training regarding multiple topics should be conducted for HCWs, including the nature, extent, and hazards of TB disease in the health-care setting. The training can be conducted in conjunction with other related training regarding infectious disease associated with airborne transmission. In addition, training topics should include the 1) risk assessment process and its relation to the respirator program, including signs and symbols used to indicate that respirators are required in certain areas and the reasons for using respirators; 2) environmental controls used to prevent the spread and reduce the concentration of infectious droplet nuclei; 3) selection of a particular respirator for a given hazard (see Selection of Respirators); 4) operation, capabilities, and limitations of respirators; 5) cautions regarding facial hair and respirator use (275,276); and 6) OSHA regulations regarding respirators, including assessment of employees' knowledge.

Trainees should be provided opportunities to handle and wear a respirator until they become proficient (see Fit Testing). Trainees should also be provided with 1) copies or summaries of lecture materials for use as references and 2) instructions to refer all respirator problems immediately to the respiratory program administrator.

Selection of Respirators

Respiratory protective devices used in health-care settings for protection against *M. tuberculosis* should meet the following criteria (277,278):

- certified by CDC/National Institute for Occupational Safety and Health (NIOSH) as a nonpowered particulate filter respirator (N-, R-, and P-series 95%, 99%, and 100% filtration efficiency), including disposable respirators, or PAPRs with high efficiency filters (279);
- ability to adequately fit respirator wearers (e.g., a fit factor of ≥ 100 for disposable and half facepiece respirators) who are included in a respiratory-protection program; and
- ability to fit the different facial sizes and characteristics of HCWs. (This criterion can usually be met by making respirators available in different sizes and models.)

The fit of filtering facepiece respirators varies because of different facial types and respirator characteristics (10,280–289). Assistance with selection of respirators should be obtained through consultation with respirator fit-testing experts, CDC, occupational health and infection-control professional organizations, peer-reviewed research, respirator manufacturers, and advanced respirator training courses.

Fit Testing

A fit test is used to determine which respirator fits the user adequately and to ensure that the user knows when the respirator fits properly. After a risk assessment is conducted to validate the need for respiratory protection, perform fit testing during the initial respiratory-protection program training and periodically thereafter in accordance with federal, state, and local regulations.

Fit testing provides a means to determine which respirator model and size fits the wearer best and to confirm that the wearer can don the respirator properly to achieve a good fit. Periodic fit testing of

respirators on HCWs can serve as an effective training tool in conjunction with the content included in employee training and retraining. The frequency of periodic fit testing should be determined by the occurrence of 1) risk for transmission of *M. tuberculosis*, 2) a change in facial features of the wearer, 3) medical condition that would affect respiratory function, 4) physical characteristics of respirator (despite the same model number), or 5) a change in the model or size of the assigned respirator (281).

Respirator Options: General Recommendations

In situations that require respiratory protection, the minimum respiratory protection device is a filtering facepiece (nonpowered, air-purifying, half-facepiece) respirator (e.g., an N95 disposable respirator). This CDC/NIOSH-certified respirator meets the minimum filtration performance for respiratory protection in areas in which patients with suspected or confirmed TB disease might be encountered. For situations in which the risk for exposure to *M. tuberculosis* is especially high because of cough-inducing and aerosol-generating procedures, more protective respirators might be needed (see Respirator Options: Special Circumstances).

Respirator Options: Special Circumstances

Visitors to AII rooms and other areas with patients who have suspected or confirmed infectious TB disease may be offered respirators and should be instructed by an HCW on the use of the respirator before entering an AII room (Supplement, Frequently Asked Questions [FAQs] User-Seal Check in Respiratory Protection section). Particulate respirators vary substantially by model, and fit testing is usually not easily available to visitors.

The risk assessment for the setting might identify a limited number of circumstances (e.g., bronchoscopy or autopsy on persons with suspected or confirmed TB disease and selected laboratory procedures) for which a level of respiratory protection that exceeds the minimum level provided by an N95 disposable respirator should be considered. In such circumstances, consider providing HCWs with a level of respiratory protection that both exceeds the minimum criteria and is compatible with patient care delivery. Such protection might include more protective respirators (e.g., full-facepiece respirators or PAPRs) (see Supplement, Respiratory Protection). Detailed information regarding these and other respirators has been published (272,273,278,290).

In certain settings, HCWs might be at risk for both inhalation exposure to *M. tuberculosis* and mucous membrane exposure to bloodborne pathogens. In these situations, the HCW might wear a nonfluid-resistant respirator with a full-face shield or the combination product surgical mask/N95 disposable respirator to achieve both respiratory protection and fluid protection.

When surgical procedures (or other procedures requiring a sterile field) are performed on persons with suspected or confirmed infectious TB disease, respiratory protection worn by HCWs must also protect the surgical field. The patient should be protected from the HCW's respiratory secretions and the HCW from infectious droplet nuclei that might be expelled by the patient or generated by the procedure. Respirators with exhalation valves and PAPRs do not protect the sterile field.

Settings in which patients with suspected or confirmed infectious TB disease will not be encountered do not need a respiratory-protection program for exposure to *M. tuberculosis*. However, these settings should have written protocols for the early identification of persons with symptoms or signs of TB disease and procedures for referring these patients to a setting where they can be evaluated and managed. Filtering facepiece respirators should also be available for emergency use by HCWs who might be exposed to persons with suspected or confirmed TB disease before transfer. In addition, respirators and the associated respiratory-protection program might be needed to protect HCWs from other infectious diseases or exposures to harmful vapors and gases. Their availability or projected need for other exposures should be considered in the selection of respirators for protection against TB to minimize replication of effort.

Surgical or procedure masks are designed to prevent respiratory secretions of the wearer from entering the air. To reduce the expulsion of droplet nuclei into the air, persons with suspected or confirmed TB disease should be instructed to observe respiratory hygiene and cough etiquette

procedures (122) and should wear a surgical or procedure mask, if possible, when they are not in AII rooms. These patients do not need to wear particulate respirators.

Patients with suspected or confirmed TB disease should never wear any kind of respiratory protection that has an exhalation valve. This type of respirator does not prevent droplet nuclei from being expelled into the air.

Cough-Inducing and Aerosol-Generating Procedures

General Recommendations

Procedures that involve instrumentation of the lower respiratory tract or induction of sputum can increase the likelihood that droplet nuclei will be expelled into the air. These cough-inducing procedures include endotracheal intubation, suctioning, diagnostic sputum induction, aerosol treatments (e.g., pentamidine therapy and nebulized treatments), bronchoscopy, and laryngoscopy. Gastric aspiration and nasogastric tube placement can also induce cough in certain patients. Other procedures that can generate aerosols include irrigating TB abscesses, homogenizing or lyophilizing tissue, performing autopsies on cadavers with untreated TB disease, and other processing of tissue that might contain tubercle bacilli and TB laboratory procedures.

If possible, postpone cough-inducing or aerosol-generating procedures on patients with suspected or confirmed infectious TB disease unless the procedure can be performed with recommended precautions. When a cough-inducing or aerosol-generating procedure must be performed on a patient with suspected or confirmed infectious TB disease, use a local exhaust ventilation device (e.g., booth or special enclosure). If using this device is not feasible, perform the procedure in a room that meets the ventilation requirements for an AII room.

After completion of cough-inducing procedures, keep patients in the AII room or enclosure until coughing subsides. Patients should be given tissues and instructed to cover the mouth and nose with tissues when coughing. Tissues should be disposed of in accordance with the infection-control plan.

Before the booth, enclosure, or room is used for another patient, allow enough time for the removal of $\geq 99\%$ of airborne contaminants. This interval will vary based on the efficiency of the ventilation or filtration system ([Table 1](#)).

For postoperative recovery, do not place the patient in a recovery room with other patients; place the patient in a room that meets the ventilation requirements for an AII room. If the room does not meet the ventilation requirements for an AII room, air-cleaning technologies (e.g., HEPA filtration and UVGI) can be used to increase the number of equivalent ACH (see Supplement, Environmental Controls).

Perform all manipulations of suspected or confirmed *M. tuberculosis* specimens that might generate aerosols in a BSC. When in rooms or enclosures in which cough-inducing or aerosol-generating procedures are being performed, respiratory protection should be worn.

Special Considerations for Bronchoscopy

Bronchoscopy can result in the transmission of *M. tuberculosis* either through the airborne route (63,81,86,162) or a contaminated bronchoscope (80,82,163–169). Whenever feasible, perform bronchoscopy in a room that meets the ventilation requirements for an AII room (see Supplement, Environmental Controls). Air-cleaning technologies can be used to increase equivalent ACH. If a bronchoscopy must be performed in a positive-pressure room (e.g., OR), exclude TB disease before performing the procedure. Examine three spontaneous or induced sputum specimens for AFB (if possible) to exclude a diagnosis of TB disease before bronchoscopy is considered as a diagnostic procedure (110,291).

In a patient who is intubated and mechanically ventilated, minimize the opening of circuitry. For HCWs present during bronchoscopic procedures on patients with suspected or confirmed TB disease, a respirator with a level of protection of at least an N95 disposable respirator should be worn.

Protection greater than an N95 disposable respirator (e.g., a full-facepiece elastomeric respirator or PAPR) should be considered.

Special Considerations for Administration of Aerosolized Pentamidine and Other Medications

Patients receiving aerosolized pentamidine (or other aerosolized medications) who are immunocompromised and have a confirmed or suspected pulmonary infection (i.e., pneumocystis pneumonia [PCP] or pneumonia caused by *P. jaroveci*, formerly *P. carinii*) are also at risk for TB disease. Patients receiving other aerosolized medications might have an immunocompromising condition that puts them at greater risk for TB disease. Patients should be screened for TB disease before initiating prophylaxis with aerosolized pentamidine; a medical history, test for infection with *M. tuberculosis*, and a chest radiograph should be performed.

Before each subsequent treatment with aerosolized pentamidine, screen patients for symptoms or signs of TB disease. If symptoms or signs are present, evaluate the patient for TB disease. Patients with suspected or confirmed TB disease should be administered oral prophylaxis for *P. jaroveci* instead of aerosolized pentamidine if clinically practical. Patients receiving other aerosolized medication might have immunocompromising conditions; therefore, if warranted, they should be similarly screened and evaluated, and treatment with oral medications should be considered.

Supplements

Estimating the Infectiousness of a TB Patient

General Principles

Transmission of *M. tuberculosis* is most likely to result from exposure to persons who have 1) unsuspected pulmonary TB disease and are not receiving antituberculosis treatment, 2) diagnosed TB disease and are receiving inadequate therapy, or 3) diagnosed TB disease and are early in the course of effective therapy. Administration of effective antituberculosis treatment has been associated with decreased infectiousness among persons who have TB disease (292). Effective treatment reduces coughing, the amount of sputum produced, the number of organisms in the sputum, and the viability of the organisms in the sputum. However, the duration of therapy required to decrease or eliminate infectiousness varies (293). Certain TB patients are never infectious, whereas those with unrecognized or inadequately treated drug-resistant TB disease might remain infectious for weeks or months (2,3,87,94,162,294–297). In one study, 17% of transmission occurred from persons with negative AFB smear results (262). Rapid laboratory methods, including PCR-based techniques, can decrease diagnostic delay and reduce the duration of infectiousness (298).

The infectiousness of patients with TB correlates with the number of organisms they expel into the air (299). The number of organisms expelled are related to the following factors: 1) presence of cough lasting ≥ 3 weeks; 2) cavitation on chest radiograph; 3) positive AFB sputum smear result; 4) respiratory tract disease with involvement of the lung or airways, including larynx; 5) failure to cover the mouth and nose when coughing; 6) lack of, incorrect, or short duration of antituberculosis treatment (300); or 7) undergoing cough-inducing or aerosol-generating procedures (e.g., sputum induction, bronchoscopy, and airway suction). Closed and effectively filtered ventilatory circuitry and minimized opening of such circuitry in intubated and mechanically ventilated patients might minimize exposure (see Intensive Care Units [ICUs]).

Persons with extrapulmonary TB disease usually are not infectious unless they have concomitant pulmonary disease, nonpulmonary disease located in the oral cavity or the larynx, or extrapulmonary disease that includes an open abscess or lesion in which the concentration of organisms is high, especially if drainage from the abscess or lesion is extensive, or if aerosolization of drainage fluid is performed (69,72,77,83,301). Persons with TB pleural effusions might also have concurrent unsuspected pulmonary or laryngeal TB disease. These patients should be considered infectious until pulmonary TB disease is excluded. Patients with suspected TB pleural effusions or extrapulmonary TB disease should be considered pulmonary TB suspects until concomitant pulmonary disease is excluded (302).

Although children with TB disease usually are less likely than adults to be infectious, transmission from young children can occur (135,137). Therefore, children and adolescents with TB disease should be evaluated for infectiousness by using the majority of the same criteria as for adults. These criteria include presence of cough lasting ≥ 3 weeks; cavitation on chest radiograph; or respiratory tract disease with involvement of lungs, airways, or larynx. Infectiousness would be increased if the patient were on nonstandard or short duration of antituberculosis treatment (300) or undergoing cough-inducing or aerosol-generating procedures (e.g., sputum induction, bronchoscopy, and airway suction). Although gastric lavage is useful in the diagnosis of pediatric TB disease, the grade of the positive AFB smear result does not correlate with infectiousness. Pediatric patients who might be infectious include those who are not on antituberculosis treatment, who have just been started on treatment or are on inadequate treatment, and who have extensive pulmonary or laryngeal involvement (i.e., coughing ≥ 3 weeks, cavitary TB disease, positive AFB sputum smear results, or undergoing cough-inducing or aerosol-generating procedures). Children who have typical primary TB lesions on chest radiograph and do not have any of these indicators of infectiousness might not need to be placed in an AII room.

No data exist on the transmission of *M. tuberculosis* and its association with the collection of gastric aspirate specimens. Children who do not have predictors for infectiousness do not need to have gastric aspirates obtained in an AII room or other special enclosure; however, the procedure should not be performed in an area in which persons infected with HIV might be exposed. Because the source case for pediatric TB patients might be a member of the infected child's family, parents and other visitors of all hospitalized pediatric TB patients should be screened for TB disease as soon as possible to ensure that they do not become sources of health-care–associated transmission of *M. tuberculosis* (303–306).

Patients who have suspected or confirmed TB disease and who are not on antituberculosis treatment usually should be considered infectious if characteristics include

- presence of cough;
- cavitation on chest radiograph;
- positive AFB sputum smear result;
- respiratory tract disease with involvement of the lung or airways, including larynx;
- failure to cover the mouth and nose when coughing; and
- undergoing cough-inducing or aerosol-generating procedures (e.g., sputum induction, bronchoscopy, and airway suction).

If a patient with one or more of these characteristics is on standard multidrug therapy with documented clinical improvement usually in connection with smear conversion over multiple weeks, the risk for infectiousness is reduced.

Suspected TB Disease

For patients placed under airborne precautions because of suspected infectious TB disease of the lungs, airway, or larynx, airborne precautions can be discontinued when infectious TB disease is considered unlikely and either 1) another diagnosis is made that explains the clinical syndrome or 2) the patient has three negative AFB sputum smear results (109–112). Each of the three consecutive sputum specimens should be collected in 8–24-hour intervals (124), and at least one specimen should be an early morning specimen because respiratory secretions pool overnight. Generally, this method will allow patients with negative sputum smear results to be released from airborne precautions in 2 days.

Hospitalized patients for whom the suspicion of TB disease remains after the collection of three negative AFB sputum smear results should not be released from airborne precautions until they are on standard multidrug antituberculosis treatment and are clinically improving. If the patient is believed to not have TB disease because of an alternate diagnosis or because clinical information is not consistent with TB disease, airborne precautions may be discontinued. Therefore, a patient suspected of having TB disease of the lung, airway, or larynx who is symptomatic with cough and not

responding clinically to antituberculosis treatment should not be released from an AII room into a non-AII room, and additional sputum specimens should be collected for AFB examination until three negative AFB sputum smear results are obtained (30,31). Additional diagnostic approaches might need to be considered (e.g., sputum induction) and, after sufficient time on treatment, bronchoscopy.

Confirmed TB Disease

A patient who has drug-susceptible TB of the lung, airway, or larynx, who is on standard multidrug antituberculosis treatment, and who has had a substantial clinical and bacteriologic response to therapy (i.e., reduction in cough, resolution of fever, and progressively decreasing quantity of AFB on smear result) is probably no longer infectious. However, because culture and drug-susceptibility results are not usually known when the decision to discontinue airborne precautions is made, all patients with suspected TB disease should remain under airborne precautions while they are hospitalized until they have had three consecutive negative AFB sputum smear results, each collected in 8–24-hour intervals, with at least one being an early morning specimen; have received standard multidrug antituberculosis treatment (minimum of 2 weeks); and have demonstrated clinical improvement.

Discharge to Home of Patients with Suspected or Confirmed TB Disease

If a hospitalized patient who has suspected or confirmed TB disease is deemed medically stable (including patients with positive AFB sputum smear results indicating pulmonary TB disease), the patient can be discharged from the hospital before converting the positive AFB sputum smear results to negative AFB sputum smear results, if the following parameters have been met:

- a specific plan exists for follow-up care with the local TB-control program;
- the patient has been started on a standard multidrug antituberculosis treatment regimen, and DOT has been arranged;
- no infants and children aged <4 years or persons with immunocompromising conditions are present in the household;
- all immunocompetent household members have been previously exposed to the patient; and
- the patient is willing to not travel outside of the home except for health-care–associated visits until the patient has negative sputum smear results.

Patients with suspected or confirmed infectious TB disease should not be released to health-care settings or homes in which the patient can expose others who are at high risk for progressing to TB disease if infected (e.g., persons infected with HIV or infants and children aged <4 years). Coordination with the local health department TB program is indicated in such circumstances.

Drug-Resistant TB Disease

Because the consequences of transmission of MDR TB are severe, certain infection-control practitioners might choose to keep persons with suspected or confirmed MDR TB disease under airborne precautions during the entire hospitalization or until culture conversion is documented, regardless of sputum smear results. The role of drug resistance in transmission is complex. Transmission of drug-resistant organisms to persons with and without HIV infection has been documented (54,307–309). In certain cases, transmission from patients with TB disease caused by drug-resistant organisms might be extensive because of prolonged infectiousness as a result of delays in diagnosis and delays in initiation of effective therapy (53,94,98,101,255,310,311).

HIV-Associated TB Disease

Although multiple TB outbreaks among HIV-infected persons have been reported (51,52,99), the risk for transmission does not appear to be increased from patients with TB disease and HIV infection, compared with TB patients without HIV infection (54,312–315). Whether persons infected with HIV are more likely to be infected with *M. tuberculosis* if exposed is unclear; however, after infected with *M. tuberculosis*, the risk for progression to TB disease in persons infected with HIV is high (316). Progression to TB disease can be rapid, as soon as 1 month after exposure (51,53,54,101).

Diagnostic Procedures for LTBI and TB Disease

LTBI is a condition that develops after exposure to a person with infectious TB disease, and subsequent infection with *M. tuberculosis* occurs where the bacilli are alive but inactive in the body. Persons who have LTBI but who do not have TB disease are asymptomatic (i.e., have no symptoms), do not feel sick, and cannot spread TB to other persons.

Use of QFT-G for Diagnosing *M. tuberculosis* Infections in Health-Care Workers (HCWs)

In the United States, LTBI has been traditionally diagnosed based on a positive TST result after TB disease has been excluded. In vitro cytokine-based immunoassays for the detection of *M. tuberculosis* infection have been the focus of intense research and development. This document uses the term "BAMT" to refer to blood assay for *M. tuberculosis* infection currently available in the United States.

One such BAMT is QFT (which is PPD-based) and the subsequently developed version, QFT-G. QFT-G measures cell-mediated immune responses to peptides representative of two *M. tuberculosis* proteins that are not present in any BCG vaccine strain and are absent from the majority of nontuberculosis mycobacteria. This assay was approved by FDA in 2005 and is an available option for detecting *M. tuberculosis* infection. CDC recommendations for the United States on QFT and QFT-G have been published (35).

QFT-G is an in vitro test based on measuring interferon-gamma (IFN- γ) released in heparinized whole blood when incubated overnight with mitogen (serving as a positive control), Nil (i.e., all reagents except antigens, which sets a baseline), and peptide simulating ESAT-6 (6-kDa early secretory antigenic target) and CFP-10 (10-kDa culture filtrate protein) (measured independently), two different proteins with similar amino acid sequences specific for *M. tuberculosis* (Box 2). The sequences of ESAT-6 and CFP-10 are not related to each other. The genes encoding these two proteins are usually found next to each other in an operon (i.e., are coexpressed and translated from an mRNA product containing both genes). Although mycobacterial genomes contain multiple copies of each family, QFT-G and Elispot detect immunoreactivity associated only with the ESAT-6 protein and CFP-10 protein encoded by the genes in the region of deletion (RD1). In addition, virulence attributes are associated with the RD1 genes only and not the other homologues.

Specific antigens of these two proteins are found in *M. tuberculosis*–complex organisms (i.e., *M. tuberculosis*, *M. bovis*, *M. africanum*, *M. microti*, *M. canetti*, *M. caprae*, and *M. pinnipedii*), but not in the majority of other mycobacteria or in vaccine-variant *M. bovis*, BCG. Lymphocytes from the majority of persons who have been infected by *M. tuberculosis* complex indicate their sensitivity to ESAT-6 or CFP-10 by releasing IFN- γ , whereas infection by the majority of other mycobacteria, including BCG, does not appear to cause this sensitivity.

The blood tests using IFN- γ methods require one less patient visit, assess responsiveness to *M. tuberculosis* antigens, and do not boost anamnestic immune responses. Interpretation of the BAMT result is less subjective than interpretation of a skin test result, and the BAMT result might be affected less by previous BCG vaccination and sensitization to environmental mycobacteria (e.g., *M. avium* complex) than the PPD-based TST. BAMT might be more efficient and cost effective than TST (35). Screening programs that use BAMT might eliminate the need for two-step testing because this test does not boost sensitization.

Other cytokine-based immunoassays are under development and might be useful in the diagnosis of *M. tuberculosis* infection. Future FDA-approved products, in combination with CDC-issued recommendations, might provide additional diagnostic alternatives. For guidance on the use of these and related technologies, CDC plans to periodically publish recommendations on the diagnosis of *M. tuberculosis* infection. BAMT can be used in both testing and infection-control surveillance programs for HCWs.

Use of Tuberculin Skin Test (TST) for Diagnosing *M. tuberculosis* Infections in HCWs

The TST is frequently the first step of a TB diagnostic evaluation that might lead to diagnosing LTBI. Although currently available preparations of PPD used in TST are <100% sensitive and specific for the detection of LTBI, the TST is currently the most widely used diagnostic test for *M. tuberculosis* infection in the United States. The TST is less sensitive in patients who have TB disease.

The TST, like all medical tests, is subject to variability (74,228,317), but many of the inherent variations in administering and reading TST results can be avoided by training and attention to detail (318). Details of TST administration and TST result reading procedures are suggested in this report to improve the technical aspects of TST placement and reading, thus reducing observer variations and improving test reliability ([Appendix F](#)). These checklists were developed for the National Health and Nutrition Examination Survey (NHANES) to standardize TST placement and reading for research purposes. The suggested TST training recommendations are not mandatory.

Adherence to TST

Operational policies, procedures, and practices at health-care settings can enhance HCW adherence to serial TST. In 2002, one focus group study identified potential barriers and facilitators to adherence with routine TST (319). HCWs identified structural factors (e.g., inconvenient TST screening schedules and locations and long waiting times) that negatively affected adherence. Facilitators to help HCWs adhere to routine TST included active follow-up by supervisors and occupational health staff and work-site visits for TST screening. Misinformation and stigma concerning TB also emerged in the discussions, indicating the need for additional training and education for HCWs.

Administering the TST

For each patient, a risk assessment should be conducted that takes into consideration recent exposure to *M. tuberculosis*, clinical conditions that increase risk for TB disease if infected, and the program's capacity to deliver treatment for LTBI to determine if the TST should be administered.

The recommended method for TST is the Mantoux method ([Appendix F](#)) (223,318,320–322). Mantoux TST training materials supporting the guidance in this report are available at <http://www.cdc.gov/tb> (223,318,320–325). Multipuncture tests (e.g., Tine(r) tests) are not as reliable as the Mantoux method of skin testing and should not be used as a diagnostic test in the United States (30). Contact the state and local health department for TST resources.

Reading the TST Result

The TST result should be read by a designated, trained HCW 48–72 hours after the TST is placed (39,326,327). If the TST was not read between 48–72 hours, ideally, another TST should be placed as soon as possible and read within 48–72 hours (39). Certain studies indicate that positive TST reactions might still be measurable from 4–7 days after testing (225,226,328). However, if a patient fails to return within 72 hours and has a negative test result, the TST should be repeated (42). Patients and HCWs should not be allowed to read their own TST results. HCWs do not typically measure their own TST results reliably (48).

Reading the TST result consists of first determining the presence or absence of induration (hard, dense, and raised formation) and, if induration is present, measuring the diameter of induration transverse (perpendicular) to the long axis of the forearm ([Figure 1](#)) (39,318). Erythema or redness of the skin should not be considered when reading a TST result ([Appendix F](#)).

Interpreting TST Results

The positive-predictive value of a TST is the probability that a person with a positive TST result is actually infected with *M. tuberculosis*. The positive predictive value is dependent on the prevalence of infection with *M. tuberculosis* in the population being tested and the sensitivity and specificity of the test (228,329,330).

In populations with a low prevalence of *M. tuberculosis* infection, the probability that a positive TST result represents true infection with *M. tuberculosis* can be substantially low, especially if the cut

point is set too low (i.e., the test is not adequately specific and a low prevalence exists in the population). In populations with a high prevalence of infection with *M. tuberculosis* and inadequate test specificity, the probability that a positive TST result using the same cut point represents true infection with *M. tuberculosis* is much higher.

Interpreting TST Results in HCWs

TST result interpretation depends on two factors: 1) measured TST induration in millimeters and 2) the person's risk for being infected with *M. tuberculosis* and risk for progression to TB disease if infected.

Interpretations of TST and QFT results vary according to the purpose of testing ([Box 3](#)). A TST result with no induration (0 mm) or a measured induration below the defined cut point for each category is considered to signify absence of infection with *M. tuberculosis*.

In the context of TST screening as part of a TB infection-control program, the interpretation of TST results occurs in two distinct parts. The first is the interpretation by standard criteria, without regard to personal risk factors or setting-specific factors of the TST results for infection control, surveillance, and referral purposes. The second is the interpretation by individualized criteria to determine the need for treatment of LTBI.

Determining the need for treatment of LTBI is a subsequent and separate task. For infection-control and surveillance purposes, TST results should be interpreted and recorded under strict criteria, without considering setting-based or personal risk factors (see Supplement, Diagnostic Procedures for LTBI and TB Disease). Any HCW with a positive TST result from serial TB screening should be referred to a medical provider for an evaluation and to determine the need for treatment of LTBI based on individual risk ([Box 3](#)).

Interpreting the TST Result for Infection Control and Surveillance

On baseline TST testing, a TST result of ≥ 10 mm is considered positive for the majority of HCWs, and a TST result of ≥ 5 mm is considered positive for HCWs who are infected with HIV or who have other immunocompromising conditions ([Box 3](#)). All HCWs with positive baseline TST results should be referred for medical and diagnostic evaluation; additional skin testing does not need to be performed.

On serial screening for the purposes of infection-control surveillance, TST results indicating an increase of ≥ 10 mm within 2 years should be interpreted and recorded as a TST conversion. For the purposes of assessing and monitoring infection control, TST conversion rates should be regularly determined. Health-care settings with a substantial number of HCWs to be tested might have systems in place that can accurately determine the TST conversion rate every month (e.g., from among a group of HCWs tested annually), whereas smaller settings might have imprecise estimates of their TST conversion rate even with annual assessments.

The precision of the setting's TST conversion rate and any analysis assessing change from baseline TST results will depend on the number and frequency of HCWs tested. These factors should be considered when establishing a regular interval for TB screening for HCWs.

After a known exposure in a health-care setting, close HCW contacts who have TST results of ≥ 5 mm should be considered to have positive TST results, which should be interpreted as new infections only in HCWs whose previous TST result is 0 mm. However, HCWs 1) with a baseline or follow-up TST result of > 0 mm but < 10 mm with a health-care-associated exposure to *M. tuberculosis* and 2) who then have an increase of ≥ 10 mm should be considered to have a TST conversion because of a new infection ([Box 3](#)).

In a contact investigation, a follow-up TST should be administered 8–10 weeks after the end of exposure (rather than 1–3 weeks later, as in two-step testing). In this instance, a change from a negative TST result to a positive TST result should not be interpreted as a boosted reaction. The change in the TST result indicates a TST conversion, recent exposure, transmission, and infection.

All HCWs who are immunocompromised should be referred for a medical and diagnostic evaluation for any TST result of ≥ 5 mm on baseline or follow-up screening. Because infection-control staff will usually not know the immune status of the HCWs being tested, HCWs who have TST results of 5–9 mm should be advised that such results can be an indication for referral for medical evaluation for HCWs who have HIV infection or other causes of severe immunosuppression.

After an HCW has met criteria for a positive TST result, including HCWs who will not receive treatment for LTBI, repeat TSTs are not necessary because the results would not provide any additional information (30). This approach applies to HCWs who have positive TST results but who will not receive treatment for LTBI after medical evaluation. For future TB screening in settings that are medium risk, instead of participating in serial skin testing, the HCW should receive a medical evaluation and a symptom screen annually.

Interpreting the TST Result for Medical and Diagnostic Referral and Evaluation

HCWs who have positive TST results and who meet the criteria for referral should have a medical and diagnostic evaluation. For HCWs who are at low risk (e.g., those from low-incidence settings), a baseline result of ≥ 15 mm of induration (instead of ≥ 10 mm) might possibly be the cut point. The criteria used to determine the need for treatment of LTBI has been presented.

When making decisions for the diagnosis and treatment of LTBI, setting-based risk factors (e.g., the prevalence of TB disease and personal risk factors such as having an immunocompromising condition or known contact with a TB case) should be assessed when choosing the cut point for a positive TST result. The medical evaluation can occur in different settings, including an occupational health clinic, local or state health department, or private medical clinic.

When 15 mm is used as the cut point, TST results of 10–14 mm can be considered clinically negative (331). These HCWs should not have repeat TST, and the referring physician might not recommend treatment for LTBI. This issue of false-positive TST results might be especially true in areas of the country where the prevalence of infection with NTM is high.

HCWs who have TST results of 5–9 mm on baseline two-step testing should be advised that such results might be an indication for treatment of LTBI if the HCW is a contact of a person with infectious TB disease, has HIV infection, or has other causes of severe immunosuppression (e.g., organ transplant and receipt of the equivalent of ≥ 15 mg/day of prednisone for ≥ 1 month). The risk for TB disease in persons treated with corticosteroids increases with higher dose and longer duration of corticosteroid use. TNF- α antagonists also substantially increase the risk for progression to TB disease in persons with LTBI (332).

HCWs with negative baseline two-step TST results who are referred for medical evaluation for an increase of ≥ 10 mm induration on follow-up TST screening, including those who are otherwise at low risk for TB disease, probably acquired *M. tuberculosis* infection since receiving the previous TST and should be evaluated for TB disease. If disease is excluded, the HCW should be offered treatment for LTBI if they have no contraindication to treatment.

QC Program for Techniques for TST Administration and Reading TST Results

Random variation (i.e., differences in procedural techniques) in TST administration and reading TST results can cause false-positive or false-negative TST results. Many of the variations in administering and reading TST results can be avoided by conducting training and maintaining attention to details. HCWs who are responsible for TST procedures should be trained to reduce variation by following standardized operational procedures and should be observed by an expert TST trainer. All TST procedures (i.e., administering, reading, and recording the results) should be supervised and controlled to detect and correct variation. Corrective actions might include coaching and demonstration by the TST trainer. Annual re-training is recommended for HCWs responsible for administering and reading TST results.

One strategy to identify TST procedure variation is to use a QC tool ([Appendix F](#)). The expert TST trainer should observe the procedures and indicate procedural variation on the observation checklists. An expert trainer includes persons who have documented training experience.

QC for Administering TST by the Mantoux Method

Ideally, the TST trainer should participate in QC TST administrations with other TST trainers to maintain TST trainer certification. State regulations specify who is qualified to administer the test by injection. The TST trainer should first ensure antigen stability by maintaining the manufacturer's recommended cold chain (i.e., controlling antigen exposure to heat and light from the time it is out of refrigeration until the time it is placed back into refrigeration or until the vial is empty or expired). The TST trainer should prevent infection during an injection by preparing the skin and preventing contamination of solution, needle, and syringe.

The TST trainer should prevent antigen administration errors by controlling the five rights of administration: 1) right antigen; 2) right dose; 3) right patient; 4) right route; and 5) right time for TST administration, reading, and clinical evaluation (333). Finally, the TST trainer should observe and coach the HCW trainee in administering multiple intradermal injections by the Mantoux method. The TST trainer should record procedural variation on the observation checklist ([Appendix F](#)). TST training and coaching should continue until more than 10 correct skin test placements (i.e., ≥ 6 mm wheal) are achieved.

For training purposes, normal saline for injection can be used instead of PPD for intradermal injections. Volunteers are usually other HCWs who agree to be tested. Attempt to recruit volunteers who have known positive TST results so the trainees can practice reading positive TST results. A previous TST is not a contraindication to a subsequent TST unless the test was associated with severe ulceration or anaphylactic shock, which are substantially rare adverse events (30,237,238).

Model TST Training Program

A model TST training program for placing TST and reading TST results has been produced by NHANES (326). The number of hours, sessions, and blinded independent duplicate reading (BIDR) readings should be determined by the setting's TB risk assessment. The following information can be useful for a model TST training program. The suggested TST training recommendations are not mandatory.

Initial training for a TST placer ideally consists of three components.

- Introductory lecture and demonstration by an expert TST placer or trainer. An expert TST trainer is a qualified HCW who has received training on administering multiple TST and reading multiple TST results (consider 3 hours of lecture).
- Supervised practical work using procedural checklists observed and coached by the expert TST trainer ([Appendix F](#)) (consider 9 hours of practical work).
- Administration of more than 10 total skin tests on volunteers by using injectable saline and producing more than 10 wheals that measure 6–10 mm.

TST training should include supervised TST administration, which is a procedure in which an expert TST trainer supervises a TST trainee during all steps on the procedural observation checklist for TST administration ([Appendix F](#)). Wheal size should be checked for all supervised TST administrations, and skin tests should be repeated if wheal size is inadequate (i.e., < 6 mm). TST training and coaching should continue until more than 10 correct skin test placements (i.e., ≥ 6 mm wheal) are achieved.

QC for Reading TST Results by the Palpation Method

The TST trainer should participate in QC readings with other TST trainers to maintain TST trainer certification. When training HCWs to read TST results, providing measurable TST responses is helpful (i.e., attempt to recruit volunteers who have known positive TST results so that the trainees can practice reading positive TST results).

TST readers should correctly read both measurable (>0 mm) and nonmeasurable responses (0 mm) (e.g., consider reading more than 20 TST results [at least 10 measurable and at least 10 nonmeasurable], if possible). The TST trainer should observe and coach the HCW in reading multiple TST results by the Palpation method and should record procedure variation on the observation checklist ([Appendix F](#)).

The TST trainer should conduct BIDRs for comparison with the HCW's reading. BIDRs are performed when two or more consecutive TST readers immediately measure the same TST result by standard procedures, without consulting or observing one another's readings, and record results independently (may use recommended procedural observation checklist; [Appendix F](#)). BIDRs help ensure that TST readers continue to read TST results correctly.

Initial training for a TST reader ideally should consist of multiple components.

- Receiving an introductory lecture and demonstration by an expert TST reader. Training materials are available from CDC (223,318) and CDC-sponsored Regional Model and Training Centers and should also be available at the local or state health department (consider 6 hours for lecture and demonstration).
- Receiving four sessions of supervised practical work using procedural checklists (observed and coached by an expert TST reader) (consider 16 hours of practical work).
- Performing BIDR readings (consider more than 80, if possible). TST trainers should attempt to organize the sessions so that at least 50% of the TST results read have a result of >0 mm according to the expert TST reader.
- Performing BIDR readings on the last day of TST training (consider more than 30 BIDR readings out of the total 80 readings, if possible). TST trainers should attempt to ensure that at least 25% of persons tested have a TST result of >0 mm, according to the expert TST reader.
- Missing no more than two items on the procedural observation checklist ([Appendix F](#)) for three random observations by an expert TST reader.
- Performing all procedures on the checklist correctly during the final observation.

TST training and coaching should continue until the HCW is able to perform all procedures correctly and until a satisfactory measurement is achieved (i.e., the trainer and the trainee read the TST results within 2 mm of each other). For example, if the trainer reads the TST result as 11 mm (this might be considered the gold standard reading), the trainee's reading should be between 9–13 mm to be considered correct. Only a single measurement in millimeters should be recorded (not 11 mm x 11 mm or 11 mm x 15 mm). QC Procedural Observation Checklists ([Appendix F](#)) are recommended by CDC as a tool for use during TST training.

Special Considerations in TST

Anergy. The absence of a reaction to a TST does not exclude a diagnosis of TB disease or infection with *M. tuberculosis*. In immunocompromised persons, delayed-type hypersensitivity (DTH) responses (e.g., tuberculin reactions) can decrease or disappear more rapidly, and a limited number of otherwise healthy persons apparently are incapable of reacting to tuberculin even after diagnosed infection with *M. tuberculosis*. This condition, called anergy, can be caused by multiple factors (e.g., advanced HIV infection, measles infection, sarcoidosis, poor nutrition, certain medications, vaccinations, TB disease itself, and other factors) (307,334–338). However, anergy testing in conjunction with TB skin testing is no longer recommended routinely for screening for *M. tuberculosis* infection (336).

Reconstitution of DTH in HIV-infected persons taking antiretroviral therapy (ART). In one prospective study (340), TB patients who initially had negative TST results had positive TST results after initiation of HAART. HCWs must be aware of the potential public health and clinical implications of restored TST reactivity among persons who have not been diagnosed with TB disease but who might have LTBI. After the initiation of HAART repeat testing for infection with *M. tuberculosis* is recommended for HIV-infected persons previously known to have negative TST results (58). Recommendations on the prevention and treatment of TB in HIV-infected persons have been published (39,53,240).

Pregnancy. Tens of thousands of pregnant women have received TST since the test was developed, and no documented episodes of TST-related fetal harm have been reported (341). No evidence exists that the TST has adverse effects on the pregnant mother or fetus (39). Pregnant HCWs should be included in serial skin testing as part of an infection-control program or a contact investigation because no contraindication for skin testing exists (342). Guidelines issued by the American College of Obstetricians and Gynecologists (ACOG) emphasize that postponement of the diagnosis of infection with *M. tuberculosis* during pregnancy is unacceptable (343).

Booster phenomenon and two-step testing. In certain persons with LTBI, the DTH responsible for TST reactions wanes over time. Repeated TST can elicit a reaction called boosting in which an initial TST result is negative, but a subsequent TST result is positive. For example, a TST administered years after infection with *M. tuberculosis* can produce a false-negative result. This TST might stimulate (or boost) the person's ability to react to tuberculin, resulting in a positive result to a subsequent test (including the second step of a two-step procedure) (36,74,316,342,343). With serial testing, a boosted reaction on a subsequent TST might be misinterpreted as a newly acquired infection, compared with the false-negative result from the initial TST. Misinterpretation of a boosted reaction as a new infection with *M. tuberculosis* or TST conversion might prompt unnecessary investigations to find the source case, unnecessary treatment for the person tested, and unnecessary testing of other HCWs. The booster phenomenon can occur in anyone, but it is more likely to occur in older persons, persons with remote infection with *M. tuberculosis* (i.e., infected years ago), persons infected with NTM, and persons with previous BCG vaccination (39,229,234,344,345).

All newly employed HCWs who will be screened with TST should receive baseline two-step TST upon hire, unless they have documentation of either a positive TST result or treatment for LTBI or TB disease (39,224). Any setting might have HCWs at risk for boosting, and a rate of boosting even as low as 1% can result in unnecessary investigation of transmission. Therefore, two-step TSTs are needed to establish a baseline for persons who will receive serial TST (e.g., residents or staff of correctional facilities or LTCFs). This procedure is especially important for settings that are classified as low risk where testing is indicated only upon exposure. A reliable baseline test result is necessary to detect health-care–associated transmission of *M. tuberculosis*. Guidance for baseline TST for HCWs is included in this report ([Box 3](#)). To estimate the frequency of boosting in a particular setting, a four-appointment schedule of TST administration and reading (i.e., appointments for TST administration and reading both TST results) is necessary, rather than the three-appointment schedule (i.e., appointments for the administration of both tests, with reading of the second-step TST result only) ([196](#)).

Two-step testing should be used only for baseline screening, not in contact investigations. In a contact investigation, for persons with a negative TST, a follow-up test should be administered 8–10 weeks after the end of exposure (rather than 1–3 weeks later, as in a two-step TST). In this instance, a change from a negative to a positive TST result suggests that recent exposure, transmission, and infection occurred and should not be interpreted as a boosted response.

After a known exposure in a health-care setting (close contact to a patient or HCW with infectious TB disease), TST results of ≥ 5 mm should be considered positive and interpreted as a new infection in HCWs whose previous TST result is 0 mm. If an HCW has a baseline or follow-up TST result of >0 mm but ≤ 10 mm, a health-care–associated exposure to *M. tuberculosis*, and an increase in the TST size of ≥ 10 mm, the result should be interpreted as the HCW having a TST conversion because of new infection.

BCG vaccination. In the United States, vaccination with BCG is not recommended routinely for anyone, including HCWs or children ([227](#)). Previous BCG vaccination is not a contraindication to having a TST or two-step skin testing administered. HCWs with previous BCG vaccination should receive baseline and serial skin testing in the same manner as those without BCG vaccination ([233](#)) ([Box 1](#)).

Previous BCG vaccination can lead to boosting in baseline two-step testing in certain persons (74,231,344–346). Distinguishing a boosted TST reaction resulting from BCG vaccination (a false-

positive TST result) and a TST result because of previous infection with *M. tuberculosis* (true positive TST result) is not possible (39). Infection-control programs should refer HCWs with positive TST results for medical evaluation as soon as possible ([Box 3](#)).

Previous BCG vaccination increases the probability of a boosted reaction that will probably be uncovered on initial two-step skin testing. For an HCW with a negative baseline two-step TST result who is a known contact of a patient who has suspected or confirmed infectious TB disease, treatment for LTBI should be considered if the follow-up TST result is ≥ 5 mm, regardless of BCG vaccination status.

PPD preparations for diagnosing infection with *M. tuberculosis*. Two PPD preparations are available in the United States: Tubersol(r) (Aventis Pasteur, Switzwater, Pennsylvania) (237) and APLISOL(r) (Parkdale Pharmaceuticals, Rochester, Michigan) (238). Compared with the U.S. reference PPD, no difference exists in TST interpretation between the two preparations (347). However, when Tubersol and Aplisol were compared with each other, a slight difference in reactivity was observed. Aplisol produced slightly larger reactions than Tubersol, but this difference was not statistically significant (347). The difference in specificity, 98% versus 99%, is limited. However, when applied in large institutional settings that test thousands of workers annually who are at low risk for infection with *M. tuberculosis*, this difference in specificity might affect the rate of positive TST results observed.

TB screening programs should use one antigen consistently and should realize that changes in products might make serial changes in TST results difficult to interpret. In one report, systematic changes in product use resulted in a cluster of pseudoconversions that were believed to have erroneously indicated a health-care-associated outbreak (348). Persons responsible for making decisions about the choice of pharmacy products should seek advice from the local or state health department's TB infection-control program before switching PPD preparations and should inform program staff of any changes.

Chest Radiography

Chest radiographic abnormalities can suggest pulmonary TB disease. Radiographic abnormalities that are consistent with pulmonary TB disease include upper-lobe infiltration, cavitation, and effusion. Infiltrates can be patchy or nodular and observed in the apical (in the top part of the lungs) or subapical posterior upper lobes or superior segment of the lower lobes in the lungs. HCWs who have positive test results for *M. tuberculosis* infection or symptoms or signs of TB disease, regardless of test results for *M. tuberculosis* infection, should have a chest radiograph performed to exclude a diagnosis of TB disease. However, a chest radiograph is not a substitute for tests for *M. tuberculosis* infection in a serial TB screening program for HCWs.

Persons who have LTBI or cured TB disease should not have repeat chest radiographs performed routinely (116). Repeat radiographs are not needed unless symptoms or signs of TB disease develop or a clinician recommends a repeat chest radiograph (39,116).

A chest radiograph to exclude pulmonary TB disease is indicated for all persons being considered for treatment of LTBI. If chest radiographs do not indicate pulmonary TB and if no symptoms or signs of TB disease are present, persons with a positive test result for infection with *M. tuberculosis* might be candidates for treatment of LTBI. In persons with LTBI, the chest radiograph is usually normal, although it might demonstrate abnormalities consistent with previous healed TB disease or other pulmonary conditions. In patients with symptoms or signs of TB disease, pulmonary infiltrates might only be apparent on a computed tomography (CT) scan. Previous, healed TB disease can produce radiographic findings that might differ from those associated with current TB disease, although a substantial overlap might exist. These findings include nodules, fibrotic scars, calcified granulomas, or basal pleural thickening. Nodules and fibrotic scars might contain slowly multiplying tubercle bacilli and pose a high risk for progression to TB disease. Calcified nodular lesions (calcified granulomas) and apical pleural thickening pose a lower risk for progression to TB disease (31).

Chest Radiography and Pregnancy

Because TB disease is dangerous to both mother and fetus, pregnant women who have a positive TST result or who are suspected of having TB disease, as indicated by symptoms or other concerns, should receive chest radiographs (with shielding consistent with safety guidelines) as soon as feasible, even during the first trimester of pregnancy (31,39,341).

Chest Radiography and HIV-Infected Persons

The radiographic presentation of pulmonary TB in persons infected with HIV might be apical; however, apical cavitary disease is less common among such patients. More common chest radiograph findings for HIV-infected persons are infiltrates in any lung zone, mediastinal or hilar adenopathy, or, occasionally, a normal chest radiograph. Typical and cavitary lesions are usually observed in patients with higher CD4 counts, and more atypical patterns are observed in patients with lower CD4 counts (31,49,94,142,349–354). In patients with symptoms and signs of TB, a negative chest radiograph result does not exclude TB. Such patients might be candidates for airborne precautions during medical evaluation.

Evaluation of Sputum Samples

Sputum examination is a critical diagnostic procedure for pulmonary TB disease (30) and is indicated for the following persons:

- anyone suspected of having pulmonary or laryngeal TB disease;
- persons with chest radiograph findings consistent with TB disease (current, previous, or healed TB);
- persons with symptoms of infection in the lung, pleura, or airways, including larynx;
- HIV-infected persons with any respiratory symptoms or signs, regardless of chest radiograph findings; and
- persons suspected of having pulmonary TB disease for whom bronchoscopy is planned.

Sputum Specimen Collection

Persons requiring sputum collection for smear and culture should have at least three consecutive sputum specimens obtained, each collected in 8–24-hours intervals (124), with at least one being an early morning specimen (355). Specimens should be collected in a sputum induction booth or in an AII room. In resource-limited settings without environmental containment or when an AII room is not available, sputum collection can be performed safely outside of a building, away from other persons, windows, and ventilation intakes. Patients should be instructed on how to produce an adequate sputum specimen (containing little saliva) and should be supervised and observed by an HCW during the collection of sputum, if possible (30). If the patient's specimen is determined to be inadequate, it should still be sent for bacteriologic testing, although the inadequate nature of the specimen should be recorded. The HCW should wear an N95 disposable respirator during sputum collection.

Sputum Induction

For patients who are unable to produce an adequate sputum specimen, expectoration can be induced by inhalation of an aerosol of warm, hypertonic saline. Because sputum induction is a cough-inducing procedure, pre-treatment with a bronchodilator should be considered in patients with a history of asthma or other chronic obstructive airway diseases. Medical assistance and bronchodilator medication should be available during any sputum induction in the event of induced bronchospasm (109,356,357).

The patient should be seated in a small, well-ventilated sputum induction booth or in an AII room (see Environmental Controls; and Supplement, Environmental Controls). For best results, an ultrasonic nebulizer that generates an aerosol of approximately 5 mL/minute should be used. A 3% hypertonic saline is commercially available, and its safety has been demonstrated. At least 30 mL of 3% saline should be administered; administration of smaller volumes will have a lower yield. Higher concentrations can be used with an adjustment in the dose and closer monitoring for adverse effects.

Patients should be instructed to breathe deeply and cough intermittently. Sputum induction should be continued for up to 15 minutes or until an adequate specimen (containing little saliva) is produced. Induced sputum will often be clear and watery. Any expectorated material produced should be labeled as expectorated sputum and sent to the laboratory.

Laboratory Examination

Detection of AFB in stained smears by microscopy can provide the first bacteriologic indication of TB disease. Laboratories should report any positive smear results within 24 hours of receipt of the specimen (30). A positive result for AFB in a sputum smear is predictive of increased infectiousness. Smears allow presumptive detection of mycobacteria, but definitive identification, strain typing, and drug-susceptibility testing of *M. tuberculosis* require that a culture be performed (30). Negative AFB sputum smear results do not exclude a diagnosis of TB disease, especially if clinical suspicion of disease is high. In the United States, approximately 63% of patients with reported positive sputum culture results have positive AFB sputum smear results (26).

A culture of sputum or other clinical specimen that contains *M. tuberculosis* provides a definitive diagnosis of TB disease. In the majority of cases, identification of *M. tuberculosis* and drug-susceptibility results are available within 28 days (or 4–6 weeks) when recommended rapid methods such as liquid culture and DNA probes are used. Negative culture results are obtained in approximately 14% of patients with confirmed pulmonary TB disease (4,5). Testing sputum with rapid techniques (e.g., NAA) facilitates the rapid detection and identification of *M. tuberculosis* but should not replace culture and drug-susceptibility testing in patients with suspected TB disease (30,125,358). Mixed mycobacterial infection can obscure the identification of *M. tuberculosis* during the laboratory evaluation (e.g., because of cross-contamination or dual infections) and can be distinguished by the use of mycobacterial species-specific DNA probes (359). Examination of colony morphology on solid culture media can also be useful.

Drug-susceptibility tests should be performed on initial isolates from all patients to assist in identifying an effective antituberculosis treatment regimen. Drug-susceptibility tests should be repeated if sputum specimens continue to be culture-positive after 3 months of antituberculosis treatment or if culture results become positive for *M. tuberculosis* after a period of negative culture results (30,31).

Bronchoscopy

If possible, bronchoscopy should be avoided in patients with a clinical syndrome consistent with pulmonary or laryngeal TB disease because bronchoscopy substantially increases the risk for transmission either through an airborne route (63,80,81,162,360) or a contaminated bronchoscope (80,82,163–169), including in persons with negative AFB sputum smear results. Microscopic examination of three consecutive sputum specimens obtained in 8–24-hour intervals, with at least one obtained in the early morning, is recommended instead of bronchoscopy, if possible. In a patient who is intubated and mechanically ventilated, closed circuitry can reduce the risk for exposure.

If the suspicion for pulmonary TB disease is high or if the patient is seriously ill with a disorder, either pulmonary or extrapulmonary, that is believed to be TB disease, multidrug antituberculosis treatment using one of the recommended regimens should be initiated promptly, frequently before AFB smear results are known (31). Obtaining three sputum samples is safer than performing bronchoscopy. For AFB smear and culture results, three sputum samples have an increased yield compared with a single specimen (110,357), and induced specimens have better yield than specimens obtained without induction. Sputum induction is well-tolerated (90,109,132,133,357,361,362), even in children (134,356), and sputum specimens (either spontaneous or induced) should be obtained in all cases before a bronchoscopy (109,356,363,364).

In circumstances where a person who is suspected of having TB disease is not on a standard antituberculosis treatment regimen and the sputum smear results (possibly including induced specimens) are negative and a reasonably high suspicion for TB disease remains, additional consideration to initiate treatment for TB disease should be given. If the underlying cause of a

radiographic abnormality remains unknown, additional evaluation with bronchoscopy might be indicated; however, in cases where TB disease remains a diagnostic possibility, initiation of a standard antituberculosis treatment regimen for a period before bronchoscopy might reduce the risk for transmission. Bronchoscopy might be valuable in establishing the diagnosis; in addition, a positive culture result can be both of clinical and public health importance to obtain drug-susceptibility results. Bronchoscopy in patients with suspected or confirmed TB disease should not be undertaken until after consideration of the risks for transmission of *M. tuberculosis* (30,63,81,162,360). If bronchoscopy is performed, because it is a cough-inducing procedure, additional sputum samples for AFB smear and culture should be collected after the procedure to increase the diagnostic yield.

Treatment Procedures for LTBI and TB Disease

Treatment for LTBI

Treatment for LTBI is essential to control and eliminate TB disease in the United States because it substantially reduces the risk that infection with *M. tuberculosis* will progress to TB disease (10,28). Certain groups of persons are at substantially high risk for developing TB disease after being infected, and every effort should be made to begin treatment for LTBI and to ensure that those persons complete the entire course of treatment ([Table 3](#)).

Before beginning treatment of LTBI, a diagnosis of TB disease should be excluded by history, medical examination, chest radiography, and, when indicated, bacteriologic studies. In addition, before offering treatment of LTBI, ensure that the patient has not experienced adverse reactions with previous isoniazid (INH) treatment (215).

Candidates for Treatment of LTBI

Persons in the following groups at high risk should be administered treatment for LTBI if their TST result is ≥ 5 mm or if their BAMT result is positive, regardless of age (31,39):

- persons infected with HIV,
- recent contacts with a person with TB disease,
- persons with fibrotic changes on chest radiograph consistent with previous TB disease,
- organ transplant recipients, and
- other immunosuppressed persons (e.g., persons receiving ≥ 15 mg/day of prednisone for ≥ 1 month).

Persons in the following groups at high risk should be considered for treatment of LTBI if their TST result is ≥ 10 mm, or if the BAMT result is positive:

- persons with TST or BAMT conversions;
- persons born or who have lived in developing countries or countries with a high-incidence of TB disease;
- persons who inject illicit drugs;
- residents and employees in congregate settings that are at high risk (i.e., correctional facilities and LTCFs [e.g., hospices and skilled nursing facilities]), hospitals and other health-care facilities, residential settings for persons with HIV/AIDS or other immunocompromising conditions, and homeless shelters;
- personnel from mycobacteriology laboratories;
- persons with any of the following clinical conditions or other immunocompromising conditions that place them at high risk for TB disease:
 - silicosis,
 - diabetes mellitus,
 - chronic renal failure,
 - certain hematologic disorders (e.g., leukemias and lymphomas),
 - other specific malignancies (e.g., carcinoma of the head, neck, or lung),
 - unexplained weight loss of $\geq 10\%$ of ideal body weight,
 - gastrectomy, or
 - jejunioileal bypass;
- persons living in areas with high incidence of TB disease;

- children aged <4 years; and
- infants, children, and adolescents exposed to adults at high risk for developing TB disease.

Persons who use tobacco or alcohol (40,41), illegal drugs, including injection drugs and crack cocaine (43–48), might also be at increased risk for infection and disease, but because of the multiple other potential risk factors that commonly occur among such persons, use of these substances has been difficult to identify as separate risk factors.

Persons with no known risk factors for TB disease can be considered for treatment of LTBI if their TST result is ≥ 15 mm. However, programs to screen HCWs for infection with *M. tuberculosis* should only be conducted among groups at high risk. All testing activities should be accompanied by a plan for follow-up care for persons with LTBI or, if it is found, TB disease. A decision to test for infection with *M. tuberculosis* should be based on a commitment to treat LTBI after a medical examination (39).

Persons who might not be good candidates for treatment of LTBI include those with a previous history of liver injury or a history of excessive alcohol consumption. Active hepatitis and end-stage liver disease (ESLD) are relative contraindications to the use of INH for treatment of LTBI (39,240). If the decision is made to treat such patients, baseline and follow-up monitoring of serum aminotransaminases should be considered.

For persons who have previous positive TST or BAMT results and who completed treatment for LTBI previously, treating them again is not necessary. Documentation of completed therapy for LTBI is critical. Instead of participating in serial skin testing, the HCW should receive a medical evaluation and a symptom screen annually. A symptom screen is a procedure used during a clinical evaluation in which patients are asked if they have experienced any departure from normal in function, appearance, or sensation related to TB disease (e.g., cough).

Screening HCWs for infection with *M. tuberculosis* is an essential administrative measure for the control of transmission of *M. tuberculosis* in health-care settings. By conducting TB screening, ongoing transmission of *M. tuberculosis* can be detected, and future transmission can be prevented by identifying lapses in infection control and identifying persons infected with *M. tuberculosis* and TB disease. The majority of individual HCWs, however, do not have the risk factors for progression to disease that serve as the basis for the current recommendations for targeted testing and treatment of LTBI. The majority of HCWs in the United States do not provide care in areas in which the prevalence of TB is high. Therefore, HCWs should be tested, as determined by risk classification for the health-care setting, and can be categorized as having a positive test result or conversion for *M. tuberculosis* infection. HCWs can be categorized as part of the TB infection-control program for the purpose of surveillance and referral, but they might not necessarily be candidates for treatment of LTBI.

HCWs should receive serial screening for infection with *M. tuberculosis* (either TST or BAMT), as determined by the health-care setting's risk classification ([Appendix B](#)). For infection-control purposes, the results of the testing should be recorded and interpreted as part of the TB infection-control program as either a 1) negative TST result, 2) previously documented positive TST or BAMT result, or 3) TST or BAMT conversion. All recordings of TST results should also document the size of the induration in millimeters, not simply as negative or positive. BAMT results should be recorded in detail. The details should include date of blood draw, result in specific units, and the laboratory interpretation (positive, negative, or indeterminate) and the concentration of cytokine measured (e.g., IFN- γ).

To determine whether treatment for LTBI should be indicated, HCWs should be referred for medical and diagnostic evaluation according to the TST result criteria ([Box 5](#)). In conjunction with a medical and diagnostic evaluation, HCWs with positive test results for *M. tuberculosis* should be considered for treatment of LTBI ([Box 5](#)) after TB disease has been excluded by further medical evaluation. HCWs cannot be compelled to take treatment for LTBI, but they should be encouraged to do so if they are eligible for treatment.

HCWs' TST or BAMT results might be considered positive as part of the TB infection-control program for the purposes of surveillance and referral (i.e., meet the criterion for a conversion), and this occurrence is important to note. However, not all of these HCWs may be considered candidates for treatment of LTBI, according to the individual medical and diagnostic evaluation. After an HCW has been classified as having a positive result or conversion for *M. tuberculosis* infection, additional testing for *M. tuberculosis* infection is not necessary.

Treatment Regimens for LTBI

For persons suspected of having LTBI, treatment of LTBI should not begin until TB disease has been excluded. Persons highly suspected of having TB disease should receive the standard multidrug antituberculosis treatment regimen for TB disease until the diagnosis is excluded. Standard drug regimens for the treatment of LTBI have been presented (Table 3); however, modifications to those regimens should be considered under certain circumstances, including HIV infection, suspected drug resistance, and pregnancy (47,365).

Reports of severe liver injury and death associated with the combination of rifampin and pyrazinamide (RZ) for treatment of LTBI (366–368) prompted the American Thoracic Society and CDC to revise previous recommendations (39,53) to indicate that RZ generally should not be offered for the treatment of LTBI (240). If the potential benefits substantially outweigh the demonstrated risk for severe liver injury and death associated with this regimen and the patient has no contraindications, a physician with experience treating LTBI and TB disease should be consulted before using this regimen (246). Clinicians should continue the appropriate use of rifampin and pyrazinamide in standard multidrug antituberculosis treatment regimens for the treatment of TB disease (31). Collaborate with the local or state health department on decisions regarding DOT arrangements.

For all regimens for treatment of LTBI, nonadherence to intermittent dosing (i.e., once or twice weekly) results in a larger proportion of total doses missed than daily dosing. DOT should be used for all doses during the course of treatment of LTBI whenever feasible (31). Collaborate with the local or state health department on decisions regarding DOT arrangements.

Contacts of patients with drug-susceptible TB disease. Persons with a previously negative TST or BAMT result who are contacts of patients with drug-susceptible TB disease and who subsequently have a positive TST result (≥ 5 mm) or positive BAMT result should be evaluated for treatment of LTBI, regardless of age. The majority of persons who are infected with *M. tuberculosis* will have a positive TST result within 6 weeks of exposure (74,228,369–371). Therefore, contacts of patients with drug-susceptible TB disease with negative TST (or BAMT) results should be retested 8–10 weeks after the end of exposure to a patient with suspected or confirmed TB disease. Persons infected with *M. tuberculosis* should be advised that they possibly can be reinfected with *M. tuberculosis* if re-exposed (246,372–375). Persons infected with HIV, persons receiving immunosuppressive therapy, regardless of TST result, and persons with a previous positive TST or BAMT result who are close contacts of a person with suspected or confirmed TB disease should be considered for treatment of LTBI.

The interpretation of TST results is more complicated in a contact investigation among HCWs who have negative baseline TST results from two-step testing but where the induration was >0 mm on the baseline TST or subsequent serial testing. Differences in the TST results between the contact investigation and previous baseline and serial TST could be a result of 1) inter-test variability in reaction size; 2) intervening exposure to NTM, BCG, or *M. tuberculosis*; and 3) reversion. In practice, for TST, only inter-test variability and exposure to or infection with NTM or *M. tuberculosis* are likely.

Treatment of LTBI should not be started until a diagnosis of TB disease has been excluded. If uncertainty exists concerning the presence of TB disease because of an ambiguous chest radiograph, a standard multidrug antituberculosis treatment regimen can be started and adjusted as necessary based on the results of sputum cultures and the patient's clinical response (31). If cultures are

obtained without initiating therapy, treatment for LTBI should not be initiated until culture results are reported as negative.

Contacts of patients with drug-resistant TB disease. Treatment for LTBI caused by drug-resistant or MDR TB disease is complex and should be conducted in consultation with the local or state health department's infection-control program and experts in the medical management of drug-resistant TB. In certain instances, medical decision making for the person with LTBI will benefit from the results of drug susceptibility testing of the isolate of the index TB case. Treatment should be guided by susceptibility test results from the isolate to which the patient was exposed and presumed to be infected (31,376,377).

Pretreatment Evaluation and Monitoring of Treatment

The pretreatment evaluation of persons who are targeted for treatment of LTBI provides an opportunity for health-care providers to 1) establish rapport with patients; 2) discuss details of the patient's risk for progression from LTBI to TB disease; 3) explain the benefits of treatment and the importance of adhering to the drug regimen; 4) review possible adverse effects of the regimen, including interactions with other medications; and 5) establish an optimal follow-up plan.

Monitoring for adverse effects of antituberculosis medications must be individualized. Persons receiving treatment for LTBI should be specifically instructed to look for symptoms associated with the most common reactions to the medications they are taking (39). Laboratory testing should be performed to evaluate possible adverse effects (31,39). Routine laboratory monitoring during treatment of LTBI is indicated for patients with abnormal baseline test results and for persons with a risk for hepatic disease. Baseline laboratory testing is indicated for persons infected with HIV, pregnant women, women in the immediate postpartum period (usually within 3 months of delivery), persons with a history of liver disease, persons who use alcohol regularly, and those who have or are at risk for chronic liver disease.

All patients being treated for LTBI should be clinically monitored at least monthly, including a brief clinical assessment conducted in the person's primary language for signs of hepatitis (e.g., nausea, vomiting, abdominal pain, jaundice, and yellow or brown urine). Patients receiving treatment for LTBI should be advised about the adverse effects of the drugs and the need for prompt cessation of treatment and clinical evaluation if adverse effects occur.

Because of the risk for serious hepatic toxicity and death, the use of the combination of RZ for the treatment of LTBI generally should not be offered. If RZ is used, a physician with experience treating LTBI and TB disease should be consulted before the use of this regimen. In addition, more extensive biochemical and clinical monitoring is recommended (240).

Treatment for TB Disease

Suspected or confirmed TB cases must be reported to the local or state health department in accordance with laws and regulations. Case management for TB disease should be coordinated with officials of the local or state health department. Regimens for treatment of TB disease must contain multiple drugs to which the organisms are susceptible. For persons with TB disease, treatment with a single drug can lead to the development of mycobacterial resistance to that drug. Similarly, adding a single drug to a failing antituberculosis treatment regimen can lead to resistance to the added drug (31).

For the majority of patients, the preferred regimen for treating TB disease consists of an initiation 2-month phase of four drugs (INH, rifampin, pyrazinamide, and ethambutol) and at least a 4-month continuation phase of INH and rifampin (for a minimum total treatment of 6 months). Ethambutol may be discontinued if supporting drug susceptibility results are available. Completion of therapy is based on the number of doses taken within a maximal period and not simply 6 months (31). Persons with cavitary pulmonary TB disease and positive culture results of sputum specimens at the completion of 2 months of therapy should receive a longer (7-month continuation) phase because of the significantly higher rate of relapse (31).

TB treatment regimens might need to be altered for persons infected with HIV who are on ART (49). Whenever feasible, the care of persons with both TB disease and HIV infection should be provided by or in consultation with experts in the management of both TB and HIV-related disease (31). To prevent the emergence of rifampin-resistant organisms, persons with TB disease, HIV infection, and CD4 cell counts of <100 cells/mm³ should not be treated with highly intermittent (i.e., once or twice weekly) regimens. These patients should receive daily treatment during the intensive phase by DOT (if feasible) and daily or three times weekly by DOT during the continuation phase (378). Detailed information on TB treatment for persons infected with HIV has been published and is available (http://www.dhfs.state.wi.us/AIDS-HIV/Resources/Overviews/AIDS_HIV.htm , <http://www.hiv-druginteractions.org> , and http://www.cdc.gov/nchstp/tb/TB_HIV_Drugs/TOC.htm) and published (31,53).

Drug-susceptibility testing should be performed on all initial isolates from patients with TB disease. When results from drug-susceptibility tests become available, the antituberculosis treatment regimen should be reassessed, and the drugs used in combination should be adjusted accordingly (376,377,379–381). If drug resistance is present, clinicians who are not experts in the management of patients with drug-resistant TB disease should seek expert consultation (31) and collaborate with the local or state health department for treatment decisions.

The major determinant of the outcome of treatment is adherence to the drug regimen. Therefore, careful attention should be paid to measures designed to enable and foster adherence (31,319,382). DOT is an adherence-enhancing strategy in which a trained HCW or other specially trained person watches a patient swallow each dose of medication and records the dates that the DOT was observed. DOT is the standard of care for all patients with TB disease and should be used for all doses during the course of therapy for TB disease and for LTBI, whenever feasible. Plans for DOT should be coordinated with the local or state health department (31).

Reporting Serious Adverse Events

HCWs should report serious adverse events associated with the administration of tuberculin antigen or treatment of LTBI or TB disease to the FDA MedWatch, Adverse Event Reporting System (AERS), telephone: 800-FDA-1088, fax: 800-FDA-0178, <http://www.fda.gov/medwatch> . Report Form 3500, Physicians' Desk Reference. Specific instructions for the types of adverse events that should be reported are included in MedWatch report forms.

Surveillance and Detection of *M. tuberculosis* Infections in Health-Care Settings

TB disease should be considered for any patient who has symptoms or signs of disease, including coughing for ≥ 3 weeks, loss of appetite, unexplained weight loss, night sweats, bloody sputum or hemoptysis, hoarseness, fever, fatigue, or chest pain. The index of suspicion for TB disease will vary by individual risk factors, geographic area, and prevalence of TB disease in the population served by the health-care setting. Persons exposed to patients with infectious TB disease might acquire LTBI, depending on host immunity and the degree and duration of exposure. Diagnostic tests for TB disease include chest radiography and laboratory tests of sputum (examination for AFB and culture). The treatment of persons with TB disease involves vital aspects of TB control by stopping transmission of *M. tuberculosis* and preventing persons with LTBI from developing infectious TB disease (36).

In the majority of the U.S. population, targeted testing for LTBI and TB disease is performed to identify persons with LTBI and TB disease who would benefit from treatment. Therefore, all testing activities should be accompanied by a plan for follow-up care of persons with LTBI or TB disease. A decision to test for infection with *M. tuberculosis* should be based on a commitment to treat LTBI after a medical examination (39). Health-care agencies or other settings should consult with the local or state health department before starting a program to test HCWs for *M. tuberculosis* infection. This step ensures that adequate provisions are in place for the evaluation and treatment of persons whose test results are positive, including the medical supervision of the course of treatment for those who are treated for LTBI or TB disease.

Groups that are not at high risk for LTBI or TB disease should not be tested routinely because testing in populations at low risk diverts resources from other priority activities. In addition, testing persons at low risk for *M. tuberculosis* infection is discouraged because a substantial proportion of persons from populations at low risk who have positive TST results might actually have false-positive TST results and might not represent true infection with *M. tuberculosis* (39,316). Testing for infection with *M. tuberculosis* should be performed for well-defined groups at high risk. These groups can be divided into two categories: 1) persons at higher risk for exposure to and infection with *M. tuberculosis* and 2) persons at higher risk for progression from LTBI to TB disease (see TB Infection-Control Program for Settings in Which Patients with Suspected or Confirmed TB Disease Are Expected To Be Encountered; and TB Infection-Control Program for Settings in Which Patients with Suspected or Confirmed TB Disease Are Not Expected To Be Encountered).

Flexibility is needed in defining high-priority groups for TB screening. The changing epidemiology of TB indicates that the risk for TB among groups currently considered as high priority might decrease over time, and groups currently not identified originally as being at high risk might be considered as high priority.

Baseline Testing with BAMT

For the purposes of establishing a baseline, a single negative BAMT result is sufficient evidence that the HCW is probably not infected with *M. tuberculosis* ([Box 2](#)). However, cautions regarding making medical care decisions for persons whose conditions are at increased risk for progressing to TB disease from *M. tuberculosis* infection have been presented ([Box 4](#)).

If BAMT is used for baseline testing of HCWs, including those in settings that are low risk, one negative BAMT result is sufficient to demonstrate that the HCW is not infected with *M. tuberculosis* ([Box 2](#)). Perform and document the baseline BAMT result preferably within 10 days of starting employment. HCWs with positive baseline results should be referred for a medical and diagnostic evaluation to exclude TB disease and then treatment for LTBI should be considered in accordance with CDC guidelines. Persons with a positive BAMT result do not need to be tested again for surveillance. For HCWs who have indeterminate test results, providers should consult the responsible laboratorian for advice on interpreting the result and making additional decisions (383).

Serial Testing with BAMT for Infection-Control Surveillance

When using BAMT for serial testing, a conversion for administrative purposes is a change from a negative to a positive result ([Box 3](#)). For HCWs who have indeterminate test results, providers should consult the responsible laboratorian for advice on interpreting the result and making additional decisions (383). Persons with indeterminate results should not be counted for administrative calculations of conversion rates.

Exposure of HCWs and Patients to *M. tuberculosis*

Known and Presumed Exposure

For HCWs with known and presumed exposure to *M. tuberculosis*, administer a symptom screen and obtain the BAMT result. A BAMT conversion probably indicates recent *M. tuberculosis* infection; therefore, TB disease must be excluded. Experience with BAMT in contact investigations is limited. Specific attention is needed in the management of certain populations (e.g., infants and children aged <4 years and immunocompromised persons, including those who are HIV-infected) ([Box 4](#)).

If the symptom screen or the BAMT result is positive, the exposed person should be evaluated for TB disease promptly, which includes a chest radiograph. If TB disease is excluded, additional medical and diagnostic evaluation for LTBI is needed, which includes a judgment regarding the extent of exposure.

Performing QFT-G

The QFT-G should be performed as described in the product insert provided with the BAMT kit. This insert is also available from the manufacturer's website (<http://www.cellestis.com> [↗](#)).

Interpretation of BAMT Results and Referral for Evaluation

HCWs who meet the criteria for referral should have a medical and diagnostic evaluation (see Supplements, Estimating the Infectiousness of a TB Patient; Diagnostic Procedures for LTBI and TB Disease; and Treatment Procedures for LTBI and TB Disease). The factors affecting treatment decisions during medical and diagnostic evaluation by risk for infection with *M. tuberculosis* have been presented ([Box 5](#)). In addition, because BAMT and other indirect tests for *M. tuberculosis* infection are diagnostic aids, the test results must be interpreted in the context of epidemiologic, historical, physical, and diagnostic findings. A higher likelihood of infection, as estimated from historical or epidemiologic details (e.g., exposure to *M. tuberculosis*) or because of the presence of an illness consistent with TB disease, increases the predictive value of a positive result. Setting-based risk factors (e.g., the prevalence of TB disease in the setting) should be considered when making decisions regarding the diagnosis and treatment of LTBI.

Medical conditions that impair or alter immune function ([Box 4](#)) decrease the predictive value of a negative result, and additional diagnostic methods (e.g., bacteriology, radiography, and histology) are required as evidence before excluding *M. tuberculosis* infection when the BAMT result is negative. Medical evaluations can occur in different settings, including an occupational health clinic, local or state health department, hospital, or private medical clinic.

Indeterminate QFT-G results are reported for either of two test conditions.

- The IFN- γ responses to all antigens (ESAT-6, CFP-10, and mitogen) are below a cut-off threshold. The weak response to mitogen could be caused by nonstandard storage or transportation of the blood sample, by laboratory errors, or by lymphocytic insensitivity caused by immune dysfunction.

OR,

- The IFN- γ response to the Nil exceeds a specified threshold, and the responses to both ESAT-6 and CFP-10 do not exceed the response to Nil by at least 50%. This response could be caused by nonstandard storage or transportation, laboratory errors, or circulating IFN- γ , which can be increased in ill HCWs or patients. For HCWs who have indeterminate test results, providers should consult the responsible laboratorian for advice on interpreting the result and making further decisions (383).

Interpreting the BAMT Result for Infection Control and Surveillance

BAMT conversion rates should be determined routinely. The precision of the BAMT conversion rate will depend, in part, on the number of HCWs tested, which should be considered when establishing a regular interval for evaluation and monitoring of HCWs with BAMT. Health-care settings with a substantial number of HCWs might have testing schedules that can accurately determine the BAMT conversion rate each month (i.e., from annual results of an HCW cohort tested within the given month), if testing is staggered throughout the year. BAMT conversion rates are more difficult to calculate in settings with fewer test results.

QC Program for the BAMT

Multiple processes are necessary to assure quality BAMT results: specimen collection, transport and handling, and conducting the test in the laboratory. BAMT must meet performance parameters for a valid test result to be achieved. QC is an ongoing laboratory issue. The infection-control team should assist the laboratory in assuring that all requisite conditions are present. The laboratory performing the BAMT will be required to validate its performance of the test before processing clinical samples. State and federal laboratory requirements regulate laboratory-testing procedures.

Additional Considerations

An indeterminate QFT-G result does not mean that the test has failed; it indicates that the specimen has inadequate responsiveness for the test to be performed. This result might reflect the condition of the HCW or patient, who, for example, might be immunosuppressed. Alternatively, the specimen

might have been handled incorrectly. For HCWs who have indeterminate test results, providers should consult the responsible laboratorian for advice on interpreting the result and making further decisions (383). Skin testing for cutaneous anergy is not useful in screening for asymptomatic LTBI or for diagnosing TB disease (339).

QFT-G use with HIV-infected persons taking ART. The effect of HIV infection and of ART on the performance of the QFT-G have not been fully evaluated.

Persons aged <17 years or pregnant women. The use of the QFT-G has not been evaluated in persons aged <17 years or pregnant women (35).

Booster phenomenon and BAMT. BAMT does not involve the injection of any substance into the persons being tested and is not affected by the booster phenomenon.

BCG vaccination. In the United States, vaccination with BCG is not routinely recommended (227). However, BCG is the most commonly used vaccine in the world. Foreign-born persons are commonly employed in the United States as HCWs. Previous BCG vaccination is not a contraindication to having a BAMT performed. BCG does not influence BAMT results with the version of the test approved in 2005 (i.e., QFT-G). HCWs who have received BCG vaccination should receive a baseline BAMT in the same manner as those without BCG vaccination, and the test result should be interpreted without reference to BCG.

Environmental Controls

Overview

Environmental controls include the following technologies to remove or inactivate *M. tuberculosis*: local exhaust ventilation, general ventilation, HEPA filtration, and UVGI. These controls help to prevent the spread and reduce the concentration of airborne infectious droplet nuclei. Environmental controls are the second line of defense in the TB infection-control program, and they work in harmony with administrative controls.

The reduction of exposures to *M. tuberculosis* can be facilitated through the effective use of environmental controls at the source of exposure (e.g., coughing patient or laboratory specimen) or in the general workplace environment. Source control is amenable to situations where the source has been identified and the generation of the contaminant is localized. Source-control techniques can prevent or reduce the spread of infectious droplet nuclei into the air by collecting infectious particles as they are released. These techniques are especially critical during procedures that will probably generate infectious aerosols (e.g., bronchoscopy, sputum induction, endotracheal intubation, suctioning, irrigating TB abscesses, aerosol treatments, autopsies on cadavers with untreated TB disease, and certain laboratory specimen manipulations) and when patients with infectious TB disease are coughing or sneezing.

Unsuspected and undiagnosed cases of infectious TB disease are believed to represent a substantial proportion of the current risk to HCWs (10,85). In such situations, source control is not a feasible option. Instead, general ventilation and air cleaning must be relied upon for control. General ventilation can be used to dilute the air and remove air contaminants and to control airflow patterns in rooms or in a health-care setting. Air-cleaning technologies include HEPA filtration to reduce the concentration of *M. tuberculosis* droplet nuclei and UVGI to kill or inactivate the microorganisms so that they no longer pose a risk for infection.

Ventilation systems for health-care settings should be designed, and modified when necessary, by ventilation engineers in collaboration with infection-control practitioners and occupational health staff. Recommendations for designing and operating ventilation systems have been published (117,118,178). The multiple types and conditions for use of ventilation systems in health-care settings and the needs of persons in these settings preclude the provision of extensive guidance in this document.

The information in this section is conceptual and intended to educate HCWs regarding environmental controls and how these controls can be used in the TB infection-control program. This information should not be used in place of consultation with experts who can give advice on ventilation system design, selection, installation, and maintenance. Because environmental controls will fail if they are not properly operated and maintained, routine training and education of staff are key components to a successful TB infection-control program. These guidelines do not specifically address mechanical ventilators in detail (see Intensive Care Units [ICUs]).

Local Exhaust Ventilation

Local exhaust ventilation captures airborne contaminants at or near their source and removes the contaminants without exposing persons in the area to infectious agents. This method is considered the most efficient way to remove airborne contaminants because it captures them before they can disperse. In local exhaust devices, hoods are typically used. Two types of hoods are 1) enclosing devices, in which the hood either partially or fully encloses the infectious source; and 2) exterior devices, in which the infectious source is near but outside the hood. Fully enclosed hoods, booths, or tents are always preferable to exterior devices because of their superior ability to prevent contaminants from escaping into the HCW's breathing space. Descriptions of both enclosing and exterior devices have been published (178).

Enclosing Devices

Enclosing devices for local exhaust ventilation include 1) booths for sputum induction or administration of aerosolized medications ([Figure 2](#)), 2) tents or hoods for enclosing and isolating a patient, and 3) BSCs (165). These devices are available in various configurations. The simplest device is a tent placed over the patient; the tent has an exhaust connection to the room-discharge exhaust system. The most complex device is an enclosure with a self-contained airflow and recirculation system ([Figure 2](#)).

Tents and booths should have sufficient airflow to remove at least 99% of airborne particles during the interval between the departure of one patient and the arrival of the next ([Table 1](#)). The time required to remove 99% or 99.9% of airborne particles from an enclosed space depends on 1) the number of ACH, which is a function of the volume (number of cubic feet of air) in the room or booth and the rate at which air is exiting the room or booth at the intake source; 2) the location of the ventilation inlet and outlet; and 3) the configuration of the room or booth. The surfaces of tents and booths should be periodically cleaned in accordance with recommendations and guidance from the manufacturers (see Supplement, Cleaning, Disinfecting, and Sterilizing Patient-Care Equipment and Rooms).

Exterior Devices

Exterior devices for local exhaust ventilation are usually hoods that are near to but not enclosing an infectious patient. The airflow produced by these devices should be sufficient to prevent cross-currents of air near the patient's face from allowing droplet nuclei to escape. Whenever possible, the patient should face directly into the opening of the hood to direct any coughing or sneezing into the hood. The device should maintain an air velocity of 200 feet per minute (fpm) at the patient's breathing zone to ensure the capture of droplet nuclei. Smoke tubes should be used to verify that the control velocity at the typical location of the patient's breathing zone is adequate to provide capture for the condition of highest expected cross-drafts and then the patient's breathing zone should be maintained at this location for the duration of the treatment.

Discharge of Exhaust from Booths, Tents, and Hoods

Air from booths, tents, and hoods is either discharged into the room in which the device is located or to the outside. If the exhaust air is discharged into the room, a HEPA filter should be incorporated at the discharge duct or vent of the device. The exhaust fan should be located on the discharge side of the HEPA filter to ensure that the air pressure in the filter housing and booth is negative compared with adjacent areas. Uncontaminated air from the room will flow into the booth through all openings, preventing infectious droplet nuclei in the booth from escaping into the room. Additional information

on the installation, maintenance, and monitoring of HEPA filters is included in this report ([Appendix A](#)).

The majority of commercially available booths, tents, and hoods are fitted with HEPA filters; additional HEPA filtration is not needed with these devices. If a device does not incorporate a HEPA filter, the air from the device should be exhausted directly to the outside and away from air-intake vents, persons, and animals, in accordance with applicable federal, state, and local regulations on environmental discharges.

General Ventilation

General ventilation is used to 1) dilute and remove contaminated air, 2) control the direction of airflow in a health-care setting, and 3) control airflow patterns in rooms.

Dilution and Removal of Contaminated Air

General ventilation maintains air quality by both air dilution and removal of airborne contaminants. Uncontaminated supply air mixes with contaminated room air (dilution), and air is subsequently removed from the room by the exhaust system (removal). These processes reduce the concentration of droplet nuclei in the room air.

Ventilation systems for air dilution and removal. Two types of general ventilation systems are used to dilute and remove contaminated air: single-pass air systems and recirculating air systems.

In a single-pass air system, the supply air is either outside air that has been heated or cooled or air that is uncontaminated from a central system that supplies multiple areas. After air passes through the room or area, 100% of the air is exhausted to the outside. A single-pass system is the preferred choice for an AII room because the system prevents contaminated air from being recirculated to other areas of the health-care setting. In a recirculating air system, a limited portion of the exhaust air is discharged directly to the outside and replaced with fresh outside air, which mixes with the portion of exhaust air that was not discharged. If the resulting air mixture is not treated, it can contain a substantial proportion of contaminated air when it is recirculated to areas serviced by the system. This air mixture can be recirculated into the general ventilation, and infectious particles can be carried from contaminated areas to uncontaminated areas. Alternatively, the air mixture could be recirculated in a specific room or area so that other areas are not affected. The use of air-cleaning technologies for removing or inactivating infectious particles in recirculated air systems has been discussed ([Appendix A](#)).

Delivery of general ventilation. General ventilation is delivered by either constant air volume (CAV) systems or VAV systems. In general, CAV systems are best for AII rooms and other negative-pressure rooms because the negative-pressure differential is easier to maintain. VAV systems are acceptable if provisions are made to maintain the minimum mechanical and outside ACH and a negative pressure ≥ 0.01 inch of water gauge compared with adjacent areas at all times.

Ventilation rates. Recommended ventilation rates (air change rates) for health-care settings are usually expressed in numbers of ACH, which is the ratio of the volume of air entering the room per hour to the room volume. ACH equals the exhaust airflow (Q cubic feet per minute [cfm]) divided by the room volume (V cubic feet) multiplied by 60.

$$\text{ACH} = (Q \div V) \times 60$$

Ventilation recommendations for selected areas in new or renovated health-care settings have been presented ([Table 2](#)). These recommendations have been adapted from those published by AIA (118). The feasibility of achieving a specific ventilation rate depends on the construction and operational requirements of the ventilation system and might differ for retrofitted and newly constructed facilities. The expense and effort of achieving a high ventilation rate might be reasonable for new construction but less reasonable when retrofitting an existing setting.

In existing settings, air-cleaning technologies (e.g., fixed or portable room-air recirculation units [also called portable air cleaners] or UVGI) can be used to increase the equivalent ACH. This equivalent

ventilation concept has been used to compare microbial inactivation by UVGI with particle-removal by mechanical ventilation (384,385) and to compare particle removal by HEPA filtration of recirculated air with particle removal by mechanical ventilation. The equivalent ventilation approach does not, however, negate the requirement to provide sufficient fresh outside air for occupant comfort ([Table 2](#)).

To dilute the concentration of normal room-air contaminants and minimize odors, a portion of the supply air should come from the outdoors ([Table 2](#)). Health-care settings should consult the American Society of Heating, Refrigerating, and Air-Conditioning Engineers, Inc. (ASHRAE), Standard 62.1, Ventilation for Acceptable Indoor Air Quality, for outside air recommendations in areas not listed in this report (386).

Control of Airflow Direction in a Health-Care Setting

Airflow direction is controlled in health-care settings to contain contaminated air and prevent its spread to uncontaminated areas.

Directional airflow. The general ventilation system should be designed and balanced so that air flows from less contaminated (more clean) to more contaminated (less clean) areas (118,117). For example, air should flow from corridors (cleaner areas) into AII rooms (less clean areas) to prevent the spread of contaminants. In certain rooms in which surgical and invasive procedures are performed and in protective environment (PE) rooms, the direction of airflow should be from the room to the hallway. Environmental control recommendations for situations involving the care and treatment of patients with TB disease in ORs and PE rooms have been presented (see Other Selected Settings). Cough-inducing or aerosol-generating procedures should not be performed on patients with suspected or confirmed TB disease in rooms where air flows from the room to the hallway.

Negative pressure for achieving directional airflow. The direction of airflow is controlled by creating a lower (negative) pressure in the area into which the flow of air is desired. Negative pressure is the approximate air-pressure difference between two areas in a health-care setting. For air to flow from one area to another, the air pressure in the two areas must be different. Air will flow from a higher pressure area to a lower pressure area. A room that is under negative pressure has a lower pressure than adjacent areas, which keeps air flowing from the adjacent rooms or areas into the room. Negative pressure is achieved by exhausting air at a higher volumetric rate than the rate that the air is being supplied.

Control of Airflow Patterns in Rooms

General ventilation systems should be designed to provide controlled patterns of airflow in rooms and to prevent air stagnation or short-circuiting of air from the supply to the exhaust (i.e., passage of air directly from the air supply to the exhaust). To provide controlled airflow patterns, the air supply and exhaust should be located so that clean air flows first to parts of the room where HCWs probably work and then across the infectious source and into the exhaust. Therefore, HCWs are not positioned between the infectious source and the exhaust. This configuration is not always possible but should be used whenever feasible.

One way to achieve a controlled airflow pattern is to supply air at the side of the room opposite the patient and exhaust it from the side where the patient is located ([Figure 3](#)). Another method, which is most effective when the supply air is cooler than the room air, is to supply air near the ceiling and exhaust it near the floor ([Figure 3](#)). Care must be taken to ensure that furniture or moveable equipment does not block the low exhausts. Airflow patterns are affected by air temperature differentials, location of the supply diffusers and exhaust grilles, location of furniture, movement of HCWs and patients, and the configuration of the space.

If the room ventilation is not designed for a plug-flow type of airflow pattern ([Figure 3](#)), then adequate mixing must be maintained to minimize air stagnation. The majority of rooms with properly installed supply diffusers and exhaust grilles will have adequate mixing. A qualitative measure of mixing is the visualization of air movement with smoke tubes at multiple locations in the room.

Smoke movement in all areas of the room indicates good mixing. Additional sophisticated studies can be conducted by using a tracer gas to quantify air-mixing and air-exchange rates.

If areas of air stagnation are present, air mixing can be improved by adding a circulating fan or repositioning the supply and exhaust vents. Room-air recirculation units positioned in the room or installed above the ceiling can also improve air mixing. If supply or exhaust vents, circulating fans, or room-air recirculation units are placed incorrectly, HCWs might not be adequately protected.

Achieving Negative Pressure in Rooms

Negative pressure is needed to control the direction of airflow between selected rooms in a health-care setting and their adjacent spaces to prevent contaminated air from escaping from the room into other areas (118) (Figure 4). Control of a room's differential airflow and total leakage area is critical to achieving and maintaining negative pressure. Differential airflow, differential pressure, and leakage area are interrelated. This relation is illustrated (Figure 4) and is expressed in an empirical equation (387).

$$A_E = 0.01138 * (\Delta Q^{1.170} / \Delta P^{0.602})$$

In the equation, AE is the leakage area in square inches; ΔQ is the differential airflow rate in cfm; and ΔP is the differential pressure drop in inches of water gauge. This empirical equation was used (Figure 4), which indicates that changing one parameter will influence one or both of the other parameters. For example, the control of differential pressure can frequently be improved by increasing the air tightness or seal of a room, maintaining the HVAC system, and ensuring continuous monitoring. In a room that is already substantially tight (e.g., with 10 square inches of leakage), however, a small change in differential pressure will have a substantial effect on differential airflow. Similarly, a room with a more substantial leakage area (e.g., 300 square inches of leakage) requires a higher differential airflow rate to achieve a pressure differential of 0.01 inch of water gauge. Reducing the leakage in a room with 300 square inches of leakage can help achieve a pressure differential of 0.01 inch of water gauge (Figure 4). If the leakage area is reduced to approximately 40 square inches, a pressure differential of 0.01 inch of water gauge can be achieved by exhausting approximately 100 cubic feet per minute (cfm) more air from the room than is supplied to the room.

Room leakage can occur through cracks or spaces near doors, windows, ceiling, and utility connections. Steps should be taken to minimize these leaks. Changes in the performance of the HVAC system will affect the pressure differential in a room and can potentially cause a negative-pressure room to become positive-pressure. Therefore, each of these parameters requires close monitoring to ensure that minor changes in the performance of the HVAC system do not adversely affect the entire system (388,389).

Pressure differential. To achieve negative pressure in a room that has a normally functioning ventilation system, first measure and balance the supply and exhaust airflows to achieve an exhaust flow higher than the supply flow. Next, measure the pressure differential across the closed door. Although the minimum pressure difference needed for airflow into a room is substantially small (approximately 0.001 inch of water gauge), a pressure differential of ≥ 0.01 inch of water gauge (≥ 2.5 Pascals [Pa]) is recommended. This higher pressure differential is easier to measure and offers a margin of safety for maintaining negative pressure as the pressure in surrounding areas changes because of the opening and closing of doors, operation of elevators, stack effect (rising of warm air, similar to a chimney), ventilation system fluctuations, and other factors. The higher pressurization value is consistent with the most recent AIA recommendations for airborne precautions in health-care settings (118) and is the generally accepted level of negative pressurization for microbiology and biomedical laboratories (390).

Opening doors and windows can substantially affect the negative pressure in an AII room. Infection-control criteria requires AII room windows and doors to remain closed, except when doors must be opened for persons to enter or leave the room. Keeping certain doors in the corridor outside the AII rooms closed might be necessary to maintain the negative-pressure differential between an AII room and the corridor. Pressurization cannot be maintained in rooms or spaces that are not enclosed.

If ≥ 0.01 inch of water gauge is not achieved and cannot be achieved by increasing the flow differential (within the limits of the ventilation system), the room should be inspected for leakage. The total room leakage is based on the previously measured pressure, and air flow differentials can be estimated (Figure 4). If the room leakage is too substantial (e.g., 300 square inches), maintaining a negative-pressure differential as high as 0.01 inch of water gauge might be difficult. A lower value is acceptable if air-pressure monitoring indicates that negative pressure is always maintained (or airflow indicators consistently demonstrate that air is flowing in the desired direction). If negative pressure cannot be maintained, the leakage area might need to be reduced by sealing cracks around windows or replacing porous suspended ceiling panels with gasketed or sealed solid panels.

Because negative pressure in an AII room can be affected by even minimal changes in the operation of the ventilation system, negative pressure can be difficult to maintain with a VAV ventilation system. To maintain negative pressure, a VAV supply system should be coupled with a compensating exhaust system that increases when the supply flow rate increases. Alternatively, the exhaust can be set at a fixed rate that ensures negative pressure throughout the VAV supply cycle. The VAV minimum flow rate must also be adequate to maintain the recommended minimum mechanical and outdoor ACH (Table 2).

Alternate methods for achieving negative pressure. An anteroom is not a substitute for negative pressure in an AII room. However, an anteroom can reduce the escape of droplet nuclei during the opening and closing of the door to an AII room and can buffer an AII room from pressure fluctuations in the corridor. To function properly, an anteroom must have more air exhausted from the room than supplied to remove *M. tuberculosis* that can enter from the AII room. An anteroom can also have its own supply diffuser, if needed, to balance the pressure with the corridor. If an anteroom is unventilated or not properly ventilated, it will function only as a lesser contaminated vestibule between the AII room and the corridor and might not prevent the escape of droplet nuclei into the corridor. To adjust airflow and pressure differentials, health-care settings should consult a ventilation engineer who is knowledgeable regarding all applicable regulations, including building fire codes.

If the desired negative pressure cannot be achieved because a room does not have a separate ventilation system or a system that can provide the proper airflow, steps should be taken to provide a method to discharge air from an AII room. One method to achieve negative pressure in a room is to add a supplemental exhaust unit. If an AII room has a window or an outside wall, a small exhaust fan can be used. An engineer should be consulted to evaluate the potential for negative effects on surrounding areas (e.g., disruption of exhaust airflow in adjoining bathrooms) and to ensure the provision of the recommended amounts of outdoor air. The exhaust must not be discharged where it can immediately re-enter the building or pose a hazard to persons outside.

Fixed room-air recirculation systems (i.e., systems that recirculate the air in an entire AII room) can be designed to achieve negative pressure by discharging a portion of the air to the outside. Some portable room-air recirculation units are also designed to discharge air to the outside to achieve negative pressure. These air cleaners must be designed specifically for this purpose.

Monitoring negative pressure. Negative pressure must be monitored to ensure that air is always flowing from the corridor (or surrounding area) into the AII room. Negative pressure can be monitored either continuously or periodically. Monitoring methods include chemical aerosols (e.g., smoke tube), differential pressure-sensing devices (e.g., manometer), and physical indicators (e.g., flutter strips).

A chemical aerosol resembling smoke can be used to observe airflow between a room and the surrounding area, or within a room. Devices called smoke tubes generate the chemical aerosol resembling smoke, which follows the local air currents wherever it is released. To check the negative pressure in a room, hold a smoke tube approximately 2 inches in front of the base of the closed door of the AII room or in front of the air transfer grille, if the door has such a feature. Hold the smoke tube parallel to the door. A small amount of smoke should be generated slowly to ensure that the velocity of smoke emanating from the tube does not overpower the air velocity (Figure 5). If the room is under negative pressure, the smoke will travel into the room (from higher to lower pressure). If the

room is not under negative pressure, the smoke will be blown outward or stay in front of the door. Room air cleaners in the room should be operating. Persons using smoke tubes should avoid inhaling the smoke, because direct inhalation of high concentrations of the smoke can be irritating (391) (Figure 5).

Manometers are used to monitor negative pressure. They provide either periodic (noncontinuous) pressure measurements or continuous pressure monitoring. A continuous monitoring indicator can simply be a visible or audible warning signal indicating that air pressure is positive. Both periodic and continuous pressure detectors generate a digital or analog signal that can be recorded for later verification or used to automatically adjust the room's ventilation control system.

Physical indicators (e.g., flutter strips) are occasionally used to provide a continuous visual sign that a room is under negative pressure. These simple and inexpensive devices are placed directly in the door and can be useful in identifying a pressure differential problem.

Pressure-measuring devices should sense the pressure just inside the airflow path into the AII room (e.g., at the base of the door). Unusual airflow patterns can cause pressure variations. For example, the air can be under negative pressure at the middle of a door and under positive pressure at the base of the same door. The ideal location of a pressure-measuring device has been illustrated (Figure 6). If the pressure-sensing ports of the device cannot be located directly across the airflow path, validating that the negative pressure at the sensing point is and remains the same as the negative pressure across the flow path might be necessary.

Pressure-sensing devices should incorporate an audible warning with a time delay to indicate an open door. When a door is open, the negative pressure cannot be maintained, but this situation should not generate an alarm unless the door is left open. Therefore, the time delay should allow adequate time for persons to enter or leave an AII room without activating the alarm.

The pressure differentials used to achieve low negative pressure (<0.005 inch) require the use of substantially sensitive mechanical devices, electronic devices, or pressure gauges to ensure accurate measurements. Pressure-measuring and monitoring devices can give false readings if the calibration has drifted. For example, a sensor might indicate that the room pressure is slightly negative compared with the corridor, but, because air current momentum effects or "drift" of the electrical signal, air might actually be flowing out of the AII room through the opening at the base of the door. In one study of 38 AII rooms with electrical or mechanical devices to continuously monitor air pressurization, one half had airflow at the door in the opposite direction of that indicated by the continuous monitors (392). The investigators attributed this problem to instrument limitations and device malfunction. A negative pressure differential of ≥ 0.01 inch of water gauge (compared with the previously recommended 0.001 inch of water gauge) might help to minimize this problem.

Periodic checks are required to maintain the desired negative pressure and the optimal operation of monitoring devices.

- AII rooms should be checked for negative pressure before occupancy.
- When occupied by a patient, an AII room should be checked daily with smoke tubes or other visual checks for negative pressure.
- If pressure-sensing devices are used in AII rooms occupied by patients with suspected or confirmed TB disease, negative pressure should be checked daily by using smoke tubes or other visual checks.
- If the AII rooms are not being used for patients who have suspected or confirmed TB disease but potentially could be used for such patients, the negative pressure should be checked monthly.
- Laboratories should be checked daily for negative pressure.

AII Rooms and Other Negative-Pressure Rooms

AII rooms are used to 1) separate patients who probably have infectious TB from other persons, 2) provide an environment in which environmental factors are controlled to reduce the concentration of droplet nuclei, and 3) prevent the escape of droplet nuclei from such rooms into adjacent areas using

directional airflow. Other negative-pressure rooms include bronchoscopy suites, sputum induction rooms, selected examination and treatment rooms, autopsy suites, and clinical laboratories.

Preventing the escape of droplet nuclei. AII rooms used for TB isolation should be single-patient rooms with negative pressure, compared with the corridor or other areas connected to the room. Opening doors and windows can substantially affect the negative pressure in an AII room. Infection-control criteria require AII room windows and doors to remain closed, except when doors must be opened for persons to enter or leave the room. It might also be necessary to keep certain doors in the corridor outside the AII rooms closed to maintain the negative-pressure differential between an AII room and the corridor. The use of self-closing doors is recommended. The openings in the room (e.g., windows, and electrical and plumbing entries) should be sealed as much as possible, with the exception of a small gap (1/8–1/2 inch) at the base of the door to provide a controlled airflow path. Proper use of negative pressure will prevent contaminated air from escaping the room (393,394).

Reducing the concentration of droplet nuclei. AII rooms in existing health-care settings should have an air change rate of ≥ 6 mechanical ACH. Whenever feasible, this airflow rate should be increased to ≥ 12 mechanical ACH by adjusting or modifying the ventilation system or should be increased to ≥ 12 equivalent ACH by supplementing with air-cleaning technologies (e.g., fixed or portable room-air recirculation systems or UVGI systems). New construction or renovation of existing health-care settings should be designed so that AII rooms achieve a total air change rate of ≥ 12 mechanical ACH. These recommendations are consistent with guidelines by ASHRAE and AIA that recommend ≥ 12 mechanical ACH for AII rooms (117,118). Ventilation recommendations for other negative-pressure rooms in new or renovated health-care settings have been presented (see Risk Classification Examples).

To dilute the concentration of normal room air contaminants and minimize odors, a portion of the supply air should come from the outdoors. A minimum of 2 ACH of outdoor air should be provided to AII rooms and other negative-pressure rooms (117,118).

Exhaust from AII rooms and other negative-pressure rooms. Air from AII rooms and other negative-pressure rooms for patients with suspected or confirmed TB disease should be exhausted directly to the outside and away from air-intake vents, persons, and animals, in accordance with applicable federal, state, and local regulations on environmental discharges. Exhaust ducts should be located away from sidewalks or windows that can be opened. Ventilation system exhaust discharges and inlets should be designed to prevent the re-entry of exhausted air. Wind blowing over a building creates a substantially turbulent recirculation zone that can cause exhausted air to re-enter the building. Exhaust flow should be discharged above this zone. Design guidelines for proper placement of exhaust ducts have been published (395). If recirculation of air from such rooms into the general ventilation system is unavoidable, the air should be passed through a HEPA filter before recirculation.

Alternatives to negative-pressure rooms. AII can also be achieved by the use of negative-pressure enclosures (e.g., tents or booths). These enclosures can provide patient isolation in EDs and medical testing and treatment areas and can supplement AII in designated negative-pressure rooms.

Other Selected Settings

Operating rooms, autopsy suites, sputum-induction rooms, and aerosolized treatment rooms pose potential hazards from infectious aerosols generated during procedures on patients with TB disease (72,90,396–398). Recommended administrative, environmental, and respiratory-protection controls for these and other selected settings have been summarized ([Appendix A](#)). Additional or specialized TB infection controls that are applicable to special circumstances and types of health-care delivery settings have also been described (see Managing Patients Who Have Suspected or Confirmed TB Disease: Considerations for Special Circumstances and Settings). Ventilation recommendations for these settings in new or renovated health-care facilities have been included in this report ([Table 2](#)). Existing facilities might need to augment the current ventilation system or use the air-cleaning methods to increase the number of equivalent ACH.

Patients with TB disease who also require a PE room (e.g., severely immunocompromised patients) are special cases. These patients require protection from common airborne infectious microorganisms and must be placed in a room that has HEPA-filtered supply air and is under positive pressure compared with its surroundings (118). If an anteroom is not available, the use of other air-cleaning methods should be considered to increase the equivalent ACH. The air-cleaning systems can be placed in the room and in surrounding areas to minimize contamination of the surroundings. Similar controls can be used in ORs that are used for patients with TB disease because these rooms must be maintained under positive pressure, compared with their surroundings to maintain a sterile field.

Air-Cleaning Methods

HEPA Filtration

HEPA filtration can be used to supplement other recommended ventilation measures by providing a minimum removal efficiency of 99.97% of particles equal to 0.3 μm in diameter. This air-cleaning method is considered an adjunct to other ventilation measures. Used alone, this method neither provides outside air for occupant comfort nor satisfies other recommended ventilation measures (e.g., using source control whenever possible and minimizing the spread of contaminants in a setting through control of airflow patterns and pressure differentials).

HEPA filters have been demonstrated to reduce the concentration of *Aspergillus* spores (range in size: 5–6 μm) to below measurable levels (399–401). Because infective droplet nuclei generated by TB patients are believed to range from 1–5 μm in diameter (300) (comparable in size to *Aspergillus* spores) (402), HEPA filters will remove *M. tuberculosis*–containing infectious droplet nuclei from contaminated air. HEPA filters can be used to clean air before it is 1) exhausted to the outside, 2) recirculated to other areas of a health-care setting, or 3) recirculated in an AII room. Because electrostatic filters can degrade over time with exposure to humid environments and ambient aerosols (403), their use in systems that recirculate air back into the general ventilation system from AII rooms and treatment rooms should be avoided. If used, the filter manufacturer should be consulted regarding the performance of the filter to ensure that it maintains the desired filtration efficiency over time and with loading.

Use of HEPA filtration when exhausting air to the outside. HEPA filters can be used as an added safety measure to clean air from AII rooms and local exhaust devices (e.g., booths, tents, and hoods) before exhausting it to the outside. This added measure is not necessary, however, if the exhaust air cannot re-enter the ventilation system supply and does not pose a risk to persons and animals where it is exhausted.

Exhaust air frequently is not discharged directly to the outside; instead, the air is directed through heat-recovery devices (e.g., heat wheels or radiator-like devices). Heat wheels are frequently used to reduce the costs of operating ventilation systems (404). As the wheel rotates, energy is transferred into or removed from the supply inlet air stream. If a heat wheel is used with a system, a HEPA filter should also be used. The HEPA filter should be placed upstream from the heat wheel because of the potential for leakage across the seals separating the inlet and exhaust chambers and the theoretical possibility that droplet nuclei might be impacted on the wheel by the exhaust air and subsequently stripped off into the supply air.

Recirculation of HEPA-filtered air. Air from AII rooms and other negative-pressure rooms should be exhausted directly to the outside. In certain instances, however, recirculation of air into the general ventilation system from such rooms is unavoidable (e.g., settings in which the ventilation system or building configuration causes venting the exhaust to the outside impossible). In such cases, HEPA filters should be installed in the exhaust duct exiting the room to remove infectious organisms from the air before it is returned to the general ventilation system.

Individual room-air recirculation can be used in areas in which no general ventilation system exists, where an existing system is incapable of providing sufficient ACH, or where air-cleaning (particulate removal) is desired without affecting the fresh air supply or negative-pressure system. Recirculation

of HEPA-filtered air in a room can be achieved by 1) exhausting air from the room into a duct, passing it through a HEPA filter installed in the duct, and returning it to the room ([Figure 7](#)); 2) filtering air through HEPA recirculation systems installed on the wall or ceiling of the room ([Figure 8](#)); or 3) filtering air through portable HEPA recirculation systems. In this report, the first two approaches are referred to as fixed room-air recirculation systems because the recirculation systems are not easily movable.

Fixed room-air recirculation systems. The preferred method of recirculating HEPA-filtered air is by using a built-in system in which air is exhausted from the room into a duct, filtered through a HEPA filter, and returned to the room ([Figure 7](#)). This technique can add equivalent ACH in areas in which the recommended minimum ACH is difficult to meet with general ventilation. This equivalent ventilation concept compares particle removal by HEPA filtration of the recirculated air with particle clearance from exhaust ventilation. Because the air does not have to be conditioned, airflow rates that are higher than those produced by the general ventilation system can usually be achieved. An alternative is to install HEPA filtration units on the wall or ceiling ([Figure 8](#)).

Fixed recirculation systems are preferred to portable (free-standing) units because they can be installed with a higher degree of reliability. In addition, certain fixed systems have a higher airflow capacity than portable systems, and the potential for short-circuiting of air is reduced as the distance between the air intake and exhaust is increased.

Portable room-air recirculation systems. Portable room-air recirculation units with HEPA filters (also called portable air cleaners) can be considered when 1) a room has no general ventilation system, 2) the system cannot provide adequate ACH, or 3) increased effectiveness in airflow is needed. Effectiveness depends on the ability of the portable room-air recirculation unit to circulate as much of the air in the room as possible through the HEPA filter. Effectiveness can vary depending on the room's configuration, the furniture and persons in the room, the placement of the HEPA filtration unit compared with the supply diffusers and exhaust grilles, and the degree of mixing of air within the room.

Portable room-air recirculation units have been demonstrated to be effective in removing bioaerosols and aerosolized particles from room air (405–410). Findings indicate that various commercially available units are useful in reducing the concentration of airborne particles and are therefore helpful in reducing airborne disease transmission. The performance of 14 units was evaluated for volumetric airflow, airborne particle reduction, noise level, and other parameters (406). The range of volumetric airflow rates was 110 cfm–1,152 cfm, and the equivalent ACH range was an average of 8–22 in a standard-sized, substantially well-mixed, single-patient room. Recommendations were provided to make subsequent models safer, more effective, quieter, and easier to use and service. Purchasers should be aware that the majority of manufacturer specifications indicated flow rates of free-wheeling fans and not the fan under the load of a filter.

Portable HEPA filtration units should be designed to 1) achieve ≥ 12 equivalent ACH, 2) ensure adequate air mixing in all areas of the rooms, and 3) be compatible with the ventilation system. An estimate of the ability of the unit to circulate the air in a room can be made by visualizing airflow patterns (estimating room air mixing [see Supplements, Environmental Controls; and General Ventilation]). If the air movement is adequate in all areas of the room, the unit should be effective.

If portable devices are used, units with high volumetric airflow rates that provide maximum flow through the HEPA filter are preferred. Placement should be selected to optimize the recirculation of AII room air through the HEPA filter. Careful consideration must be given to obstacles (e.g., furnishings, medical equipment, and walls) that could disrupt airflow and to system specifications (e.g., physical dimensions, airflow capacity, locations of air inlet and exhaust, and noise) to maximize performance of the units, minimize short-circuiting of air, and reduce the probability that the units will be switched off by room occupants.

Installing, maintaining, and monitoring HEPA filters. The performance of HEPA filters depends on proper installation, testing, and meticulous maintenance (411), especially if the system

recirculates air to other parts of the health-care setting. Improper design, installation, or maintenance could allow infectious particles to circumvent filtration and escape into the general ventilation system (117). These failures also could impede proper ventilation performance.

HEPA filters should be installed to prevent leakage between filter segments and between the filter bed and its frame. A regularly scheduled maintenance program is required to monitor filters for possible leakage and filter loading. A quantitative filter performance test (e.g., the dioctyl phthalate penetration test [412,413]) should be performed at the initial installation and each time the filter is changed. Records should be maintained for all filter changes and testing. A leakage test using a particle counter or photometer should be performed every 6–12 months for filters in general-use areas and in areas with systems that will probably be contaminated with *M. tuberculosis* (e.g., AII rooms).

A manometer or other pressure-sensing device should be installed in the filter system to provide an accurate and objective means of determining the need for filter replacement. Pressure-drop characteristics of the filter are supplied by the manufacturer. Installation of the filter should allow for maintenance that will not contaminate the delivery system or the area served. For general infection-control purposes, special care should be taken to avoid jarring or dropping the filter element during or after removal.

The scheduled maintenance program should include procedures for installation, removal, and disposal of filter elements. HEPA filter maintenance should be performed only by adequately trained personnel and only while the ventilation system or room-air recirculation unit is not being operated.

Laboratory studies indicate that re-aerosolization of viable mycobacteria from filter material (HEPA filters and N95 disposable respirator filter media) is not probable under normal conditions (414–416). Although these studies indicate that *M. tuberculosis* becoming an airborne hazard is not probable after it is removed by a HEPA filter (or other high efficiency filter material), the risks associated with handling loaded HEPA filters in ventilation systems under field-use conditions have not been evaluated. Therefore, persons performing maintenance and replacing filters on any ventilation system that is probably contaminated with *M. tuberculosis* should wear a respirator (see Respiratory Protection) in addition to eye protection and gloves. When feasible, HEPA filters can be disinfected in 10% bleach solution or other appropriate mycobacteriacide before removal (417). In addition, filter housing and ducts leading to the housing should be labeled clearly with the words "TB-Contaminated Air" or other similar warnings. Disposal of filters and other potentially contaminated materials should be in accordance with applicable local or state regulations.

One or more lower-efficiency disposable pre-filters installed upstream can extend the life of a HEPA filter by at least 25%. If the disposable filter is replaced by a 90% extended surface filter, the life of the HEPA filter can be extended by approximately 900% (178). Pre-filters should be handled and disposed of in the same manner as the HEPA filter.

UVGI

Ultraviolet germicidal irradiation (UVGI) is a form of electromagnetic radiation with wavelengths between the blue region of the visible spectrum and the radiograph region. UV-C radiation (short wavelengths; range: 100–280 nm) (418) can be produced by various artificial sources (e.g., arc lamps and metal halide lamps). The majority of commercially available UV lamps used for germicidal purposes are low-pressure mercury vapor lamps that emit radiant energy in the UV-C range, predominantly at a wavelength of 253.7 nm (418).

Research has demonstrated that UVGI is effective in killing or inactivating *M. tuberculosis* under experimental conditions (292,385,419–423) and in reducing transmission of other infectious agents in hospitals (424), military housing (425), and classrooms (426–428). Because of the results of multiple studies (384,429–432) and the experiences of clinicians and mycobacteriologists during the preceding decades, UVGI has been recommended as a supplement or adjunct to other TB infection-control and ventilation measures in settings in which the need to kill or inactivate *M. tuberculosis* is

essential (6,7,196,433,434). UVGI alone does not provide outside air or circulate interior air, both of which are essential in achieving acceptable air quality in occupied spaces.

Applications of UVGI. UVGI is considered a method of air cleaning because it can kill or inactivate microorganisms so that they are no longer able to replicate and form colonies. UVGI is not a substitute for HEPA filtration before exhausting the air from AII rooms back into the general circulation. UVGI lamps can be placed in ducts, fixed or portable room air-recirculation units, or upper-air irradiation systems. The use of this air-cleaning technique has increased, particularly in substantial open areas in which unsuspected or undiagnosed patients with TB disease might be present (e.g., ED waiting rooms, shelters, and correctional facilities), and the costs of conditioning substantial volumes of outdoor air are prohibitive.

For each UVGI system, guidelines should be followed to maximize effectiveness. Effectiveness can be expressed in terms of an equivalent air change rate (427,435–437), comparing the ability of UVGI to inactivate organisms with removal through general ventilation. Initially, understanding and characterizing the application for which UVGI will be used is vital. Because the effectiveness of UVGI systems will vary, the use of UVGI must be carefully evaluated and the level of efficacy clearly defined and monitored.

The effective use of UVGI is associated with exposure of *M. tuberculosis*, as contained in an infectious droplet, to a sufficient dose of UV-C radiation at 253.7 nm to ensure inactivation. Because dose is a function of irradiance and time, the effectiveness of any application is determined by its ability to deliver sufficient irradiance for enough time to result in inactivation of the organism within the infectious droplet. Achieving a sufficient dose can be difficult with airborne inactivation because the exposure time can be substantially limited; therefore, attaining sufficient irradiance is essential.

The number of persons who are properly trained in the design and installation of UVGI systems is limited. One critical recommendation is that health-care facility managers consult a UVGI system designer to address safety and efficacy considerations before such a system is procured and installed. Experts who can be consulted include industrial hygienists, engineers, and health physicists.

Duct irradiation. Duct irradiation is designed to kill or inactivate *M. tuberculosis* without exposing persons to UVGI. In duct irradiation systems, UVGI lamps are placed inside ducts to disinfect the exhaust air from AII rooms or other areas in which *M. tuberculosis* might be present before it is recirculated to the same room (desirable) or to other areas served by the system (less desirable). When UVGI duct systems are not properly designed, installed, and maintained, high levels of UVGI can be produced in the duct that can potentially cause high UVGI exposures during maintenance operations.

Duct-irradiation systems depend on the circulation of as much of the room air as possible through the duct. Velocity profiles and mixing are important factors in determining the UVGI dose received by airborne particles. Design velocity for a typical UVGI unit is approximately 400 fpm (438). The particle residence time must be sufficient for inactivation of the microorganisms.

Duct irradiation can be used in three ways.

- Ventilation systems serving AII rooms to recirculate air from the room, through a duct containing UV lamps, and back into the same room. UVGI duct systems should not be used either in place of HEPA filters, if air from AII rooms must be recirculated to other areas of a setting, or as a substitute for HEPA filtration of air from booths, tents, or hoods used for cough-inducing or aerosol-generating procedures.
- Return air ducts serving patient rooms, waiting rooms, EDs, and general-use areas in which patients with undiagnosed TB disease could potentially contaminate the recirculated air.
- Recirculating ventilation systems serving rooms or areas in which ceiling heights are too low for the safe and effective use of upper-air UVGI.

Upper-air irradiation. In upper-air irradiation, UVGI lamp fixtures are suspended from the ceiling and installed on walls. The base of the lamps are shielded to direct the radiation upward and outward to create an intense zone of UVGI in the upper air while minimizing the levels of UVGI in the

lower part of the room where the occupants are located. The system depends on air mixing to move the air from the lower part of the room to the upper part where microbial-contaminated air can be irradiated.

A major consideration is the placement of UVGI fixtures to achieve sufficient irradiance of the upper-air space. The ceiling should be high enough (≥ 8 feet) for a substantial volume of upper air to be irradiated without overexposing occupants in the lower part of the room to UVGI. System designers must consider the mechanical ventilation system, room geometry, and emission characteristics of the entire fixture.

Upper-air UVGI can be used in various settings.

- All rooms and rooms in which aerosol-generating or aerosol-producing procedures (e.g., bronchoscopy, sputum induction, and administration of aerosolized medications) are performed.
- Patient rooms, waiting rooms, EDs, corridors, central areas, and other substantial areas in which patients with undiagnosed TB disease could potentially contaminate the air.
- Operating rooms and adjacent corridors where procedures are performed on patients with TB disease.
- Medical settings in correctional facilities.

Portable room air recirculation systems. In portable room air-recirculation units containing UVGI, a fan moves a volume of room air across UVGI lamps to disinfect the air before it is recirculated back to the room. Some portable units contain both a HEPA filter (or other high efficiency filter) and UVGI lamps.

In addition to the guidelines described for the use of portable room air-recirculation systems containing HEPA filtration, consideration must be given to the volume of room air that passes through the unit, the UVGI levels, particle residence time, and filtration efficiency (for devices with a filter). One study in which a bioaerosol chamber was used demonstrated that portable room air cleaners with UVGI lamps as the primary air-cleaning mechanism are effective ($>99\%$) in inactivating or killing airborne vegetative bacteria (439). Additional studies need to be performed in rooms with portable air cleaners that rely only on UVGI for air cleaning.

Portable room air cleaners with UVGI can be used in 1) All rooms as an adjunct method of air cleaning and 2) waiting rooms, EDs, corridors, central areas, or other substantial areas in which patients with undiagnosed TB disease could potentially contaminate the air.

Effectiveness of UVGI. Air mixing, air velocity, relative humidity, UVGI intensity, and lamp configuration affect the efficacy of all UVGI applications. For example, with upper-air systems, airborne microorganisms in the lower, occupied areas of the room must move to the upper part of the room to be killed or inactivated by upper-air UVGI. Air mixing can occur through convection caused by temperature differences, fans, location of supply and exhaust ducts, or movement of persons.

Air-mixing. UVGI has been demonstrated to be effective in killing bacteria in the upper-air applications under conditions in which air mixing was accomplished primarily by convection. In a 1976 study on aerosolization of *M. bovis* BCG (a surrogate for *M. tuberculosis*) in a room without mechanical ventilation that relied primarily on convection and infiltration resulted in 10–25 equivalent ACH, depending on the number of UVGI fixtures used (384). Other early studies examined the effect of air-mixing on UVGI efficacy (440,441). These studies indicated that the efficacy of UVGI was substantially increased if cold supply air relative to the lower portion of the room entered through diffusers in the ceiling. The findings indicated that substantial temperature gradients between the upper and lower portions of the room favored (cold air in the upper portion of the room) or inhibited (hot air in the upper portion of the room) vertical mixing of air between the two zones.

When large-bladed ceiling fans were used to promote mixing in the experimental room, the ability of UVGI to inactivate *Serratia marcescens*, an organism known to be highly sensitive to UVGI, was doubled (442,443). Similar effects were reported in studies conducted during 2000–2002 in which louvered UVGI fixtures were used. One study documented an increase in UVGI effectiveness of 16% at

2 ACH and 33% at 6 ACH when a mixing fan was used (444). Another study conducted in a simulated health-care room determined that 1) at 0 ACH, a high degree of efficacy of upper-air UVGI was achieved in the absence or presence of mixing fans when no temperature gradient was created; and 2) at 6 ACH, bringing in warm air at the ceiling resulted in a temperature gradient with cooler room air near the floor and a UVGI efficacy of only 9% (422). Turning on box fans under these winter conditions increased UVGI efficacy nearly 10-fold (to 89%) (445).

To reduce variability in upper-air UVGI efficacy caused by temperature gradients in the room, a fan should be routinely used to continually mix the air, unless the room has been determined to be well mixed under various conditions of operation. Use of a fan would also reduce or remove the variable winter versus summer ACH requirements for optimal upper-air UVGI efficacy (446).

Relative humidity. In studies conducted in bioaerosol chambers, the ability of UVGI to kill or inactivate microorganisms declined substantially when the relative humidity exceeded 60% (447–450). In room studies, declines in the ability of upper-air UVGI to kill or inactivate microorganisms at high relative humidity (65%, 75%, and 100%) (384,422) have also been reported. The exact mechanism responsible for the reduced effectiveness of UVGI at these higher levels of relative humidity is unknown but does not appear to be related to changes in UV irradiance levels. Relative humidity changes from 55%–90% resulted in no corresponding changes in measured UVGI levels (437). In another study, an increase in relative humidity from 25%–67% did not reduce UVGI levels (422). Bacteria have been demonstrated to absorb substantial amounts of water from the air as the relative humidity increases. At high humidity, the UV irradiance levels required to inactivate bacteria might approach the higher levels that are needed for liquid suspensions of bacteria (448). The ability of bacteria to repair UVGI damage to their DNA through photoreactivation has also been reported to increase as relative humidity increases (422,448).

For optimal efficacy of upper-air UVGI, relative humidity should be maintained at $\leq 60\%$, a level that is consistent with recommendations for providing acceptable indoor air quality and minimizing environmental microbial contamination in indoor environments (386,451).

Ventilation rates. The relation between ventilation and UVGI has also been evaluated. Certain predicted inactivation rates have been calculated and published for varying flow rates, UV intensity, and distances from the lamp, based on radiative heat transfer theory (438). In room studies with substantially well-mixed air, ventilation rates (0 ACH, 3 ACH, and 6 ACH) were combined with various irradiation levels of upper-air UVGI. All experiments were conducted at 50% relative humidity and 70° F (21.2° C). When *M. parafortuitum* was used as a surrogate for *M. tuberculosis*, ventilation rates usually had no adverse effect on the efficiency of upper-air UVGI. The combined effect of both environmental controls was primarily additive in this artificial environment, with possibly a small loss of upper-air UVGI efficiency at 6 ACH (422). Therefore, ventilation rates of up to 6 ACH in a substantially well-mixed room might achieve ≥ 12 ACH (mechanical ACH plus equivalent ACH) by combining these rates with the appropriate level of upper-air irradiation (422). Higher ventilation rates (>6 ACH) might, however, decrease the time the air is irradiated and, therefore, decrease the killing of bacteria (429,452).

Ventilation rates up to six mechanical ACH do not appear to adversely affect the performance of upper-air UVGI in a substantially well-mixed room. Additional studies are needed to examine the combined effects of mechanical ventilation and UVGI at higher room-air exchange rates.

UVGI intensity. UVGI intensity field plays a primary role in the performance of upper-air UVGI systems. The UVGI dose received by microorganisms is a function of UVGI times duration of exposure. Intensity is influenced by the lamp wattage, distance from the lamp, surface area, and presence of reflective surfaces. The number of lamps, location, and UVGI level needed in a room depends on the room's geometry, area, and volume, and the location of supply air diffusers (422,436). UVGI fixtures should be spaced to reduce overlap while maintaining an even irradiance zone in the upper air.

The emission profile of a fixture is a vital determinant of UVGI effectiveness. Information regarding total UVGI output for a given fixture (lamp plus housing and louvers) should be requested from the manufacturer and used for comparison when selecting UVGI systems. Information concerning only the UVGI output of the lamp is inadequate; the lamp output will be higher than the output for the fixture because of losses from reflectors and nonreflecting surfaces and the presence of louvers and other obstructions (436,437). In addition, information provided by the manufacturer reflects ideal laboratory conditions; damage to fixtures or improper installation will affect UV radiation output. Because old or dust-covered UVGI lamps are less effective, routine maintenance and cleaning of UVGI lamps and fixtures is essential. UVGI system designers should consider room geometry, fixture output, room ventilation, and the desired level of equivalent ACH in determining the types, numbers, and placement of UVGI fixtures in a room to achieve target irradiance levels in the upper air.

Health and safety issues. Short-term overexposure to UV radiation can cause erythema (i.e., abnormal redness of the skin), photokeratitis (inflammation of the cornea), and conjunctivitis (i.e., inflammation of the conjunctiva) (453). Symptoms of photokeratitis and conjunctivitis include a feeling of sand in the eyes, tearing, and sensitivity to light. Photokeratitis and conjunctivitis are reversible conditions, but they can be debilitating while they run their course. Because the health effects of UVGI are usually not evident until after exposure has ended (typically 6–12 hours later), HCWs might not recognize them as occupational injuries.

In 1992, UV-C (100–280 nm) radiation was classified by the International Agency for Research on Cancer as "probably carcinogenic to humans (Group 2A)" (454). This classification was based on studies indicating that UV-C radiation can induce skin cancers in animals and create DNA damage, chromosomal aberrations, and sister chromatid exchange and transformation in human cells in vitro. In addition, DNA damage in mammalian skin cells in vivo can be caused. In the animal studies, a contribution of UV-C radiation to the tumor effects could not be excluded, but the effects were higher than expected for UV-B radiation alone (454). Certain studies have demonstrated that UV radiation can activate HIV gene promoters (i.e., genes in HIV that prompt replication of the virus) in laboratory samples of human cells (455–460). The potential for UV-C radiation to cause cancer and promote HIV in humans is unknown, but skin penetration might be an important factor. According to certain reports, only 20% of incident 250 nm UV penetrates the stratum corneum, compared with approximately 30–60% of 300 nm UV (UV-B) radiation (461).

In upper-air UVGI systems, fixtures must be designed and installed to ensure that UVGI exposures to occupants are below current safe exposure levels. Health-hazard evaluations have identified potential problems at some settings using UVGI systems. These problems include overexposure of HCWs to UVGI and inadequate maintenance, training, labeling, and use of personal protective equipment (PPE) (398,462,463).

An improperly maintained (unshielded) germicidal lamp was believed to be the cause of dermatosis or photokeratitis in five HCWs in an ED (464) and three HCWs who were inadvertently exposed to an unshielded UVGI lamp in a room that had been converted from a sputum induction room to an office (465). These case reports highlight the importance of posting warning signs to identify the presence of UVGI (see Supplement, Labeling and Posting) and are reminders that shielding should be used to minimize UVGI exposures to occupants in the lower room. In the majority of applications, properly designed, installed, and maintained UVGI fixtures provide protection from the majority of, if not all, the direct UVGI in the lower room. However, radiation reflected from glass, polished metal, and high-gloss ceramic paints can be harmful to persons in the room, particularly if more than one UVGI fixture is in use. Surfaces in irradiated rooms that can reflect UVGI into occupied areas of the room should be covered with non-UV-reflecting material.

Although more studies need to be conducted, lightweight clothing made of tightly woven fabric and UV-absorbing sunscreens with solar-protection factors (SPFs) of ≥ 15 might help protect photosensitive persons. Plastic eyewear containing a UV inhibitor that prevents the transmission of $\geq 95\%$ of UV radiation in the 210–405 nm range is commercially available. HCWs should be advised

that any eye or skin irritation that develops after UVGI exposure should be evaluated by an occupational health professional.

Exposure criteria. In 1972, CDC published a recommended exposure limit (REL) for occupational exposure to UV radiation (453). REL is intended to protect HCWs from the acute effects of UV light exposure. Photosensitive persons and those exposed concomitantly to photoactive chemicals might not be protected by the recommended standard.

The CDC/NIOSH REL for UV radiation is wavelength dependent because different wavelengths have different adverse effects on the skin and eyes (453). At 254 nm, the predominant wavelength for germicidal UV lamps, the CDC/NIOSH REL is 0.006 joules per square centimeter (J/cm²) for a daily 8-hour work shift. ACGIH has a Threshold Limit Value(r) for UV radiation that is identical to the REL for this spectral region (466). HCWs frequently do not stay in one place in the setting during the course of their work and, therefore, are not exposed to UV irradiance levels for 8 hours. Permissible exposure times (PET) for HCWs with unprotected eyes and skin can be calculated for various irradiance levels as follows:

$$\text{PET (seconds)} = \frac{0.006 \text{ J/cm}^2 \text{ (CDC/NIOSH REL at 254 nm)}}{\text{Measured irradiance level (at 254 nm) in W/cm}^2}$$

Exposures exceeding the CDC/NIOSH REL require the use of PPE to protect the skin and eyes.

Labeling, Maintenance, and Monitoring

Labeling and posting. Health-care settings should post warning signs on UV lamps and wherever high-intensity (i.e., UVGI exposure greater than the REL) UVGI irradiation is present to alert maintenance staff, HCWs, and the general public of the hazard. The warning signs should be written in the languages of the affected persons ([Box 6](#)).

Maintenance. Because the UVGI output of the lamps declines with age, a schedule for replacing the lamps should be developed in accordance with manufacturer recommendations. The schedule can be determined from a time-use log, a system based on cumulative time, or routinely (e.g., at least annually). UVGI lamps should be checked monthly for dust build-up, which lessens radiation output. A dirty UVGI lamp should be allowed to cool and then should be cleaned in accordance with the manufacturer recommendations so that no residue remains.

UVGI lamps should be replaced if they stop glowing, if they flicker, or if the measured irradiance (see Supplement, Environmental Controls) drops below the performance criteria or minimum design criterion set forth by the design engineers. Maintenance personnel must switch off all UVGI lamps before entering the upper part of the room or before accessing ducts for any purpose. Only limited seconds of direct exposure to the intense UVGI in the upper-air space or in ducts can cause dermatosis or photokeratitis. Protective clothing and equipment (e.g., gloves, goggles, face shield, and sunscreen) should be worn if exposure greater than the recommended levels is possible or if UVGI radiation levels are unknown.

Banks of UVGI lamps can be installed in ventilation system ducts. Safety devices and lock-out or tag-out protocols should be used on access doors to eliminate exposures of maintenance personnel. For duct irradiation systems, the access door for servicing the lamps should have an inspection window through which the lamps are checked periodically for dust build-up and to ensure that they are functioning properly. The access door should have a warning sign written in appropriate languages to alert maintenance personnel to the health hazard of looking directly at bare UV lamps. The lock for this door should have an automatic electric switch or other device that turns off the lamps when the door is opened.

Types of fixtures used in upper-air irradiation include wall-mounted, corner-mounted, and ceiling-mounted fixtures that have louvers or baffles to block downward radiation and ceiling-mounted fixtures that have baffles to block radiation below the horizontal plane of the fixtures. If possible, light switches that can be locked should be used to prevent injury to persons who might unintentionally turn the lamps on during maintenance procedures. Because lamps must be discarded after use,

consideration should be given to selecting germicidal lamps that are manufactured with relatively low amounts (i.e., ≤ 5 mg) of mercury. UVGI products should be listed with the Underwriters Laboratories (UL) or Electrical Testing Laboratories (ETL) for their specific application and installed in accordance with the National Electric Code.

Monitoring. UVGI intensity should be measured by an industrial hygienist or other person knowledgeable in the use of UV radiometers with a detector designed to be most sensitive at 254 nm. Equipment used to measure UVGI should be maintained and calibrated on a regular schedule, as recommended by the manufacturer.

UVGI should be measured in the lower room to ensure that exposures to occupants are below levels that could result in acute skin and eye effects. The monitoring should consider typical duties and locations of the HCWs and should be done at eye level. At a minimum, UVGI levels should be measured at the time of initial installation and whenever fixtures are moved or other changes are made to the system that could affect UVGI. Changes to the room include those that might result in higher exposures to occupants (e.g., addition of UV-reflecting materials or painting of walls and ceiling). UVGI monitoring information, lamp maintenance, meter calibration, and lamp and fixture change-outs should be recorded.

UVGI measurements should also be made in the upper air to define the area that is being irradiated and determine if target irradiance levels are met (467). Measurements can be made using UVGI radiometers or other techniques (e.g., spherical actinometry), which measures the UVGI in an omnidirectional manner to estimate the energy to which microorganisms would be exposed (468). Because high levels of UVGI can be measured in the upper air, persons making the measurements should use adequate skin and eye protection. UVGI radiation levels close to the fixture source can have permissible exposure times on the order of seconds or minutes for HCWs with unprotected eyes and skin. Therefore, overexposures can occur with brief UVGI exposures in the upper air (or in ventilation system ducts where banks of unshielded UV lamps are placed) in HCWs who are not adequately protected.

Upper-air UVGI systems and portable room-air recirculation units. A study in 2002 examined the relation between three portable room-air recirculation units with different capture or inactivation mechanisms and an upper-air UVGI system in a simulated health-care room (409). The study determined that the equivalent ACH produced by the recirculation units and produced by the upper-air UVGI system were approximately additive. For example, one test using aerosolized *M. parafortuitum* provided an equivalent ACH for UVGI of 17 and an equivalent ACH for the recirculation unit of 11; the total experimentally measured equivalent ACH for the two systems was 27. Therefore, the use of portable room-air recirculation units in conjunction with upper-air UVGI systems might increase the overall removal of *M. tuberculosis* droplet nuclei from room air.

Environmental Controls: Program Concerns

To be most effective, environmental controls must be installed, operated, and maintained correctly. Ongoing maintenance is a critical part of infection control that should be addressed in the written TB infection-control plan. The plan should outline the responsibility and authority for maintenance and address staff training needs. At one hospital, improperly functioning ventilation controls were believed to be an important factor in the transmission of MDR TB disease to three patients and a correctional officer, three of whom died (469). In three other multihospital studies evaluating the performance of AII rooms, failure to routinely monitor air-pressure differentials or a failure of the continuous monitoring devices installed in the AII rooms resulted in a substantial percentage of the rooms being under positive pressure (57,392,470,471).

Routine preventive maintenance should be scheduled and should include all components of the ventilation systems (e.g., fans, filters, ducts, supply diffusers, and exhaust grilles) and any air-cleaning devices in use. Performance monitoring should be conducted to verify that environmental controls are operating as designed. Performance monitoring can include 1) directional airflow assessments using smoke tubes and use of pressure monitoring devices that are sensitive to pressures

as low as approximately 0.005 inch of water gauge and 2) measurement of supply and exhaust airflows to compare with recommended air change rates for the respective areas of the setting. Records should be kept to document all preventive maintenance and repairs.

Standard procedures should be established to ensure that maintenance staff notifies infection-control personnel before performing maintenance on ventilation systems servicing patient-care areas. Similarly, infection-control staff should request assistance from maintenance personnel in checking the operational status of AII rooms and local exhaust devices (e.g., booths, hoods, and tents) before use. A protocol that is well-written and followed will help to prevent unnecessary exposures of HCWs and patients to infectious aerosols. Proper labeling of ventilation system components (e.g., ducts, fans, and filters) will help identify air-flow paths. Clearly labeling which fan services a given area will help to prevent accidental shutdowns (472).

In addition, provisions should be made for emergency power to avoid interruptions in the performance of essential environmental controls during a power failure.

Respiratory Protection

Considerations for Selection of Respirators

The overall effectiveness of respiratory protection is affected by 1) the level of respiratory protection selected (e.g., the assigned protection factor), 2) the fit characteristics of the respirator model, 3) the care in donning the respirator, and 4) the adequacy of the fit-testing program. Although data on the effectiveness of respiratory protection from various hazardous airborne materials have been collected, the precise level of effectiveness in protecting HCWs from *M. tuberculosis* transmission in health-care settings has not been determined.

Information on the transmission parameters of *M. tuberculosis* is also incomplete. Neither the smallest infectious dose of *M. tuberculosis* nor the highest level of exposure to *M. tuberculosis* at which transmission will not occur has been defined conclusively (159,473,474). In addition, the size distribution of droplet nuclei and the number of particles containing viable *M. tuberculosis* organisms that are expelled by patients with infectious TB disease have not been adequately defined, and accurate methods of measuring the concentration of infectious droplet nuclei in a room have not been developed. Nonetheless, in certain settings (e.g., AII rooms and ambulances during the transport of persons with suspected or confirmed infectious TB disease), administrative and environmental controls alone might not adequately protect HCWs from infectious airborne droplet nuclei.

On October 17, 1997, OSHA published a proposed standard for occupational exposure to *M. tuberculosis* (267). On December 31, 2003, OSHA announced the termination of rulemaking for a TB standard (268). Previous OSHA policy permitted the use of any Part 84 particulate filter respirator for protection against infection with *M. tuberculosis* (269). Respirator usage for TB had been regulated by OSHA under CFR Title 29, Part 1910.139 (29 CFR 1910.139) (270) and compliance policy directive (CPL) 2.106 (Enforcement Procedures and Scheduling for Occupational Exposure to Tuberculosis). Respirator usage for TB is now regulated under the general industry standard for respiratory protection (29 CFR 1910.134) (271). General information on respiratory protection for aerosols, including *M. tuberculosis*, has been published (272–274).

Performance Criteria for Respirators

Performance criteria for respirators are derived from data on 1) effectiveness of respiratory protection against noninfectious hazardous materials in workplaces other than health-care settings and an interpretation of how these data can be applied to respiratory protection against *M. tuberculosis*, 2) efficiency of respirator filters in filtering biologic aerosols, 3) face-seal leakage, and 4) characteristics of respirators used in conjunction with administrative and environmental controls in outbreak settings to stop transmission of *M. tuberculosis* to HCWs and patients.

Particulate filter respirators certified by CDC/NIOSH, either nonpowered respirators with N95, N99, N100, R95, R99, R100, P95, P99, and P100 filters (including disposable respirators), or PAPRs with high efficiency filters can be used for protection against airborne *M. tuberculosis*.

The most essential attribute of a respirator is the ability to fit the different facial sizes and characteristics of HCWs. Studies have demonstrated that fitting characteristics vary substantially among respirator models. The fit of filtering facepiece respirators varies because of different facial types and respirator characteristics (10,280–289). Selection of respirators can be done through consultation with respirator fit-testing experts, CDC, occupational health and infection-control professional organizations, peer-reviewed research, respirator manufacturers, and from advanced respirator training courses. Data have determined that fit characteristics cannot be determined solely by physical appearance of the respirator (282).

Types of Respiratory Protection for TB

Respirators encompass a range of devices that vary in complexity from flexible masks covering only the nose and mouth, to units that cover the user's head (e.g., loose-fitting or hooded PAPRs), and to those that have independent air supplies (e.g., airline respirators). Respirators must be selected from those approved by CDC/NIOSH under the provisions of 42 CFR, Part 84 (475).

Nonpowered air-purifying respirators. Nine classes of nonpowered, air-purifying, particulate-filter respirators are certified under 42 CFR 84. These include N-, R-, and P-series respirators of 95%, 99%, and 100% (99.7%) filtration efficiency when challenged with 0.3 μm particles (filters are generally least efficient at this size) (Table 4). The N, R, and P classifications are based on the capacity of the filter to withstand exposure to oil. All of these respirators meet or exceed CDC's filtration efficiency performance criteria during the service life of the filter (1,272,273).

Nonpowered air-purifying respirators work by drawing ambient air through the filter during inhalation. Inhalation causes negative pressure to develop in the tight-fitting facepiece and allows air to enter while the particles are captured on the filter. Air leaves the facepiece during exhalation because positive pressure develops in the facepiece and forces air out of the mask through the filter (disposable) or through an exhalation valve (replaceable and certain ones are disposable).

The classes of certified nonpowered air-purifying respirators include both filtering facepiece (disposable) respirators and elastomeric (rubber-like) respirators with filter cartridges. The certification test for filtering facepieces and filter cartridges consists only of a filter performance test. It does not address respirator fit. Although all N-, R-, and P-series respirators are recommended for protection against *M. tuberculosis* infection in health-care settings and other workplaces that are usually free of oil aerosols that could degrade filter efficiency, well-fitting N-series respirators are usually less expensive than R- and P-series respirators (272,273). All respirators should be replaced as needed, based on hygiene considerations, increased breathing resistance, time-use limitations specified in the CDC/NIOSH approval guidelines, respirator damage, and in accordance with manufacturer user's instructions.

PAPRs. PAPRs use a blower that draws air through the filters into the facepiece. PAPRs can be equipped with a tight-fitting or loose-fitting facepiece, a helmet, or a hood. PAPR filters are classified as high efficiency and are different from those presented in this report (Table 4). A PAPR high efficiency filter meets the N100, R100, and P100 criteria at the beginning of their service life. No loading tests using 0.3 μm particles are conducted as part of certification. PAPRs can be useful for persons with facial hair or other conditions that prevent an adequate face to facepiece seal (476).

Atmosphere-supplying respirators. Positive-pressure airline (supplied-air) respirators are provided with air from a stationary source (compressor) or an air tank.

Effectiveness of Respiratory-Protection Devices

Data on the effectiveness of respiratory protection against hazardous airborne materials are based on experience in the industrial setting; data on protection against transmission of *M. tuberculosis* in health-care settings are not available. The parameters used to determine the effectiveness of a respiratory protective device are face-seal efficacy and filter efficiency.

Face-seal leakage. Face-seal leakage is the weak link that limits a respirator's protective ability. Excessive face-seal leakage compromises the ability of particulate respirators to protect HCWs from

airborne materials (477). A proper seal between the respirator's sealing surface and the face of the person wearing the respirator is essential for the effective and reliable performance of any tight-fitting, negative-pressure respirator.

For tight-fitting, negative-pressure respirators (e.g., N95 disposable respirators), the amount of face-seal leakage is determined by 1) the fit characteristics of the respirator, 2) the care in donning the respirator, and 3) the adequacy of the fit-testing program. Studies indicate that a well-fitting respirator and a fit test produces better results than a well-fitting respirator without a fit test or a poor-fitting respirator with a fit test. Increased face-seal leakage can result from additional factors, including incorrect facepiece size, failure to follow the manufacturer's instructions at each use, beard growth, perspiration or facial oils that can cause facepiece slippage, improper maintenance, physiological changes of the HCW, and respirator damage.

Face-seal leakage is inherent in tight-fitting negative-pressure respirators. Each time a person wearing a nonpowered particulate respirator inhales, negative pressure (relative to the workplace air) is created inside the facepiece. Because of this negative pressure, air containing contaminants can leak into the respirator through openings at the face-seal interface and avoid the higher-resistance filter material. A half-facepiece respirator, including an N95 disposable respirator, should have <10% leakage. Full facepiece, nonpowered respirators have the same leakage (<2%) as PAPRs with tight-fitting full-facepieces.

The more complex PAPRs and positive-pressure airline respirators reduce or eliminate this negative facepiece pressure and, therefore, reduce leakage into the respirator and enhance protection. A PAPR is equipped with a blower that forcibly draws ambient air through high efficiency filters and then delivers the filtered air to the facepiece. This air is blown into the facepiece at flow rates that generally exceed the expected inhalation flow rates. The pressure inside the facepiece reduces face-seal leakage to low levels, particularly during the relatively low inhalation rates expected in health-care settings. PAPRs with a tight-fitting facepiece have <2% face-seal leakage under routine conditions (278). PAPRs with loose-fitting facepieces, hoods, or helmets have <4% inward leakage under routine conditions (278). Therefore, a PAPR might offer lower levels of face-seal leakage than nonpowered, half-mask respirators.

Filter penetration. Aerosol penetration through respirator filters depends on at least five independent variables: 1) filtration characteristics for each type of filter, 2) size distribution of the droplets in the aerosol, 3) linear velocity through the filtering material, 4) filter loading (i.e., amount of contaminant deposited on the filter), and 5) electrostatic charges on the filter and on the droplets in the aerosol (284).

When N95 disposable respirators are used, filter penetration might approach 5% (50% of the allowable leakage of 10% for an N95 disposable respirator). When high efficiency filters are used in PAPRs or for half-facepiece respirators, filter efficiency is high (effectively 100%), and filter penetration is less of a consideration. Therefore, for high efficiency or 100-series filter respirators, the majority of inward leakage of droplet nuclei occurs at the respirator's face seal or exhalation valve.

Implementing a Respiratory-Protection Program

If respirators are used in a health-care setting, OSHA requires the development, implementation, administration, and periodic reevaluation of a respiratory-protection program (271,277,278). The most critical elements of a respiratory-protection program include 1) assigning of responsibility, 2) training, and 3) fit testing (1). All HCWs who use respirators for protection against infection with *M. tuberculosis* should be included in the respiratory-protection program.

Visitors to AII rooms and other areas with patients who have suspected or confirmed infectious TB disease may be offered respirators (e.g., N95 disposable respirators) and should be instructed by an HCW on the use of the respirator before entering an AII room (see Respiratory Protection section for User-Seal Check FAQs). The health-care setting should develop a policy on use of respirators by visitors.

The number of HCWs included in the respiratory-protection program will vary depending on the 1) number of persons who have suspected or confirmed TB disease examined in a setting, 2) number of rooms or areas in which patients with suspected or confirmed infectious TB disease stay or are encountered, and 3) number of HCWs needed to staff these rooms or areas. In settings in which respiratory-protection programs are required, enough HCWs should be included to provide adequate care for patients with suspected or confirmed TB disease. However, administrative measures should be used to limit the number of HCWs exposed to *M. tuberculosis* (see Prompt Triage).

Information on the development and management of a respiratory-protection program is available in technical training courses that cover the basics of respiratory protection. Such courses are offered by OSHA, the American Industrial Hygiene Association, universities, manufacturers, and private contractors. To be effective and reliable, respiratory-protection programs must include at least the following elements (274,277,278).

Assignment of Responsibility

One person (the program administrator) must be in charge of the respiratory-protection program and be given the authority and responsibility to manage all aspects of the program. The administrator must have sufficient knowledge (obtained by training or experience) to develop and implement a respiratory-protection program. Preferably, the administrator should have a background in industrial hygiene, safety, health care, or engineering. The administrator should report to the highest official possible (e.g., manager of the safety department, supervisor of nurses, HCWs' health manager, or infection-control manager) and should be allocated sufficient time to administer the respiratory-protection program in addition to other assigned duties.

Standard Operating Procedures

The effectiveness of a respiratory-protection program requires the development of written standard procedures. These procedures should include information and guidance for the proper selection, use, and care of respirators (274).

Screening

HCWs should not be assigned a task requiring use of respirators unless they are physically able to perform job duties while wearing the respirator. HCWs who might need to use a respirator should be screened by a physician or other licensed health-care professional for pertinent medical conditions at the time they are hired and then re-screened periodically (274). The screening process should begin with a screening questionnaire for pertinent medical conditions, the results of which should be used to identify HCWs who need further evaluation ([Appendix G](#)). Unless prescribed by the screening physician, serial physical examination or testing with chest radiographs or spirometry is neither necessary nor required (287).

Training

HCWs should be provided annual training on multiple topics.

- Nature, extent, and hazards of TB disease in the health-care setting. This training can be conducted in conjunction with other related training on infectious disease associated with airborne transmission (e.g., severe acute respiratory syndrome [SARS]-coronavirus [CoV] and measles) and with serial TB screening.
- The risk assessment process and its relation to the respirator program.
- Signs and symbols used to demonstrate that respirators are required in an area.
- Reasons for using respirators.
- Environmental controls used to prevent the spread and reduce the concentration of infectious droplet nuclei.
- Reasons for selecting a particular respirator for a given hazard (see Selection of Respirators; and Respirator Options: Special Circumstances).
- Operation, capabilities, and limitations of respirators.
- Respirator care.
- Cautions regarding facial hair and respirator use.

- Applicable federal, state, and local regulations regarding respirators, including assessment of employees' knowledge.

Trainees should be provided resources as an adjunct to the respiratory-protection program.

- Opportunities to handle and wear a respirator until they are proficient (see Supplement, Fit Testing).
- Educational material for use as references.
- Instructions to refer all respirator problems immediately to the respirator program administrator.

Selection

Filtering facepiece respirators used for protection against *M. tuberculosis* must be selected from those approved by CDC/NIOSH under the provisions of 42 CFR 84 (<http://www.cdc.gov/niosh/celintro.html>). A listing of CDC/NIOSH-approved disposable particulate respirators (filtering facepieces) is available at http://www.cdc.gov/niosh/npptl/topics/respirators/disp_part. If a health-care setting uses respirators for protection against other regulated hazards (e.g., formaldehyde and ethylene oxide), then these potential exposures should be specifically addressed in the program. Combination product surgical mask/N95 disposable respirators (respirator portion certified by CDC/NIOSH and surgical mask portion listed by FDA) are available that provide both respiratory protection and bloodborne pathogen protection. Selection of respirators can be chosen through consultation with respirator fit-testing experts, CDC, occupational health and infection-control professional organizations, peer-reviewed research, respirator manufacturers, and advanced respirator training courses (10,280–289).

Fit Testing

A fit test is used to determine which respirator fits the user adequately and to ensure that the user knows when the respirator fits properly. After a risk assessment is conducted to validate the need for respiratory protection, perform fit testing during the initial respiratory-protection program training and periodically thereafter, in accordance with federal, state, and local regulations.

Fit testing provides a method to determine which respirator model and size fits the wearer best and to confirm that the wearer can properly fit the respirator. Periodic fit testing for respirators used in environments where a risk for *M. tuberculosis* transmission exists can serve as an effective training tool in conjunction with the content included in employee training and retraining. The frequency of periodic fit testing should be determined by the occurrence of 1) a risk for transmission of *M. tuberculosis*, 2) a change in facial features of the wearer, 3) a medical condition that would affect respiratory function, 4) physical characteristics of respirator (despite the same model number), or 5) a change in the model or size of the assigned respirator (281).

Inspection and Maintenance

Respirator maintenance should be an integral part of an overall respirator program. Maintenance applies both to respirators with replaceable filters and to respirators that are classified as disposable but are reused. Manufacturer instructions for inspecting, cleaning, maintaining, and using (or reuse) respirators should be followed to ensure that the respirator continues to function properly (278).

When respirators are used for protection against noninfectious aerosols (e.g., wood dust) that might be present in the air in heavy concentrations, the filter can become obstructed with airborne material. This obstruction in the filter material can result in increased resistance, causing breathing to be uncomfortable. In health-care settings in which respirators are used for protection against biologic aerosols, the concentration of infectious particles in the air is probably low. Thus, the filter in a respirator is unlikely to become obstructed with airborne material. In addition, no evidence exists to indicate that particles that affect the filter material in a respirator are reaerosolized easily. Therefore, the filter material used in respirators in health-care settings might remain functional for weeks. Because electrostatic filter media can degrade, the manufacturer should be contacted for the product's established service life to confirm filter performance.

Respirators with replaceable filters are reusable, and a respirator classified as disposable can be reused by the same HCW as long as it remains functional and is used in accordance with local infection-control procedures. Respirators with replaceable filters and filtering facepiece respirators can be reused by HCWs as long as they have been inspected before each use and are within the specified service life of the manufacturer. If the filter material is physically damaged or soiled or if the manufacturer's service life criterion has been exceeded, the filter (in respirators with replaceable filters) should be changed or the disposable respirator should be discarded according to local regulations. Infection-control personnel should develop standard procedures for storing, reusing, and disposing of respirators that have been designated for disposal.

Evaluation

The respirator program must be evaluated periodically to ensure its continued effectiveness.

Cleaning, Disinfecting, and Sterilizing Patient-Care Equipment and Rooms

General

Medical instruments and equipment, including medical waste, used on patients who have TB disease are usually not involved in the transmission of *M. tuberculosis* (478–480). However, transmission of *M. tuberculosis* and pseudo-outbreaks (e.g., contamination of clinical specimens) have been linked to inadequately disinfected bronchoscopes contaminated with *M. tuberculosis* (80,81,160,163,164,166). Guidelines for cleaning, disinfecting, and sterilizing flexible endoscopic instruments have been published (481–485).

The rationale for cleaning, disinfecting, or sterilizing patient-care instruments and equipment can be understood more readily if medical devices, equipment, and surgical materials are divided into three general categories (486). The categories are critical, semicritical, and noncritical and are based on the potential risk for infection if an item remains contaminated at the time of use.

Critical Medical Instruments

Instruments that are introduced directly into the bloodstream or other normally sterile areas of the body (e.g., needles, surgical instruments, cardiac catheters, and implants) are critical medical instruments. These items should be sterile at the time of use.

Semicritical Medical Instruments

Instruments that might come into contact with mucous membranes but do not ordinarily penetrate body surfaces (e.g., noninvasive flexible and rigid fiberoptic endoscopes or bronchoscopes, endotracheal tubes, and anesthesia breathing circuits) are semicritical medical instruments. Although sterilization is preferred for these instruments, high-level disinfection that destroys vegetative microorganisms, the majority of fungal spores, mycobacteria (including tubercle bacilli), and small nonlipid viruses can be used. Meticulous cleaning of such items before sterilization or high-level disinfection is essential (481). When an automated washer is used to clean endoscopes and bronchoscopes, the washer must be compatible with the instruments to be cleaned (481,487). High-level disinfection can be accomplished with either manual procedures alone or use of an automated endoscope reprocessor with manual cleaning (80,481). In all cases, manual cleaning is an essential first-step in the process to remove debris from the instrument.

Noncritical Medical Instruments or Devices

Instruments or devices that either do not ordinarily touch the patient or touch only the patient's intact skin (e.g., crutches, bed boards, and blood pressure cuffs) are noncritical medical instruments. These items are not associated with transmission of *M. tuberculosis*. When noncritical instruments or equipment are contaminated with blood or body substances, they should be cleaned and then disinfected with a hospital-grade, Environmental Protection Agency (EPA)-registered germicide disinfectant with a label claim for tuberculocidal activity (i.e., an intermediate-level disinfectant). Tuberculocidal activity is not necessary for cleaning agents or low-level disinfectants that are used to clean or disinfect minimally soiled noncritical items and environmental surfaces (e.g., floors, walls, tabletops, and surfaces with minimal hand contact).

Disinfection

The rationale for use of a disinfectant with tuberculocidal activity is to ensure that other potential pathogens with less intrinsic resistance than that of mycobacteria are killed. A common misconception in the use of surface disinfectants in health care relates to the underlying purpose of products labeled as tuberculocidal germicides. Such products will not interrupt and prevent transmission of *M. tuberculosis* in health-care settings, because TB is not acquired from environmental surfaces. The tuberculocidal claim is used as a benchmark by which to measure germicidal potency. Because mycobacteria have the highest intrinsic level of resistance among the vegetative bacteria, viruses, and fungi, any germicide with a tuberculocidal claim on the label (i.e., an intermediate-level disinfectant) is considered capable of inactivating many pathogens, including much less resistant organisms such as the bloodborne pathogens (e.g., hepatitis B virus, hepatitis C virus, and HIV). Rather than the product's specific potency against mycobacteria, a germicide that can inactivate many pathogens is the basis for protocols and regulations indicating the appropriateness of tuberculocidal chemicals for surface disinfection.

Policies of health-care settings should specify whether cleaning, disinfecting, or sterilizing an item is necessary to decrease the risk for infection. Decisions regarding decontamination processes should be based on the intended use of the item, not on the diagnosis of the condition of the patient for whom the item is used. Selection of chemical disinfectants depends on the intended use, the level of disinfection required, and the structure and material of the item to be disinfected.

The same cleaning procedures used in other rooms in the health-care setting should be used to clean AII rooms. However, personnel should follow airborne precautions while cleaning these rooms when they are still in use. Personal protective equipment is not necessary during the final cleaning of an AII room after a patient has been discharged if the room has been ventilated for the appropriate amount of time ([Table 1](#)).

Frequently Asked Questions (FAQs)

The following are FAQs regarding TST, QFT-G, BAMT, treatment for LTBI, risk assessment, environmental controls, respiratory protection, and cough-inducing and aerosol-generating procedures.

TST and QFT-G

- **Does having more than one TST placed in 1 year pose any risk?** No risk exists for having TSTs placed multiple times per year.
- **Can repeated TSTs, by themselves, cause the TST result to convert from negative to positive?** No, the TST itself does not cause false-positive results. Exposure to other mycobacteria or BCG vaccination can cause false-positive TST results.
- **What defines a negative TST result?** A TST result of 0 mm or a measurement below the defined cut point for each criteria category is considered a negative TST result ([Box 3](#)).
- **What defines a positive TST result?** A TST result of any millimeter reading above or at the defined cut point for each criteria category is considered a positive TST result ([Box 3](#)). The cut point (5 mm, 10 mm, and 15 mm) varies according to the purpose of the test (e.g., infection-control surveillance or medical and diagnostic evaluation, or contact investigation versus baseline testing).
- **What defines a false-negative result?** A false-negative TST or QFT-G result is one that is interpreted as negative for a particular purpose (i.e., infection-control surveillance versus medical and diagnostic evaluation) in a person who is actually infected with *M. tuberculosis*. False-negative TST results might be caused by incorrect TST placement (too deeply or too shallow), incorrect reading of the TST result, use of an incorrect antigen, or if the person being tested is anergic (i.e., unable to respond to the TST because of an immunocompromising condition) or sick with TB disease.
- **What defines a false-positive result?** A false-positive TST or QFT-G result is one that is interpreted as positive for a particular purpose (i.e., infection-control surveillance versus medical and diagnostic evaluation) in a person who is actually not infected with *M. tuberculosis*. False-positive TST results are more likely to occur in persons who have been vaccinated with BCG or who are infected with NTM, also known as mycobacteria other than TB (MOTT). A false-positive

TST result might also be caused by incorrect reading of the TST result (reading erythema rather than induration) or use of incorrect antigen (e.g., tetanus toxoid).

- **Is placing a TST on a nursing mother safe?** Yes, placing a TST on a nursing mother is safe.
- **A pregnant HCW in a setting is reluctant to get a TST. Should she be encouraged to have the test administered?** Yes, placing a TST on a pregnant woman is safe. The HCW should be encouraged to have a TST or offered BAMT. The HCW should receive education that 1) pregnancy is not a contraindication to having a TST administered and 2) skin testing does not affect the fetus or the mother. Tens of thousands of pregnant women have received TST since the test was developed, and no documented episodes of TST-related fetal harm have been reported. Guidelines issued by ACOG emphasize that postponement of the application of a TST as indicated and postponement of the diagnosis of infection with *M. tuberculosis* during pregnancy is unacceptable.
- **A pregnant HCW in a setting has a positive TST result and is reluctant to get a chest radiograph. Should she be encouraged to have the chest radiograph performed?** Pregnant women with positive TST results or who are suspected of having TB disease should not be exempted from recommended medical evaluations and radiography. Shielding consistent with safety guidelines should be used even during the first trimester of pregnancy.
- **Are periodic chest radiographs recommended for HCWs (or staff or residents of LTCFs) who have positive TST or BAMT results?** No, persons with positive TST or BAMT results should receive one baseline chest radiograph to exclude a diagnosis of TB disease. Further chest radiographs are not needed unless the patient has symptoms or signs of TB disease or unless ordered by a physician for a specific diagnostic examination. Instead of participating in serial skin testing, HCWs with positive TST results should receive a medical evaluation and a symptom screen. The frequency of this medical evaluation should be determined by the risk assessment for the setting. HCWs who have a previously positive TST result and who change jobs should carry documentation of the TST result and the results of the baseline chest radiograph (and documentation of treatment history for LTBI or TB disease, if applicable) to their new employers.
- **What is boosting?** Boosting is a phenomenon in which a person has a negative TST (i.e., false-negative) result years after infection with *M. tuberculosis* and then a positive subsequent TST result. The positive TST result is caused by a boosted immune response of previous sensitivity rather than by a new infection (false-positive TST conversion). Two-step testing reduces the likelihood of mistaking a boosted reaction for a new infection.
- **What procedure should be followed for a newly hired HCW who had a documented negative TST result 3 months ago at their previous job?** This person should receive one baseline TST upon hire (ideally before the HCW begins assigned duties). The negative TST result from the 3 months preceding new employment (or a documented negative TST result anytime within the previous 12 months) should be considered the first step of the baseline two-step TST. If the HCW does not have documentation of any TST result, the HCW should be tested with baseline two-step TST (one TST upon hire and one TST placed 1–3 weeks after the first TST result was read).
- **Why are two-step TSTs important for the baseline (the beginning of an HCW's employment)?** If TST is used for TB screening (rather than BAMT), performing two-step TST at baseline minimizes the possibility that boosting will lead to suspicion of transmission of *M. tuberculosis* in the setting during a later contact investigation or during serial testing (false-positive TST conversions). HCWs who do not have documentation of a positive TST result or who have not been previously treated for LTBI or TB disease should receive baseline two-step TST.
- **If a person does not return for a TST reading within 48–72 hours, when can a TST be placed on them again?** A TST can be administered again as soon as possible. If the second step of a two-step TST is not read within 48–72 hours, administer a third test as soon as possible (even if several months have elapsed), and ensure that the result is read within 48–72 hours.
- **Should a TST reading of ≥ 10 mm be accepted 7 days after the TST was placed?** If the TST was not read between 48–72 hours, another TST should be placed as soon as possible and read within 48–72 hours. However, certain studies indicate that positive TST reactions might still be measurable 4–7 days after the TST was placed. If the TST reaction is read as ≥ 15 mm 7 days after placement, the millimeter result can be recorded and considered to be a positive result.
- **Do health-care settings or areas in the United States exist for which baseline two-step TST for newly hired HCWs is not needed?** Ideally, all newly hired HCWs who might share air space with patients should receive baseline two-step TST (or one-step BAMT) before starting duties. In certain settings, a choice might be offered not to perform baseline TST on HCWs who will never be in contact with or share air space with patients who have TB disease, or who will never be in contact with clinical specimens (e.g., telephone operators in a separate building from patients).

- **In our setting, workers are hired to provide health care in homes, and they are not medically trained. Two-step skin testing is difficult because of the requirement to return for testing and reading multiple times. Can the two-step TST be omitted?** No, ideally, all HCWs who do not have a previously documented positive TST result or treated LTBI or TB disease should receive two-step baseline skin testing in settings that have elected to use TST for screening. BAMT is a single test procedure. Baseline testing for *M. tuberculosis* infection will ensure that TB disease or LTBI is detected before employment begins and treatment for LTBI or TB disease is offered, if indicated.
- **When performing two-step skin testing, what should be done if the second-step TST is not placed in 1–3 weeks?** Perform the second-step TST as soon as possible, even if several months have passed.
- **Should gloves be worn when placing TST?** Specific CDC recommendations do not exist regarding this topic. If your local area indicates that universal precautions should be practiced with skin testing, the local areas should determine what precautions should be followed in their setting.
- **Is TST QC important?** Yes, performing QC for HCWs during training and retraining of placing and reading TST is important to avoid false-negative and false-positive TST results, and to ensure appropriate treatment decisions.
- **If the longitudinal reading of the induration of the TST result is 12 mm and the horizontal reading is 8 mm, what should be recorded?** The correct TST reading should be recorded as 8 mm (not 12 mm or 8 x 12 mm). For purposes of standardization, only record the millimeters of induration, which should be measured transversely (i.e., perpendicular), to the long axis of the forearm. Erythema (redness) around the TST site should not be read as part of the TST result. Consideration should be given to retesting if the selected area for placement was on or near a muscle margin, scar, heavy hair, veins, or tattoos, which could be barriers to reading the TST result, or consider offering a BAMT. BAMT results should be recorded in detail. The details should include date of blood draw, result in specific units, and the laboratory interpretation (positive, negative, or indeterminate—and the concentration of cytokine measured, e.g., IFN- γ).
- **Should HCWs who report upon hire that they have had a positive TST result or have been previously treated for LTBI or TB disease receive baseline two-step TST when beginning work at a new health-care setting?** Unless the HCW has documentation of a positive TST result or previously treated LTBI or TB disease, they should usually receive baseline two-step testing before starting duties. If documentation is available of a positive TST result, that result can be considered as the baseline TST result for the HCW at the new setting, and additional testing is not needed. Recommendations for testing HCWs who transfer from one setting to another where the risk assessment might be different are presented (see Use of Risk Classification to Determine Need for TB Screening and Frequency of Screening HCWs).
- **If an HCW has a baseline first-step TST result between 0–9 mm, does a second-step TST need to be placed?** Yes, if the baseline first-step TST result is <10 mm, a second-step TST should be applied 1–3 weeks after the first TST result was read. HCWs who are immunocompromised are still subject to the 10 mm cutoff for baseline two-step testing for surveillance purposes but would be referred for medical evaluation for LTBI using the 5 mm cutoff.
- **An HCW in a medium-risk setting who had a two-step baseline TST result of 8 mm is retested 1 year later for serial TB screening and had a TST result of 16 mm. No known exposure to *M. tuberculosis* had occurred. Although the TST is now >10 mm, a ≥ 10 mm increase did not occur in the TST result to meet the criteria for a TST conversion. How should this reading be interpreted?** The TST result needs to be interpreted from two perspectives: 1) administrative and 2) individual medical interpretation. Because an increase by ≥ 10 mm did not occur, the result would not be classified as a TST conversion for administrative purposes. However, this HCW should be referred for a medical evaluation. The following criteria are used to determine whether a TST result is positive or negative, considering individual clinical grounds: 1) absolute measured induration (i.e., ≥ 5 , ≥ 10 , or ≥ 15 mm induration, depending on the level of risk and purpose of testing); 2) the change in the size of the TST result; 3) time frame of the change; 4) risk for exposure, if any; and 5) occurrence of other documented TST conversions in the setting. For HCWs at low risk for LTBI, TST results of 10–14 mm can be considered negative from a clinical standpoint, and these HCWs should not have repeat TST, because an additional increase in induration of ≥ 10 mm will not be useful in determining the likelihood of LTBI.
- **Are baseline two-step TSTs needed for HCWs who begin jobs that involve limited contact with patients (e.g., medical records staff)?** Yes, all HCWs who might share air space with patients should receive baseline two-step TST (or one-time BAMT) before starting duties. However, in certain settings, a choice might be offered not to perform baseline TST on

HCWs who will never be in contact with or share air space with patients who have TB disease, or who will never be in contact with clinical specimens (e.g., telephone operators in a separate building from patients).

- **A setting conducts skin testing annually on the anniversary of each HCW's employment. Last year, multiple TST conversions occurred in April; therefore, all HCWs received a TST during that month. In the future, do all HCWs need to be tested annually in April?** No, after a contact investigation is performed, the best and preferred schedule for annual TB screening is on the anniversary of the HCW's employment date or on their birthday (rather than testing all HCWs at the same time each year), because it increases the opportunity for early recognition of infection-control problems that can lead to TST conversions.
- **An HCW who has been vaccinated with BCG is being hired. She states that BCG will make her TST result positive and that she should not have a TST. Should this HCW be exempted from baseline two-step TST?** Unless she has documentation of a positive TST result or previously treated LTBI or TB disease, she should receive baseline two-step TST or one BAMT. Some persons who received BCG never have a positive TST result. For others, the positive reaction wanes after 5 years. U.S. guidelines state that a positive TST result in a person who received BCG should be interpreted as indicating LTBI.
- **Does BCG affect TST results and interpretations?** BCG is the most commonly used vaccine in the world. BCG might cause a positive TST (i.e., false-positive) result initially; however, tuberculin reactivity caused by BCG vaccination typically wanes after 5 years but can be boosted by subsequent TST. No reliable skin test method has been developed to distinguish tuberculin reactions caused by vaccination with BCG from reactions caused by natural mycobacterial infections, although TST reactions of ≥ 20 mm of induration are not usually caused by BCG.
- **What steps should be taken when an HCW has had a recent BCG vaccination?** When should the TST be placed? A TST may be placed anytime after a BCG vaccination, but a positive TST result after a recent BCG vaccination can be a false-positive result. QFT-G should be used, because the assay test avoids cross reactivity with BCG.
- **A hospital HCW has not had a TST in 18 months because she was on maternity leave and missed her annual TST. She has been employed at the hospital for the previous 5 years. Is two-step testing necessary on her next skin test date?** No, two-step TSTs are needed only to establish a baseline for a specific setting for newly hired HCWs and others who will receive serial TST (e.g., residents or staff of correctional facilities or LTCFs). The HCW should have a single TST or BAMT upon returning to work and should then resume a routine testing schedule on the next normal TST anniversary date.
- **Should two-step testing be performed in a contact investigation for HCWs who have not had a TST within the preceding 12 months?** No, two-step testing should only be used for baseline TST screening and has no role in a contact investigation. In a contact investigation, a follow-up TST should be placed 8–10 weeks after an initial negative TST result is read.
- **What length of time should a person who has had contact with someone with TB disease be included in a contact investigation?** This decision can best be made in consultation with the local TB program, which frequently has experience responding to similar situations. A minimum exposure time has not been established, but the minimum length of contact time with a person who has TB disease necessary for transmission will depend on multiple factors. Begin by estimating the duration of the infectious period (see Supplement, Contact Investigations). The highest priority for evaluation should be given to 1) persons with a medical risk factor for TB disease (e.g., HIV infection or immunosuppressive therapy); 2) infants and children <4 years; 3) household or congregate setting contacts; and 4) persons present during medical procedures (e.g., bronchoscopies, sputum induction, or autopsies). In addition, offer TB screening to all persons named by the patient as work or social contacts during the infectious period. Determining whether to broaden the investigation will depend on whether evidence of transmission to any of the above contacts exists (positive TST or BAMT results or conversions), the duration of the potential exposure, and the intensity of the exposure (e.g., in a poorly ventilated environment versus outdoors). If the exposure was to pulmonary TB that was cavitary on chest radiograph or if the patient had positive AFB sputum smear results, usually the minimum exposure duration for a person to be considered a contact would be shorter. Nonetheless, infection with *M. tuberculosis* requires some degree of prolonged or regular exposure (i.e., days to weeks, not just a few hours).
- **If an HCW in a setting has a latex allergy, should this person receive a TST?** A person with a latex allergy can receive a TST when latex-free products are used. Latex allergy can be a contraindication to skin testing if the allergy is severe and the products used to perform the test (e.g., syringe plungers, PPD antigen bottle stopper, and gloves) contain latex. Latex-free products are, however, usually available. If a person with a latex allergy does have a TST performed using

products or equipment that contain latex, interpretation of the TST results can be difficult, because the TST reaction might be the result of the latex allergy, reaction to PPD, or a combination of both. Consider repeating the TST using latex-free products or use BAMT.

- **Should the TST site be covered with an adhesive bandage?** No, avoid covering the TST site with anything that might interfere with reading the TST result (e.g., adhesive bandages, cream, ointment, lotion, liquids, and medication).
- **When can a TST be placed if other vaccines are also being administered (e.g., measles, varicella, yellow fever, and smallpox)?** A TST should be administered either on the same day as vaccination with live virus or 4–6 weeks later. Vaccines that might cause a false-negative TST result are measles, varicella, yellow fever, smallpox, BCG, mumps, rubella, oral polio, oral typhoid, and live-attenuated influenza.
- **How frequently should persons in the general public receive TST?** Testing for LTBI in the general public is not necessary unless the person is at risk for exposure to *M. tuberculosis* (e.g., someone who had contact with a person with TB disease) or at increased risk for progression to TB disease (e.g., someone infected with HIV).
- **Should we use a multiple puncture (Tine®) skin test to perform a TST?** No, in the United States, the Mantoux method of skin testing is the preferred method because it is more accurate than Tine(r) skin tests. BAMT (currently QFT-G) is also now recommended as a test for *M. tuberculosis* infection.
- **What steps should be taken if an HCW has a baseline TST result of 16 mm and 1 year later the TST result was read as 0 mm?** If documentation existed for the 16 mm result, administering another TST to the HCW subsequently was not necessary. One or both of these TST results could be false results. The first result might have been documented as 16 mm, but perhaps 16 mm of erythema was measured and no induration was present. The second result of 0 mm might have been caused by incorrect administration of the TST (i.e., too deeply or too shallow), or was read and recorded incorrectly (if it was actually positive). In this instance, another TST should be placed, or a BAMT should be offered, or if TB disease is suspected, a chest radiograph should be performed.
- **What steps should be taken if the TST is administered intramuscularly instead of intradermally?** QC for administering TST is critical. If the TST is administered intramuscularly (too deeply), repeat the skin test immediately, or offer BAMT.
- **How are annual TST conversion rates for HCWs calculated?** A TST conversion is a change in the result of a test for *M. tuberculosis* infection wherein the condition is interpreted as having progressed from uninfected to infected. Annual TST conversion rates are calculated for a given year by dividing the number of test conversions among HCWs in the setting that year (numerator) by the total number of HCWs who received tests in the setting that year (denominator) multiplied by 100. By calculating annual TST conversion rates, year-to-year comparisons can be used to identify transmission of *M. tuberculosis* that was not previously detected.
- **Where can PPD be obtained?** Local and state health departments can provide PPD antigen for TST without charge to selected targeted testing and treatment programs. Purchase of the antigen and supplies is regulated by local and state laws related to professional licensure.
- **Where can millimeter rulers be obtained to measure TST results?** A TST training kit, which includes a TST training video, guide for facilitators, and a TST millimeter ruler is available free of charge from CDC (https://www2.cdc.gov/nchstp_od/PIWeb/TBorderform.asp). In addition, check with your local or state health department and TST antigen manufacturers.
- **Where can materials be obtained for educating HCWs regarding TB?** A list of TB websites and resources is available ([Appendix E](#)). Local or state health departments should have additional materials and access to resources and might be able to help develop a setting-specific TB education program.
- **Where can self-reading TST cards be obtained that allow HCWs to report their own results?** HCWs and patients should not be allowed to read and report their own TST results; therefore, self-reading cards for reporting TST results are not recommended. All TST results should be read and recorded by a trained TST reader other than the person on whom the TST was placed.

Treatment for LTBI

- **Who should be treated for LTBI?** Persons with LTBI who are at increased risk for developing TB disease should be offered treatment for LTBI regardless of age, if they have no contraindication to the medicine.
- **What are contraindications to treatment of LTBI?** Active hepatitis and ESLD are contraindications to the use of INH for treatment of LTBI. Persons who have these conditions

might be eligible for rifampin for 4 months for treatment of LTBI. Because of the substantial and complex drug-drug interactions between rifamycins and HIV protease inhibitors (PI) and nonnucleoside reverse transcriptase inhibitors (NNRTI), clinicians are encouraged to seek expert advice if the concurrent use of these drugs is being considered in persons infected with HIV. Information regarding use of these drugs is available at http://www.cdc.gov/nchstp/tb/tb_hiv_drugs/toc.htm.

- **Do persons need to be in a specific age range to be eligible for treatment of LTBI?** No age restriction for eligibility of treatment for LTBI currently exists. Targeted TST programs should be conducted for persons at high risk, and these programs are discouraged for persons or settings considered to be low risk. However, for infection-control programs that conduct TB screening that includes HCWs who are frequently at low risk, proper medical evaluation needs to be conducted when an HCW with a positive TST result is identified. In this context, age might be a factor in the decision to administer treatment, because older persons are at increased risk for hepatic toxicity caused by INH.
- **What is the preferred regimen for treatment of LTBI?** Nine months of daily INH is the preferred treatment regimen for patients who have LTBI. The 6-month regimen of INH or the 4-month regimen of rifampin are also acceptable alternatives.
- **Why is the 2-month regimen of RZ generally not offered for treatment of LTBI?** Although the 2-month regimen of RZ was previously recommended as an option for the treatment of LTBI, reports of severe liver injury and death prompted the American Thoracic Society and CDC to revise recommendations to indicate that this regimen should generally not be offered for treatment of LTBI.
- **Can sputum specimens collected over a 2-day period that are reported as negative for AFB be used to exclude a diagnosis of TB disease?** Yes, airborne precautions can be discontinued when infectious TB disease is considered unlikely and either 1) another diagnosis is made that explains the clinical syndrome or 2) the patient has three negative AFB sputum smear results (109–112). Each of the three consecutive sputum specimens should be collected 8–24 hours apart (124), and at least one specimen should be an early morning specimen, because respiratory secretions pool overnight. Generally, this method will allow patients with negative sputum smear results to be released from airborne precautions in 2 days.
- **When does an infectious TB patient become noninfectious?** Historically, health-care professionals have believed that the effect of antituberculosis treatment to reduce infectiousness was virtually immediate; older texts state that patients on antituberculosis treatment are not infectious. Surrogates that are used for noninfectiousness include conversion of positive sputum AFB results to negative AFB results and clinical response to antituberculosis treatment (i.e., improvement of symptoms and chest radiograph result).

Risk Assessment

- **In certain health-care settings (e.g., outpatient clinics or emergency medical settings) where patients are evaluated before a hospitalization during which TB disease is diagnosed, determining the number of TB patients who were encountered can be difficult. How should the risk classification be assigned?** These situations underscore the importance of obtaining an accurate patient history, completing contact investigations for all persons with suspected or confirmed TB disease, and ensuring effective communication to all settings in which persons with TB disease are encountered before diagnosis. Collaboration between infection-control personnel at the setting and the TB-control program staff at the local health department can help with this estimation.
- **At a pediatric hospital, the parents are normally with the child at the time of the TB diagnosis, and the parents can be diagnosed with TB disease at the same time as the child. To determine the number of patients diagnosed at the health-care setting, should the parents with TB disease who are visiting also be included in the total TB patient count?** Only patients with TB disease who were evaluated or treated in the health-care setting count, not visitors who have TB (unless they were diagnosed at the same setting).
- **In a 160-bed hospital, three HCWs have had TST conversions during a 2-month period, which is usually the number of TST conversions detected in the hospital in 1 year. Should the setting be classified as potential ongoing transmission?** If the HCWs with TST conversions can be linked together in some way, either through a job type, location of work, or DNA fingerprinting, then the classification of potential ongoing transmission might apply to one group of HCWs or one part of the setting. Evidence of ongoing transmission in this setting appears to exist, and a problem evaluation should be conducted to ascertain the reason for the TST conversions (see Problem Evaluation). Reasons could range from an undiagnosed case of TB in the setting to incorrect placement or reading of TST. Early consultation with the

local health department and an expert in TB infection control might be helpful in identifying and resolving the problem.

- **If a health-care setting has a risk classification of potential ongoing transmission, how long should that classification be applied?** The classification of potential ongoing transmission should be assigned only on a temporary basis and always warrants a problem evaluation (see Problem Evaluation). After resolution of problems, settings with a classification of potential ongoing transmission should be reclassified as a medium-risk classification for at least 1 year.

Environmental Controls

- **What is the difference between environmental controls and engineering controls ?** "Environmental controls" is a more inclusive term than "engineering controls". Examples of environmental controls are UVGI, HEPA filters and AII rooms. Examples of engineering controls are local exhaust ventilation (e.g., booths, hoods, and tents) and general ventilation (including directional airflow and negative pressure).
- **Is an AII room the same as a negative-pressure isolation room?** "AII room" is an accepted term and is used in the AIA guidelines that describe the purpose for and details of ventilation of AII rooms. An AII room is a special negative-pressure room for the specific purpose of isolating persons who might have suspected or confirmed infectious TB disease from other parts of the setting. Not all negative-pressure rooms are AII rooms, because they might not have the required air flow or differential pressure of an AII room.
- **Our TB clinic only treats persons with LTBI. Do we need an AII room and a respiratory-protection program?** Ideally, yes, because persons with LTBI are at risk for developing TB disease. TB clinics usually should have at least one AII room and a respiratory-protection program. An AII room and a respiratory-protection program might not be needed if 1) each person treated in the clinic will be adequately screened before admission and are determined to not have TB disease, 2) a system exists to promptly detect and triage persons who have symptoms or signs of TB disease, and 3) no cough-inducing procedures will ever be performed in the clinic.
- **Can airborne precautions be discontinued for a patient with suspected TB disease who has positive AFB sputum smear results but has a negative NAA for *M. tuberculosis*?** Yes, if the NAA test result is negative and dual infection with *M. tuberculosis* and another mycobacterial species is not clinically suspected, the patient may be released from airborne precautions. An NAA test is highly sensitive and specific for the identification of *M. tuberculosis* when performed properly on a patient who has a positive AFB sputum smear result.
- **During the winter months at a hospital, inadequate numbers of AII rooms are available for all patients with suspected or confirmed infectious TB disease. Can only two negative sputum smear results be obtained for AFB before releasing patients from airborne precautions?** In general, the criterion for the release of a patient with suspected infectious TB disease from airborne precautions is that infectious TB disease is considered unlikely and either 1) another diagnosis is made that explains the clinical syndrome or 2) the patient has three negative AFB sputum smear results (109–112). Each of the three consecutive sputum specimens should be collected 8–24 hours apart (124), and at least one specimen should be an early morning specimen. Generally, this method will allow patients with negative sputum smear results to be released from airborne precautions in 2 days. If the number of AII rooms in the setting is inadequate, consider adding one or more AII rooms. Before undertaking this expense, however, ensure that the criteria for placing patients in AII rooms are correct and that the available rooms are not being used for patients in whom infectious TB disease is not suspected. In addition, the following intervals should be reviewed to identify any delays that could be corrected and decrease time for patients in AII rooms: 1) time between admission and ordering of sputum specimens for AFB examination, 2) time between ordering and collecting specimens, and 3) time between collection of specimens and receipt of results from the laboratory.
- **How many AII rooms are required in a 120-bed hospital?** For a hospital with 120 beds, a minimum of one AII room is needed. Although no available data exist to quantify the number of rooms needed for a given number of cases of suspected or confirmed TB disease, a reasonable choice is one additional AII room for every 200 patient-days of cases of suspected or confirmed TB disease. The setting's risk assessment will help determine the number of AII rooms needed.
- **Who is responsible for ensuring that negative pressure is achieved in AII rooms?** Ensuring that negative pressure is achieved in AII rooms is a function of the infection-control program at each health-care setting. This responsibility may be delegated to engineering, maintenance, or other appropriate staff to perform the actual negative pressure tests. AII rooms should be checked for negative pressure before occupation by a patient with suspected or

confirmed infectious TB disease, and when in use by a person with TB disease, negative pressure should be checked daily with smoke tubes or other visual checks.

- **What is the difference between VAV and CAV?** How do I determine which settings need them? VAV is variable air volume, and CAV is constant air volume. These terms refer to how the ventilation system is designed to deliver air to and maintain temperature and relative humidity control within a room. CAV systems usually are best for AII rooms and other negative-pressure rooms, because the negative-pressure differential is easier to maintain. VAV systems are acceptable if provisions are made to maintain the minimum total and outside ACH and a negative pressure ≥ 0.01 inch of water gauge relative to adjacent areas at all times.
- **Why was the differential pressure requirement for an AII room increased from 0.001 inch of water gauge to ≥ 0.01 inch of water gauge?** In an ideal, controlled environment, 0.001 inches of water gauge has been demonstrated to ensure negative pressure in AII rooms. However, AIA and other organizations have demonstrated that a minimum of 0.01 inches of water gauge is needed in certain installations to ensure that negative pressure is consistently achieved.
- **How can a portable HEPA filter unit help control TB?** Portable HEPA filtration units recirculate room air, and the HEPA filters effectively remove all particles from the air in the size range of droplet nuclei, resulting in a dilution of the concentration of infectious particles in the room.

Respiratory Protection

- **What is the difference between a CDC/NIOSH-certified respirator and a surgical or procedure mask?** Respirators are designed to help reduce the wearer's (i.e., HCW's) exposure to airborne particles. The primary purpose of a surgical or procedure mask is to help prevent biologic particles from being expelled into the air by the wearer (i.e., patient).
- **How important is the fit of the respirator?** This step is critical. The fit of a respirator is substantially important. If a respirator does not fit tightly on the face, airborne hazards can penetrate or enter underneath the facepiece seal and into the breathing zone. Before each use, the wearer of a respirator should perform a user-seal check on themselves to minimize contaminant leakage into the facepiece (<http://www.cdc.gov/niosh/topics/respirators>).
- **How do I perform a respirator user-seal check?** Performing a user-seal check (formerly called "fit check") after redonning the respirator each time is critical to ensure adequate respiratory protection. The seal checks for respirators are described in the respirator user instructions and should be consulted before the respirator is used. The two types of user-seal checks usually are positive-pressure and negative-pressure checks.
To check positive pressure seal after donning the respirator, the wearer should cover the surface of the respirator with their hands or with a piece of household plastic film and exhale gently. If air is felt escaping around the facepiece, the respirator should be repositioned, and the user-seal check should be performed again. If the wearer does not feel air escaping around the facepiece, the positive pressure user-seal check was successful.
To check the negative pressure seal after donning the respirator, the wearer should cover the surface of the respirator and gently inhale, which should create a vacuum, causing the respirator to be drawn in toward the face. If the respirator is not drawn in toward the face or if the wearer feels air leaking around the face seal, the respirator should be removed and examined for any defects (e.g., a small hole or poor molding of the respirator to the face [especially around the nose area]). If no holes are found, the respirator should be repositioned and readjusted, and a second attempt at negative pressure user-seal check should be made. If the check is not successful, try a new respirator.
- **Is performing a user-seal check (formerly called "fit check") on a respirator before each use always necessary?** Yes, performing a user-seal check on respirators before each use is essential to minimize contaminant leakage into the facepiece. Each respirator manufacturer has a recommended user-seal check procedure that should be followed by the user each time the respirator is worn.
- **What is a respirator fit test and who does fit testing?** A fit test is used to determine which respirator does or does not fit the user adequately and to ensure that the user knows when the respirator fits properly. Fit testing must be performed by a qualified health professional. Fit testing should be performed during the initial respiratory-protection program training and periodically thereafter, based on the risk assessment for the setting and in accordance with applicable federal, state, or local regulations.
Periodic fit testing for respirators used in TB environments can serve as an effective training tool in conjunction with the content included in employee training and retraining. The frequency of fit testing should be determined by a change in the 1) risk for transmission of *M. tuberculosis*, 2) facial features of the wearer, 3) medical condition that would affect respiratory function, 4)

physical characteristics of the respirator (despite the same model number), or 5) model or size of the assigned respirator.

- **What kind of respiratory protection should HCWs use when providing care to persons with suspected or confirmed infectious TB disease in the home?** The recommended respiratory protection for HCWs who provide care in the homes of patients with suspected or confirmed infectious TB disease is at least an N95 respirator.
